Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

This book is dedicated to the Children's Hospital of Wisconsin residents. Their enthusiasm, thirst for knowledge, and desire to become outstanding pediatricians inspire us.

This book is intended to help the reader begin with a specific chief complaint that may be seen in many different disease entities. It is arranged in chapters that cover specific symptoms mirroring clinical practice. Patients do not usually present with a chief complaint of cystic fibrosis; rather, they may present with a cough, respiratory distress, or chronic diarrhea.

With a user-friendly, well-tabulated, illustrated approach, this text will help the reader differentiate between the many disease states causing a common symptom. The inclusion of many original tables and figures should help the reader identify distinguishing features of diseases and work through a diagnostic approach to the symptom. Modified and borrowed artwork and tables from other outstanding current sources have been added as well. The combination of all of these illustrations and tables with diagnostic clues within the text will help provide a quick visual guide to the differential diagnosis of the various diseases under discussion. The diagnostic approach includes standard laboratory and radiologic testing, as well as advanced imaging studies and genetic-based analysis.

We appreciate the hard work of our contributing authors. Writing a chapter in this type of format is quite different from writing in the format of a disease-based book. In addition, we thank Kate Dimock and Jennifer Ehlers of Elsevier, whose patience and expertise contributed to the publication of this book. We are all also greatly appreciative of Carolyn Redman at the Medical College of Wisconsin Department of Pediatrics, whose editorial assistance and organization have made this new edition a reality. Finally, we are ever grateful for the understanding and patience of Diane Basel, Jessica Bordini, Ryan Festerling, Sharon Kliegman, and Dale Lye in supporting this work.

1

Sore Throat

Robert R. Tanz

Most causes of sore throat are nonbacterial and neither require nor are alleviated by antibiotic therapy (Tables 1.1, 1.2, and 1.3). Accurate diagnosis is essential: Acute streptococcal pharyngitis warrants diagnosis and therapy to ensure prevention of serious suppurative and nonsuppurative complications. Life-threatening infectious complications of oropharyngeal infections, whether streptococcal or nonstreptococcal, may manifest with mouth pain, pharyngitis, parapharyngeal space infectious extension, and/or airway obstruction (Tables 1.4 and 1.5). In many cases, the history and/or physical exam can help direct diagnosis and treatment, but the enormous number of potential causes is too large to address all of them.

VIRAL PHARYNGITIS

Most episodes of pharyngitis are caused by viruses (see Tables 1.2 and 1.3). It is difficult to clinically distinguish between viral and bacterial pharyngitis with a very high degree of precision, but certain clues may help the physician. Accompanying symptoms of conjunctivitis, rhinitis, cough, discrete ulcerations, croup, or laryngitis are common with viral infection but rare in bacterial pharyngitis.

Many viral agents can produce pharyngitis (see Tables 1.2 and 1.3). Some cause distinct clinical syndromes that are readily diagnosed without laboratory testing (Table 1.6; see also Tables 1.1 and 1.4). In pharyngitis caused by parainfluenza and influenza viruses, rhinoviruses, coronaviruses, and respiratory syncytial virus (RSV), the symptoms of coryza and cough often overshadow sore throat, which is generally mild. Influenza virus may cause high fever, cough, headache, malaise, myalgia, and cervical adenopathy in addition to pharyngitis. In young children, croup or bronchiolitis may develop. When influenza is suspected on clinical and epidemiologic grounds or confirmed by testing (polymerase chain reaction [PCR] is most accurate), specific antiviral therapy is available for treatment of patients and prophylaxis of family members. RSV is associated with bronchiolitis, pneumonia, and croup in young children. RSV infection in older children is usually indistinguishable from a simple upper respiratory tract infection. Pharyngitis is not a prominent finding of RSV infection in any age group. Parainfluenza viruses are associated with croup and bronchiolitis; minor sore throat and signs of pharyngitis are common at the outset but rapidly resolve. Infections caused by parainfluenza, influenza, and RSV are often seen in seasonal (winter) epidemics. *Many agents can be identified using multiplex or targeted PCR testing, but there is rarely reason to test outpatients and infrequent benefit to testing inpatients except to confirm and treat influenza.*

Adenoviruses can cause upper and lower respiratory tract disease, ranging from ordinary colds to severe pneumonia and multisystem disease, including hepatitis, myocarditis, and myositis. The incubation period of adenovirus infection is 2-4 days. Upper respiratory tract infection typically produces fever, erythema of the pharynx, and follicular hyperplasia of the tonsils, together with exudate. Enlargement of the cervical lymph nodes occurs frequently. When conjunctivitis occurs in association with adenoviral pharyngitis, the resulting syndrome is called **pharyngoconjunctival fever**. Pharyngitis may last as long as 7 days and does not respond to antibiotics. There are many adenovirus serotypes; adenovirus infections may therefore develop in children more than once. Laboratory studies may reveal a leukocytosis and an elevated erythrocyte sedimentation rate. Adenovirus outbreaks have been associated with swimming pools and contamination in health care workers.

The **enteroviruses** (coxsackievirus and echovirus) can cause sore throat, especially in the summer. High fever is common, and the throat is erythematous but usually not bright red; tonsillar exudate and cervical adenopathy are unusual. Symptoms resolve within a few days. Enteroviruses can also cause meningitis, myocarditis, rash, and two specific syndromes that involve the oropharynx.

Herpangina is characterized by distinctive discrete, painful, gray-white papulovesicular lesions distributed over the posterior oropharynx (see Table 1.6). The vesicles are 1-2 mm in diameter and are initially surrounded by a halo of erythema before they ulcerate. Fever may reach 39.5°C. The illness is due to enteroviruses and generally lasts less than 7 days, but severe pain may impair fluid intake and occasionally necessitates medical support.

Hand-foot-mouth disease is caused by coxsackievirus A16. Painful vesicles that ulcerate can occur throughout the oropharynx. Vesicles also develop on the palms, soles, and, less often, on the trunk or extremities. Fever is present in most cases, but many children do not appear seriously ill. This disease lasts less than 7 days.

Primary infection caused by **herpes simplex virus (HSV)** usually produces high fever with acute gingivostomatitis, involving vesicles (which become ulcers) throughout the anterior portion of the mouth, including the lips. There is sparing of the posterior pharynx in herpes gingivostomatitis; the infection usually occurs in young children. High fever is common, pain is intense, and intake of oral fluids is often impaired, which may lead to dehydration. In addition, HSV may

Corynebacterium diphtheriae
Arcanobacterium haemolyticum
Neisseria gonorrhoeae
Epstein-Barr virus
Parainfluenza viruses (types 1–4)
Influenza viruses
Rhinoviruses
Coronavirus
Adenovirus (types 3, 4, 7, 14, 21, others)
Respiratory syncytial virus
Herpes simplex virus (types 1, 2)

Probable or Occasional Causes
Group C streptococci
Group G streptococci
Chlamydia pneumoniae
Chlamydia trachomatis
Mycoplasma pneumoniae

TABLE 1.3   Additional Potential Pathogens Associated with Sore Throat

Bacteria
Fusobacterium necrophorum (Lemierre syndrome)
Neisseria meningitidis
Yersinia enterocolitica
Tularemia (oropharyngeal)
Yersinia pestis
Bacillus anthracis
Chlamydia psittaci
Secondary syphilis
Mycobacterium tuberculosis
Lyme disease
Corynebacterium ulcerans
Leptospira species
Mycoplasma hominis

Virus
Coxsackievirus A, B
Cytomegalovirus
Viral hemorrhagic fevers
Human immunodeficiency virus (HIV) (primary infection)
Human herpesvirus 6
Measles
Varicella
Rubella

Fungus
Candida species
Histoplasmosis
Cryptococcosis

manifest as pharyngitis in adolescents. Approximately 35% of new-onset HSV-positive adolescent patients have herpetic lesions; most teenage patients with HSV pharyngitis cannot be distinguished from patients with other causes of pharyngitis. The classic syndrome of herpetic gingivostomatitis in infants and toddlers lasts up to 2 weeks; data on the course of more benign HSV pharyngitis are lacking. The differential diagnosis of vesicular-ulcerating oral lesions is noted in Table 1.6.

A common cause of a local and large lesion of unknown etiology is **aphthous stomatitis** (Fig. 1.1). *PFAPA* (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis) is an idiopathic periodic fever syndrome that occurs predictably every 2-8 weeks. The onset of PFAPA is usually before the age of 5 years. In addition to aphthous stomatitis and pharyngitis, PFAPA is characterized by high fever lasting 4-6 days. Individual episodes resolve spontaneously but may respond

TABLE 1.4 Distinguishing Features of Parapharyngeal–Upper Respiratory Tract Infections

	Peritonsillar Abscess	Retropharyngeal Abscess (Cellulitis)	Submandibular Space (Ludwig Angina)*	Lateral Pharyngeal Space	Masticator Space*	Epiglottitis	Laryngotracheo-bronchitis (Croup)	Bacterial Tracheitis	Postanginal Sepsis (Lemierre Syndrome)
Etiology	Group A streptococci, oral anaerobes†	Staphylococcis aureus, oral anaerobes,† group A streptococci, "suppurative adenitis"	Oral anaerobes†	Oral anaerobes†	Oral anaerobes†	Haemophilus influenzae type b (rarely), group A streptococci, Streptococcus pneumoniae, Staphylococcus aureus, and non-type b H. influenzae	Parainfluenza virus; influenza, adenovirus, and respiratory syncytial virus less common	Moraxella catarrhalis, S. aureus, H. influenzae type b or nontypable	Fusobacterium necrophorum
Age	Teens	Infancy, preteens, occasionally teens	Teens	Teens	Teens	2-5 yr	3 mo-3 yr	3-10 yr	Teens
Manifestations	Initial episode of pharyngitis, followed by sudden worsening of unilateral odynophagia, trismus, hot potato (muffled) voice, drooling, displacement of uvula	Fever, dyspnea, stridor, dysphagia, drooling, stiff neck, pain, cervical adenopathy, swelling of posterior pharyngeal space Descending mediastinitis (rare) Lateral neck radiograph reveals swollen retropharyngeal prevertebral space: infants, >1 × width of adjacent vertebral body (>2-7 mm); teens, > ⅓ × width of vertebral body (>1-7 mm) CT distinguishes cellulitis from abscess	Fever, dysphagia, odynophagia, stiff neck, dyspnea; airway obstruction, swollen tongue and floor of mouth (tender) Muffled voice	Severe pain, fever, trismus, dysphagia, edematous appearing, painful lateral facial (jaw) or neck swelling (induration) May lead to Lemierre syndrome	Pain, prominent trismus, fever Swelling not always evident	Sudden-onset high fever, "toxic" appearance, muffled voice, anxiety, pain, retractions, dysphagia, drooling, stridor, sitting up, leaning forward tripod position, cherry-red swollen epiglottis Usually not hoarse or coughing Lateral neck radiograph shows "thumb sign" of swollen epiglottis	Low-grade fever, barking cough, hoarseness, aphonia, stridor; mild retractions; radiograph shows "steeple sign" of subglottic narrowing on anteroposterior neck view	Prior history of croup with sudden onset of respiratory distress, high fever, "toxic" appearance, hoarseness, stridor, barking cough, tripod sitting position; radiograph as per croup plus ragged tracheal air column	Prior pharyngitis with sudden-onset fever, chills, odynophagia, neck pain, septic thrombophlebitits of internal jugular vein with septic emboli (e.g., lungs, joints), bacteremia

*Often odontogenic; check for tooth abscess, caries, tender teeth.
†Peptostreptococcus, Fusobacterium, Bacteroides.

TABLE 1.5	Red Flags Associated with Sore Throat

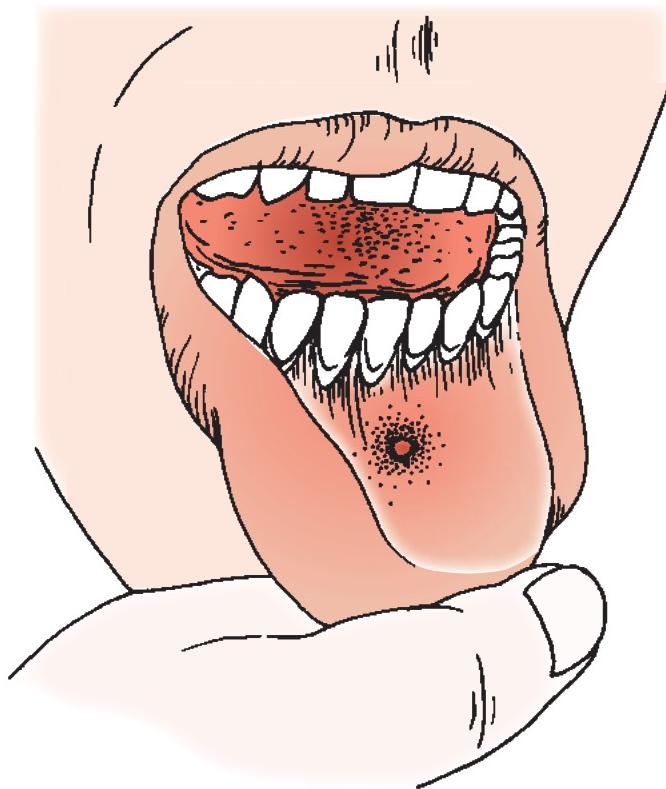
Toxic appearance
Shock
Fever >2 wk
Duration of sore throat >2 wk
Trismus
Drooling
Cyanosis
Hemorrhage
Asymmetric tonsillar swelling or asymmetric cervical adenopathy
Respiratory distress (airway obstruction or pneumonia)
Suspicion of parapharyngeal space infection
Suspicion of diphtheria (bull neck, uvula paralysis, thick membrane)
Apnea
Severe, unremitting pain
"Hot potato" voice
Chest or neck pain
Weight loss


FIGURE 1.1 Aphthous stomatitis ("canker sore"). (From Reilly BM. Sore throat. In: *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991.)

to oral prednisone or cimetidine. There are reports of improvement after tonsillectomy. In most patients PFAPA completely resolves before puberty without sequelae. The diagnosis is based on clinical criteria after excluding cyclic neutropenia, other periodic fever syndromes, infections, and malignancy.

Infants and toddlers with **measles** often have prominent oral findings early in the course of the disease. In addition to high fever, cough, coryza, and conjunctivitis, the pharynx may be intensely and diffusely erythematous, without tonsillar enlargement or exudate. The presence of **Koplik spots**, the pathognomonic white or blue-white enanthem of measles, on the buccal mucosa near the mandibular molars provides the evidence of the correct diagnosis before the rash develops. Measles can be complicated by pneumonia and encephalitis. In the United States, widespread use of the measles vaccine has virtually eliminated transmission of natural measles infection except among unvaccinated subpopulations (children <12 months old, families who have refused immunization). Most cases are imported by unimmunized visitors from countries with endemic measles.

INFECTIOUS MONONUCLEOSIS

◆ Pathogenesis

Acute exudative pharyngitis commonly occurs with infectious mononucleosis caused by primary infection with the Epstein-Barr virus (EBV). Mononucleosis is a febrile, systemic, self-limited lymphoproliferative disorder that is usually associated with hepatosplenomegaly and generalized lymphadenopathy. Acute pharyngitis may be mild or severe, with significant tonsillar hypertrophy (possibly producing airway obstruction), erythema, and impressive tonsillar exudates. Regional lymph nodes may be particularly enlarged and slightly tender. Infectious mononucleosis usually occurs in adolescents and young adults; EBV infection is generally milder or subclinical in preadolescent children. In U.S. high school and college students, attack rates are 200-800 per 100,000 per year. EBV is transmitted primarily by saliva.

◆ Clinical Features

After a 2-4 week incubation period, patients with infectious mononucleosis usually experience an abrupt onset of malaise, fatigue, fever, and headache, followed closely by pharyngitis. The tonsils are enlarged with exudates and cervical adenopathy. More generalized adenopathy with hepatosplenomegaly often follows. Fever and pharyngitis typically last 1-3 weeks, and lymphadenopathy and hepatosplenomegaly resolve over 3-6 weeks. Malaise and lethargy can persist for several months and can affect school or work performance.

◆ Diagnosis

Laboratory studies of diagnostic value include atypical lymphocytosis; these lymphocytes are primarily EBVspecific, cytotoxic T lymphocytes that represent a reactive response to EBV-infected B lymphocytes. A modest elevation of serum transaminase levels, reflecting EBV hepatitis, is common. Tests useful for diagnosis include detection of heterophile antibodies that react with bovine erythrocytes (most often detected by the monospot test) and a specific antibody against EBV viral capsid antigen (VCA), early antigen (EA), and nuclear antigen (EBNA). Acute infectious mononucleosis is usually associated with a positive heterophile test result and antibody to VCA and EA (Fig. 1.2).

The findings of acute exudative pharyngitis together with hepatomegaly, splenomegaly, and generalized lymphadenopathy suggest infectious mononucleosis. Early in the disease and in cases without liver or spleen enlargement, differentiation from other causes of pharyngitis, including streptococcal pharyngitis, is difficult. Indeed, a small number of patients with infectious mononucleosis have a throat culture positive for group A streptococci. (They are likely streptococcal carriers; see subsequent text.) An indistinguishable syndrome can occur with cytomegalovirus, but differentiation is rarely of clinical importance. Serologic evidence of mononucleosis should be sought

(See *Nelson Textbook of Pediatrics*, p. 1586)

TABLE 1.6 Vesicular-Ulcerating Eruptions of the Mouth and Pharynx

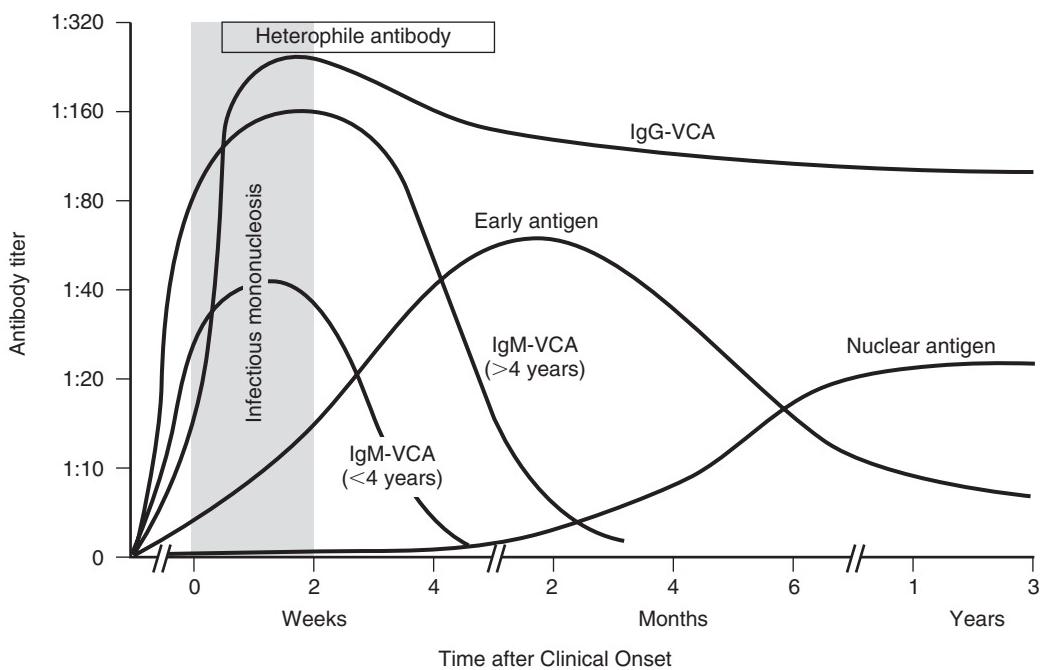
|	Gingivostomatitis	Herpangina	Hand-Foot-Mouth Disease	Chickenpox	Systemic Lupus Erythematosus (SLE)	Inflammatory Bowel Disease (IBD)	Aphthous Stomatitis	Behçet Disease	Vincent Stomatitis	Recurrent Scarifying Ulcerative Stomatitis (Sutton Disease)
Etiology	Herpes simplex virus (HSV I)	Cocksackievirus A, B; echovirus or HSV (rarely)	Cocksackievirus A, cocksackievirus B (rarely)	Varicella-zoster virus	Autoimmune	Autoimmune	Unknown	Unknown; vasculitis	Unknown; or anaerobic bacteria	Unknown
Location	Ulcerative vesicles of pharynx, tongue, and palate plus lesions of mucocutaneous (perioral) margin	Anterior fauces (tonsils), soft palate (uvula), less often pharynx	Tongue, buccal mucosa, palate, palms, soles, anterior oral cavity	Tongue, gingiva, buccal mucosa, marked cutaneous lesions; trunk > face	Oral, nasal mucosa; palate, pharynx, buccal mucosa	Lips, tongue, buccal mucosa, oropharynx	As in IBD	Oral (similar to IBD); genital ulcers	Gingiva; ulceration at base of teeth	Tongue; buccal mucosa
Age	Less than 5 yr	3-10 yr	1 yr-teens	Any age	Any age	Any age	Teens and adulthood	Teens, adulthood, occasionally <10 yr	Teens; if younger, consider immunodeficiency and blood dyscrasia	Teens
Manifestations	Fever, mouth pain, toxic, fetid breath, drooling, anorexia, cervical lymphadenopathy; cracked, swollen hemorrhagic gums; secondary inoculation possible (fingers, eye, skin); reactivation with long latency (any age)	Fever, sore throat, odynophagia; summer outbreaks; 6-12 lesions (2-4 mm papule) → vesicle → ulceration; headache, myalgias	Painful bilateral vesicles, fever	Fever, pruritic cutaneous vesicles, painful oral lesions	Renal, central nervous system, arthritis, cutaneous, hematologic, other organ involvement; ulcers minimally to moderately painful; may be painless	Multiple recurrences; painful ulcerations 1-2 mm, but may be 5-15 mm	Similar to IBD	Painful ulcerations (heal without scarring); uveitis, arthralgia, arthritis, lower gastrointestinal ulceration (similar to IBD); recurrences; spontaneous remissions	Fever, bleeding gums; gray membrane	Deep, large, painful ulcerations; relapsing; scarring with distortion of mucosa


FIGURE 1.2 Schematic representation of the evolution of antibodies to various Epstein-Barr virus antigens in patients with infectious mononucleosis. The titers are geometric mean values expressed as reciprocals of the serum dilution. The minimal titer tested for viral capsid antigen (VCA) and early antigen antibodies was 1:10; for Epstein-Barr nuclear antigen, it was 1:2.5. The immunoglobulin (Ig)M response to capsid antigen was divided because of the significant differences noted according to age. (From Jenson HB, Ench Y, Sumaya CV. Epstein-Barr virus. In: Rose NR, de Macario EC, Folds JD, et al, editors. *Manual of Clinical Laboratory Immunology.* 5th ed. Washington, DC: American Society for Microbiology; 1997. p. 634-43.)

when splenomegaly or other features are present or if symptoms persist longer than expected.

Primary infection with **human immunodeficiency virus** (HIV) may produce a mononucleosis-like illness with sore throat, fever, lymphadenopathy, rash, myalgias, and hepatosplenomegaly. Early infection may be detected by viral RNA or DNA load because immunoglobulin (Ig)M or IgG titers may have not yet developed.

GROUP A STREPTOCOCCAL INFECTION

In the evaluation of a patient with sore throat, the primary concern in the United States is usually accurate diagnosis and treatment of pharyngitis caused by group A streptococci (GAS) or *Streptococcus pyogenes*, which accounts for about 15% of all episodes of pharyngitis. The sequelae of GAS pharyngitis, especially acute rheumatic fever (ARF) and acute glomerulonephritis (AGN), at one time resulted in considerable morbidity and mortality in the United States and continue to do so in other parts of the world. Prevention of ARF in particular depends on timely diagnosis of streptococcal pharyngitis and prompt antibiotic treatment. Group A streptococci are characterized by the presence of group A carbohydrate in the cell wall, and they are further distinguished by several cell wall protein antigens (M, R, T). These protein antigens, especially the M protein, a virulence factor, are useful for studies of epidemiology and pathogenesis but are not used in clinical care.

◆ Epidemiology

GAS pharyngitis is endemic in the United States; epidemics occur sporadically. Episodes peak in the late winter and early spring. Rates of GAS pharyngitis are highest among children aged 5-11 years old.

Spread of GAS in classrooms and among family members is common, especially in the presence of crowded living conditions. Transmission occurs primarily by the inhalation of organisms in large droplets or by direct contact with respiratory secretions. Pets do not appear to be a frequent reservoir. Untreated streptococcal pharyngitis is particularly contagious early in the acute illness and for the first 2 weeks after the organism has been acquired, but antibiotic therapy effectively prevents disease transmission. Within 24 hours of institution of therapy with penicillin, it is difficult to isolate GAS from patients with acute streptococcal pharyngitis, and infected children can return to school.

Molecular epidemiology studies of streptococcal pharyngitis have shown that the prevalent M protein types vary among communities and over time. Numerous distinct strains of GAS can circulate simultaneously in a community during the peak season. GAS M proteins can be identified in research studies by using PCR to establish the specific M protein gene (*emm* gene); M protein identification is not available for use in clinical care. Children with streptococcal pharyngitis can serve as a local reservoir for strains that cause invasive disease (e.g., sepsis, streptococcal toxic shock syndrome, cellulitis, necrotizing fasciitis) in the same geographic area and season.

◆ Clinical Features

The classic patient presentation of acute streptococcal pharyngitis involves a sudden onset of fever and sore throat. Headache, malaise, abdominal pain, nausea, and vomiting occur frequently. *Cough, rhinorrhea, conjunctivitis, stridor, diarrhea, discrete ulcerated lesions, and hoarseness are distinctly unusual and suggest a viral etiology.*

Examination of the patient reveals marked pharyngeal erythema. Petechiae may be noted on the palate, but they can also occur in viral pharyngitis, especially mononucleosis. Tonsils are enlarged, symmetric, and red, with patchy exudates on their surfaces. The papillae of the

(See *Nelson Textbook of Pediatrics*, p. 2018)

tongue may be red and swollen, hence the designation "strawberry tongue." Anterior cervical lymph nodes are often tender and enlarged.

Combinations of these signs can be used to assist in diagnosis; in particular, tonsillar exudates in association with fever, palatal petechiae, and tender anterior cervical adenitis strongly suggest infection with GAS. However, other diseases can produce this constellation of findings, including infectious mononucleosis. Some or all of these classic characteristics may be absent in patients with streptococcal pharyngitis. Symptoms usually resolve within 5 days even in the absence of antibiotic therapy. Younger children can have a syndrome called **streptococcosis**—coryza with crusting below the nares, more generalized adenopathy, and a more chronic course. When rash accompanies the illness, accurate clinical diagnosis is easier. **Scarlet fever**, so-called because of the characteristic fine, diffuse red rash, is essentially pathognomonic for infection with group A streptococci. Scarlet fever is rarely seen in children younger than 3 years old or in adults.

Scarlet Fever

The rash of scarlet fever is caused by infection with a strain of GAS that contains a bacteriophage encoding for production of an erythrogenic (redness producing) toxin, usually erythrogenic (also called pyrogenic) exotoxin A (designated SPE A). Scarlet fever is simply GAS pharyngitis with a rash and should be explained as such to patients and their families. Although patients with the streptococcal toxic shock syndrome are also infected with GAS that produces SPE A, most GAS pharyngeal infections are not associated with development of severe invasive or systemic disease.

The rash of scarlet fever has a texture like sandpaper and blanches with pressure. It usually begins on the face, but after 24 hours, it becomes generalized. The face is red, especially over the cheeks, and the area around the mouth often appears pale in comparison, giving the appearance of circumoral pallor. Accentuation of erythema occurs in flexor skin creases, especially in the antecubital fossae (Pastia lines). The erythema begins to fade within a few days. Desquamation begins within a week of onset on the face and progresses downward, often resembling that seen after mild sunburn. On occasion, sheet-like desquamation occurs around the free margins of the fingernails; this is usually coarser than the desquamation seen with Kawasaki disease. The differential diagnosis of scarlet fever includes Kawasaki disease, measles, and staphylococcal toxic shock syndrome (Table 1.7).

◆ Diagnosis

Although signs and symptoms may strongly suggest acute streptococcal pharyngitis, laboratory diagnosis is strongly recommended, even for patients with scarlet fever (Fig. 1.3). Scoring systems for diagnosing acute GAS pharyngitis on clinical grounds have not proved very satisfactory. Using clinical criteria alone, physicians overestimate the likelihood that patients have streptococcal infection. The throat culture on blood agar plate has traditionally been used to diagnose streptococcal pharyngitis. Plating a swab of the posterior pharynx and tonsils on sheep blood agar, identifying β-hemolytic colonies, and testing them for the presence of sensitivity to a bacitracin-impregnated disk has long been the "gold standard" diagnostic test, but it takes 24-48 hours to obtain results. Rapid antigen detection tests (RADTs) that take less than 15 minutes can detect the presence of the cell wall group A carbohydrate antigen after acid extraction of organisms obtained by throat swab. RADTs are highly specific (generally >95%) when compared to throat culture. In comparison to hospital or reference laboratory throat culture results, the sensitivities of these tests are generally 75-85% and can be lower. The low sensitivity of these tests, coupled

| TABLE 1.7	Differential Diagnosis of Scarlet Fever				
	Scarlet Fever	**Kawasaki Disease**	**Measles**	**Staphylococcal Toxic Shock Syndrome**	**Staphylococcal Scalded Skin Syndrome**
Agent	Group A streptococci	Unknown	Measles virus	*Staphylococcus aureus*	*S. aureus*
Age range	All (peak, 5-15 yr)	Usually <5 yr	<2 yr, 10-20 yr	All (especially >10 yr)	Usually <5 yr
Prodrome	No	No	Fever, coryza, cough, conjunctivitis	Usually no	No
Enanthem	No	Occasionally	Koplik spots	No	Limited
Mouth	Strawberry tongue, exudative pharyngitis, palatal petechiae	Erythema; red, cracked lips, strawberry tongue	Diffusely red, no cracked lips	Usually normal	Erythema
Rash	Fine, red, "sandpaper," membranous desquamation, circumoral pallor, Pastia lines	Variable polymorphic; erythematous face, trunk, and diaper area; tips of fingers and toes desquamate 10–28 days after onset	Maculopapular; progressing from forehead to feet; may desquamate	Diffuse erythroderma; desquamates	Erythema, painful bullous lesions; positive Nikolsky sign; desquamates
Other	Cervical adenitis, gallbladder hydrops, fever	Coronary artery disease; fever >5 days; conjunctival (nonpurulent) injection; tender, swollen hands and feet; cervical adenopathy (size >1.5 cm); thrombocytosis; pyuria (sterile); gallbladder hydrops	"Toxic" appearance; dehydration; encephalitis, pneumonia; fever	Shock (hypotension, including orthostatic); encephalopathy; diarrhea; headache	Fever, cracked lips; conjunctivitis

with their excellent specificity, has led to the recommendation that two throat swabs be obtained simultaneously from patients with suspected GAS pharyngitis. One swab is used for a rapid test. When the RADT result is positive, it is highly likely that the patient has GAS pharyngitis, and the extra swab can be discarded. When the RADT is negative, GAS may nonetheless be present; thus, the extra swab should be processed for culture. The sensitivity of rapid tests can be improved by restricting testing to patients most likely to have acute GAS pharyngitis and avoiding testing patients more likely to have viral pharyngitis. This takes advantage of the spectrum effect (or spectrum bias) associated with many clinical tests including RADTs and throat cultures; the pretest probability of having the disease affects test results. One of the best validated scoring systems for children was developed by McIsaac, et al. Patients with greater likelihood of GAS infection tend to have more McIsaac criteria (fever, cervical adenopathy, tonsillar exudates, no cough, 3-15 years old), but the positive predictive value of the highest McIsaac score is only about 60% (Table 1.8). In contrast, a score ≤2 is

associated with a negative predictive value of about 80%. The presence of viral symptoms such as cough, rhinorrhea, conjunctivitis, laryngitis, stridor, croup, or diarrhea decreases the likelihood that the illness is due to GAS. Patients with a negative RADT result should not be treated before culture verification unless there is a particularly high suspicion of GAS infection (e.g., scarlet fever, peritonsillar abscess, or tonsillar exudates in addition to tender cervical adenopathy, palatal petechiae, fever, and recent exposure to a person with GAS pharyngitis).

Molecular "PCR-like" tests for GAS are available for use in hospital and reference laboratories. Some are cleared by the Food and Drug Administration (FDA) for use in physician office laboratories, particularly those offices that are certified to perform CLIA-moderate tests. These simplified molecular tests use methods that amplify the DNA of a specific GAS gene. They take less than 1 hour to perform and are reported to have both sensitivity and specificity ≥99% when compared to standard throat culture and PCR. They can be used as a "stand-alone" test for GAS or as a confirmatory test when the RADT is negative. There are three concerns with these molecular tests: (1) they are so sensitive it is likely they will identify more patients who are carriers than would ordinarily be identified by RADT and/or culture; (2) unless rigorous technique is followed they may be prone to contamination with exogenous GAS DNA from other swabs, a particular concern in physician offices when performed by staff who are not trained laboratory technologists; and (3) they are much more expensive than throat culture, and their costs may not be covered by all insurance plans.

Testing patients for serologic evidence of an antibody response to extracellular products of GAS is not useful for diagnosing acute pharyngitis. Because it generally takes several weeks for antibody levels to rise, streptococcal antibody tests are valid only for determining past infection. Specific antibodies that are often measured in the appropriate clinical setting include antistreptolysin O (ASO), anti-DNase B, and antihyaluronidase (AHT). When antibody testing is desired in order to evaluate a possible poststreptococcal illness, more than one of these tests should be performed to improve sensitivity.

◆ Treatment

Treatment begun within 9 days of the onset of GAS pharyngitis is effective in preventing acute rheumatic fever (ARF). Therapy does not

TABLE 1.9	Recommended Treatment Regimens for Acute Streptococcal Pharyngitis*		
	Dose/Route	**Duration**	**Frequency**
Standard Treatment			
Amoxicillin	50 mg/kg up to 1000 mg/Oral	10 days	Once daily
Penicillin V	250 mg (500 mg for adolescents and adults)/Oral	10 days	bid
Benzathine penicillin G	600,000 U (weight <27 kg)/IM	N/A	Once
	1.2 million U (weight ≥27 kg)/IM	N/A	
	Oral Dose	**Duration**	**Frequency**
Treatment for Penicillin-Allergic Patients			
Clarithromycin	15 mg/kg/day up to 500 mg/day	10 days	bid
Azithromycin[†]	12 mg/kg on day 1 then 6 mg/kg/d on days 2-5	5 days	Once daily
Clindamycin	21 mg/kg/day 20 mg/kg/day up to 900 mg/day	10 days	tid
Cephalosporins[‡]			
Cephalexin	40 mg/kg/day up to 1000 mg/day	10 days	bid
Cefadroxil	30 mg/kg/day up to 1000 mg/day	10 days	Once daily

*Based on Infectious Diseases Society of America 2012 and AAP Red Book recommendations.
[†]Maximum dose for children is 500 mg/day. Adult dosage: 500 mg the first day, 250 mg the subsequent 4 days.
[‡]First-generation cephalosporins (e.g., cephalexin and cefadroxil) are preferred but all cephalosporins are effective. Dosage and frequency vary among agents. Avoid use in patients with history of immediate (anaphylactic) hypersensitivity to penicillin or other β-lactam antibiotics.

appear to affect the risk of acute poststreptococcal glomerulonephritis (AGN). Antibiotic therapy also reduces the incidence of suppurative sequelae of GAS pharyngitis, such as peritonsillar abscess and cervical adenitis. In addition, treatment produces a more rapid resolution of signs and symptoms and terminates contagiousness within 24 hours. For these reasons, antibiotics should be instituted as soon as the diagnosis is supported by laboratory studies.

There are numerous antibiotics available for treating streptococcal pharyngitis (Table 1.9). The drugs of choice are penicillin and amoxicillin. Despite the widespread use of penicillin to treat streptococcal and other infections for many decades, resistance of GAS to penicillin or any other β-lactam antibiotic has not developed. Amoxicillin has been demonstrated to be effective in eradicating GAS when given by mouth once daily for 10 days. The convenience of once-daily dosing and palatability make amoxicillin an attractive approach despite its somewhat broader spectrum of antimicrobial activity. Penicillin can be given by mouth twice daily for 10 days or intramuscularly as a single injection of benzathine penicillin. Intramuscular benzathine penicillin alleviates concerns about patient compliance. A less painful parenteral alternative is benzathine penicillin in combination with procaine penicillin. Intramuscular procaine penicillin alone is not effective for prevention of ARF because adequate levels of penicillin are not present in blood and tissues for a sufficient time. Other β-lactams, including semisynthetic derivatives of penicillin and the cephalosporins, are at least as effective as penicillin for treating streptococcal pharyngitis. The broader spectrum of the cephalosporins and their higher cost relegate them to second-line status. The decreased dosing frequency of amoxicillin and some cephalosporins may improve patient adherence.

Patients who are allergic to penicillin can receive a cephalosporin if they have not had an immediate hypersensitivity reaction. Erythromycin or another non-β-lactam antibiotic, such as clarithromycin, azithromycin, or clindamycin, can be used. Resistance of GAS to macrolides has increased dramatically in many areas of the world where erythromycin has been widely used. Macrolide resistance also affects azithromycin and can affect clindamycin. Although this resistance has

not yet emerged as a major problem in the United States, where the rate of macrolide resistance among GAS is generally 5-8%, there is much local variation. GAS resistance to clindamycin is in the range of 1-2%. Of note, both macrolide and clindamycin resistance are more common in Canada than in the United States. Sulfa drugs (including sulfamethoxazole combined with trimethoprim), tetracyclines, and chloramphenicol should not be used for treatment of acute streptococcal pharyngitis because they do not eradicate GAS.

Suppurative Complications

Antibiotic therapy has greatly reduced the likelihood of developing suppurative complications caused by spread of GAS from the pharynx or middle ear to adjacent structures. **Peritonsillar abscess** ("quinsy") manifests with fever, severe throat pain, dysphagia, "hot potato voice," pain referred to the ear, and bulging of the peritonsillar area with asymmetry of the tonsils and sometimes displacement of the uvula (Fig. 1.4; see also Table 1.4). There can be peritonsillar cellulitis without a well-defined abscess cavity. Trismus may be present. When an abscess is found clinically or by an imaging study such as a computed tomographic (CT) scan, surgical drainage is indicated. Peritonsillar abscess occurs most commonly in older children and adolescents.

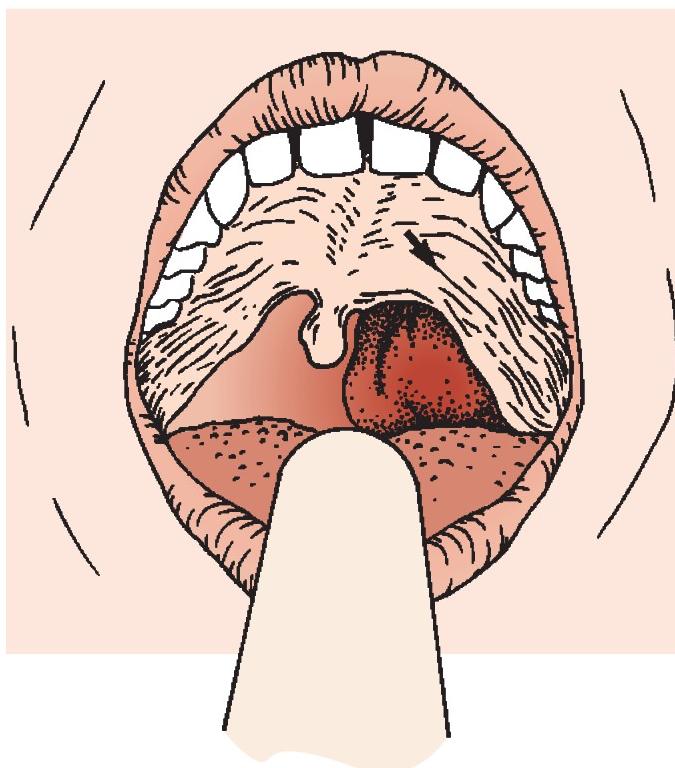
Retropharyngeal abscess represents extension of an infection from the pharynx or peritonsillar region into the retropharyngeal (prevertebral) space, which is rich in lymphoid structures (Figs. 1.5 and 1.6; see also Table 1.4). Children younger than 4 years old are most often affected. Fever, dysphagia, drooling, stridor, extension of the neck, and a mass in the posterior pharyngeal wall may be noted. Surgical drainage is often required if frank suppuration has occurred. Spread of GAS via pharyngeal lymphatic vessels to regional nodes can cause **cervical lymphadenitis**. The markedly swollen and tender anterior cervical nodes that result can suppurate. Otitis media, mastoiditis, and sinusitis also may occur as complications of GAS pharyngitis. Additional parapharyngeal suppurative infections that may mimic streptococcal disease are noted in Table 1.4. Furthermore, any pharyngeal infectious process may produce **torticollis** if there is inflammation that extends


FIGURE 1.4 Peritonsillar abscess (quinsy, sore throat). The left tonsil is asymmetrically inflamed and swollen; there is displacement of the uvula to the opposite side. The supratonsillar space *(arrow)* is also swollen; this is the usual site of the surgical incision for drainage. Prominent unilateral cervical adenopathy typically coexists. (From Reilly BM. Sore throat. In: *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991.)

to the paraspinal muscles and ligaments, producing pain, spasm, and, on occasion, rotary subluxation of the cervical spine. Oropharyngeal torticollis lasts less than 2 weeks and is not associated with abnormal neurologic signs or pain over the spinous process. Invasive sterile site or bacteremic infection with GAS is unusual as sequelae to pharyngitis.

Nonsuppurative Sequelae

Nonsuppurative complications include acute rheumatic fever (ARF), acute glomerulonephritis (AGN), and possibly reactive arthritis/synovitis. In addition, an association between streptococcal infection and neuropsychiatric disorders such as tic disorder, obsessive-compulsive disorder, and Tourette syndrome has been postulated. This possible association has been called PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococci). The terminology has been modified to "pediatric acute-onset neuropsychiatric syndrome" (PANS) or "childhood acute neuropsychiatric syndrome" (CANS), in recognition that the etiologic role of GAS and benefit from antibiotic treatment have been difficult to establish, and it is likely that infections other than GAS infection are associated with the development, recurrence, or exacerbation of neuropsychiatric symptoms.

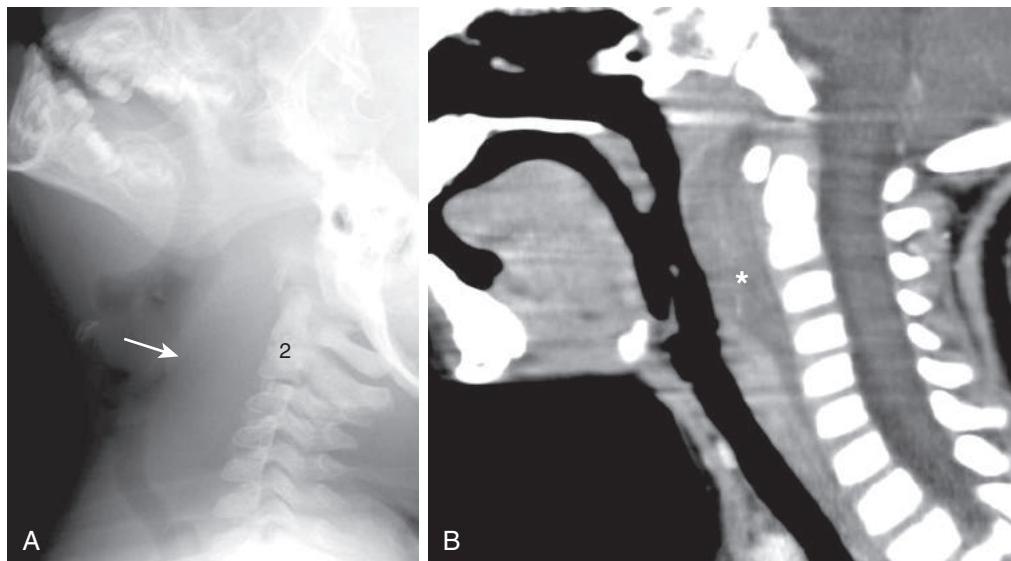
Therapy with an appropriate antibiotic within 9 days of onset of symptoms is highly effective in preventing ARF. Except in certain geographic areas (e.g., Salt Lake City) and populations (e.g., Hasidic Jewish communities) ARF is quite rare in North America. The impressive reduction in ARF prevalence in the United States since the mid-1960s may be related to reductions in the prevalence of so-called "rheumatogenic" GAS M types. The reason for the near disappearance of rheumatogenic types in the United States is unknown. Areas of the world with persistently high rates of ARF have different M types than the United States had in the past and has currently. AGN is not prevented by treatment of the antecedent streptococcal infection. Pharyngitis caused by one of the "nephritogenic" strains of GAS precedes


FIGURE 1.5 Retropharyngeal abscess in a 3-year-old female with sore throat and fever. *A,* Lateral soft tissue neck radiograph reveals extensive soft tissue swelling displacing the airway anteriorly from the skull base to C6 *(arrow)*. *B,* Sagittal reconstructed contrast-enhanced computed tomography confirms thickened, enhancing retropharyngeal soft tissues indicating cellulitis. Region of hypoattenuating fluid is concerning for retropharyngeal abscess *(asterisk)*. (From Lowe LH, Smith CJ. Infection and inflammation. In: *Caffey's Pediatric Diagnostic Imaging.* 12th ed. Vol 1. Philadelphia: Elsevier; 138; Figure 15.4.)
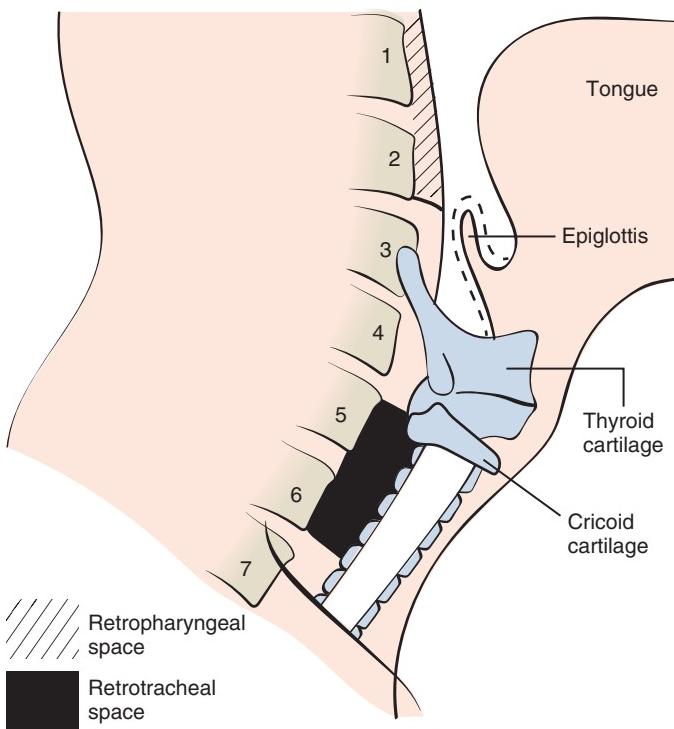

FIGURE 1.6 In an adolescent, the retropharyngeal space normally does not exceed 7 mm when measured from the anterior aspect of the C2 vertebral body to the posterior pharynx. In infants the retropharyngeal space is usually less than one width of the adjacent vertebral body. However, during crying, this distance may be three widths of the vertebral body. In addition, under normal circumstances, the retrotracheal space does not exceed 22 mm in adolescents when measured from the anterior aspect of C6 to the trachea. *Dotted lines* depict the "thumbprint" sign, noted on a lateral neck radiograph, made by a swollen epiglottis. (From Reilly BM. Sore throat. In: *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991.)

FIGURE 1.7 Management of patients with repeated or frequent positive rapid tests or throat cultures. GAS, group A streptococci; IM, intramuscular.

glomerulonephritis by about 10 days. Unlike ARF, which occurs only after GAS pharyngitis, AGN also can follow GAS skin infection.

Treatment Failure and Chronic Carriage

Treatment with penicillin cures GAS pharyngitis but does not eradicate GAS from the pharynx in as many as 25% of patients (Fig. 1.7). This causes considerable consternation among affected patients and their families. Resistance to penicillin is not the cause of treatment failure. A few such patients are symptomatic and are characterized as having clinical treatment failure. Re-infection with the same strain or a different strain is possible, as is intercurrent viral pharyngitis. Some of these patients may be chronic pharyngeal carriers of GAS who are suffering from a new superimposed viral infection; others may have been non-adherent to therapy. Many patients who continue to have positive tests for GAS despite antimicrobial treatment are asymptomatic and are identified only when follow-up throat swabs are obtained, a practice that is usually unnecessary in North America. Patients who adhered to therapy are at minimal risk for ARF. One explanation for asymptomatic persistence of GAS after treatment is that these patients are chronically colonized with GAS, were initially symptomatic because of a viral pharyngitis, and did not truly have acute streptococcal pharyngitis.

Patients who are chronically colonized with GAS are called chronic carriers. Carriers do not appear to be at risk for ARF or for development of suppurative complications, and they are rarely sources of

spread of GAS in the community. There is no reason to exclude carriers from school. There is no easy way to identify chronic carriers prospectively among patients with symptoms of acute pharyngitis. The pathophysiology of chronic carriage is unknown. As resistance to penicillin is not a factor, many other causes have been hypothesized including non-adherence to antibiotic treatment, tolerance to antibiotics (suppression but lack of killing by antimicrobials), internalization of GAS by epithelial cells, and presence of β-lactamase-producing "co-pathogens," but none has been proven. The clinician should consider the possibility of chronic GAS carriage when a patient or a family member has multiple test-positive episodes of pharyngitis, especially when symptoms are mild or atypical. A culture or other test is usually positive for GAS when the suspected carrier is symptom-free or is receiving antibiotic treatment (intramuscular benzathine penicillin is recommended in order to eliminate concerns about compliance).

Carriers often receive multiple unsuccessful courses of antibiotic therapy in attempts to eliminate GAS. Physician and patient anxiety is common and can develop into "streptophobia." Unproven and ineffective therapies include tonsillectomy, prolonged administration of antibiotics, use of β-lactamase-resistant antibiotics, and culture or treatment of pets. Available treatment options for the physician faced with a chronic streptococcal carrier include the following:

1. Evaluate for GAS pharyngitis by throat swab each time the patient has pharyngitis with features that suggest streptococcal pharyngitis. Treat as acute GAS pharyngitis with amoxicillin or penicillin (or an alternative agent) each time a test is positive; this will prevent ARF if the GAS identified has been newly acquired. Avoid testing patients who do not have signs and symptoms suggestive of acute GAS pharyngitis.

2. Treating with one of the regimens effective for terminating chronic carriage.

The first option is simple, as safe as amoxicillin and penicillin, and appropriate for most patients. The second option should be reserved for particularly anxious patients; those with a history of ARF or living with someone who had it; or those living or working in nursing homes, chronic care facilities, and hospitals. Two antibiotic treatment regimens have been demonstrated in randomized trials to be effective for eradication of the carrier state:

- Intramuscular benzathine penicillin plus oral rifampin (10 mg/kg/dose up to 300 mg, given twice daily for 4 days beginning on the day of the penicillin injection)
- Oral clindamycin, given for 10 days (20 mg/kg/day up to 450 mg, divided into three equal doses)

Clindamycin is easier to use than intramuscular penicillin plus oral rifampin and may be somewhat more effective. Amoxicillin-clavulanate (40 mg amoxicillin/kg/day up to 2000 mg amoxicillin/day divided tid for 10 days) has also been used. Successful eradication of the carrier state makes evaluation of subsequent episodes of pharyngitis much easier, although chronic carriage can recur upon re-exposure to GAS.

Recurrent Acute Pharyngitis

Some patients seem remarkably susceptible to developing GAS pharyngitis. The reasons for frequent *bona fide* acute GAS pharyngitis are obscure. In contrast to chronic carriers, appropriate antibiotic treatment of each episode results in eradication of the organism.

The role of tonsillectomy in the management of patients with multiple episodes of streptococcal pharyngitis is controversial. The presence of tonsils is not necessary for GAS to infect the throat. Fewer episodes of sore throat were reported among patients treated with tonsillectomy (in contrast to patients treated without surgery) during the first 2 years after operation. Patients had experienced numerous episodes of pharyngitis over several years, and it appears that not all episodes were caused by GAS. By 2 years after tonsillectomy there was no difference between the groups in the frequency of pharyngitis. The postoperative complication rate among tonsillectomy patients was 14%. *Tonsillectomy cannot be recommended for treatment of* recurrent *pharyngitis except in unusual circumstances.* It is preferable to treat most patients with penicillin or amoxicillin whenever symptomatic GAS pharyngitis occurs. Obtaining follow-up throat specimens for culture can help distinguish recurrent pharyngitis from chronic carriage but is unnecessary in most instances.

INFECTION WITH STREPTOCOCCI THAT ARE NOT GROUP A (NON-A STREPTOCOCCI)

Certain β-hemolytic streptococci of serogroups other than group A cause acute pharyngitis. Well-documented *epidemics* of food-borne group C and group G streptococcal pharyngitis have been reported in young adults. In these situations, a high percentage of individuals who had ingested the contaminated food promptly developed acute pharyngitis, and throat cultures yielded virtually pure growth of the epidemiologically linked organism. There have been outbreaks of group G streptococcal pharyngitis among children. However, the role of non-A streptococcal organisms as etiologic agents of acute pharyngitis in *endemic* circumstances has been difficult to establish. Group C and group G streptococci may be responsible for acute pharyngitis, particularly in adolescents. However, the exact role of these agents, most of which are carried asymptomatically in the pharynx of some children and young adults, remains to be fully characterized. When they are implicated as agents of acute pharyngitis, groups C and G organisms do not appear to necessitate treatment, inasmuch as they cause self-limited infections. Acute rheumatic fever is not a sequela to these infections but acute glomerulonephritis has been documented in rare cases after epidemic group C and group G streptococcal pharyngitis.

FUSOBACTERIUM NECROPHORUM

Fusobacterium necrophorum, an anaerobic gram-negative organism, is increasingly recognized as a cause of pharyngitis in older adolescents and adults (ages 15-30 years). Prevalence in studies in Europe is reported to be about 10% in patients with pharyngitis not caused by GAS, but large surveillance studies have not been performed. In a U.S. study of students at a university health clinic, *F. necrophorum* was detected by PCR in 20.5% of patients with pharyngitis and 9.4% of an asymptomatic convenience sample; some had more than one bacterium detected by PCR of throat swabs. Many of the pharyngitis patients with *F. necrophorum* had signs and symptoms indistinguishable from patients with increased likelihood for GAS pharyngitis: About one-third had fever, one-third had tonsillar exudates, two-thirds had anterior cervical adenopathy, and most did not have cough. The symptomatic overlap of *F. necrophorum* and GAS and the presence of asymptomatic carriage could complicate the clinical assessment of sore throat in adolescents but *F. necrophorum* is difficult to culture from the throat and neither a rapid test nor PCR is available for use in clinical care.

F. necrophorum pharyngitis can be associated with development of septic thrombophlebitis of the internal jugular vein, known as Lemierre syndrome (Fig. 1.8). Approximately 80% of cases of Lemierre syndrome are due to this bacterium, but the proportion of patients infected or colonized with *F. necrophorum* who develop pharyngitis and Lemierre syndrome is unknown. Patients present initially with fever, sore throat, exudative pharyngitis, and/or peritonsillar abscess. The symptoms persist, severe neck pain and swelling develop, and the patient appears toxic. Septic shock may ensue along with metastatic complications, especially septic pulmonary emboli. Diagnosis is confirmed by computed tomography or magnetic resonance imaging of the neck and isolation of the organism on anaerobic blood culture. *F. necrophorum* is usually sensitive in vitro to penicillin, but some isolates produce β-lactamases, and treatment failure with penicillin has been reported. Many expert clinicians use metronidazole, clindamycin, a β-lactam in combination with a β-lactamase inhibitor (such as ampicillin-sulbactam), or a carbapenem. The septic thrombophlebitis of Lemierre syndrome can be polymicrobial; combination antibiotic therapy may be beneficial. Some patients require surgical debridement and/or incision and drainage. The case-fatality rate may be as high as 4-9%.

ARCANOBACTERIUM INFECTION

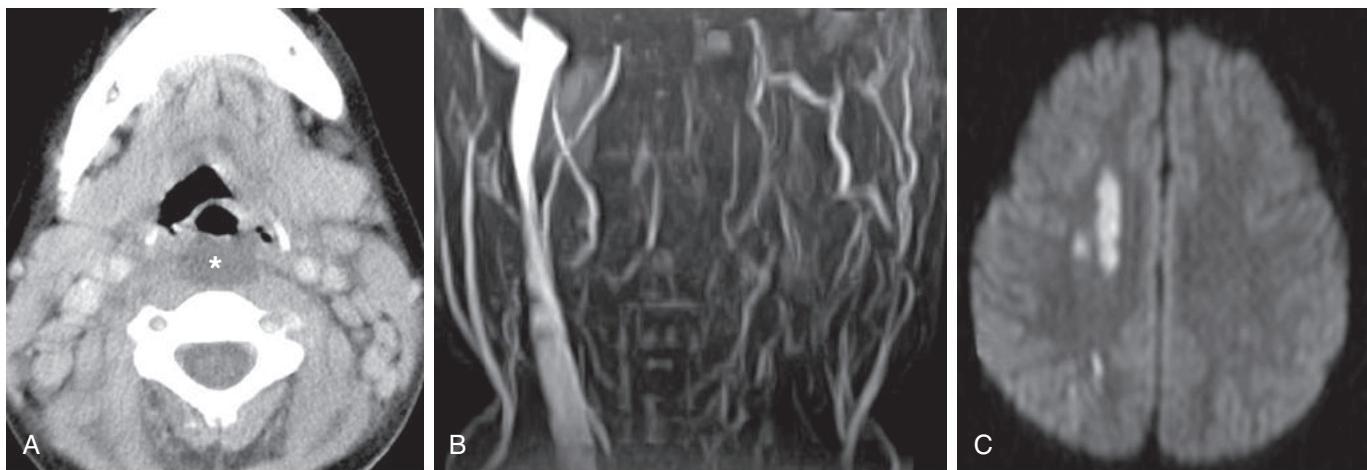
Arcanobacterium haemolyticum is a gram-positive rod that has been reported to cause acute pharyngitis and scarlet fever-like rash, particularly in teenagers and young adults. Detecting this agent requires special methods for culture, and it has not routinely been sought in patients with scarlet fever or pharyngitis. The clinical features of *A. haemolyticum* are indistinguishable from GAS pharyngitis; pharyngeal erythema is present in almost all patients, patchy white to gray exudates in about 70%, cervical adenitis in about 50%, and moderate fever in 40%. Palatal petechiae and strawberry tongue may also occur. The scarlatiniform rash usually spares the face, palms, and soles. The rash is erythematous and blanches; it may be pruritic and demonstrate minimal desquamation. Erythromycin appears to be the treatment of choice.


FIGURE 1.8 Lemierre syndrome (*Fusobacterium necrophorum* infection) complicated by stroke in a 6-year-old female presenting with fever, difficulty swallowing, and nuchal rigidity. *A,* Axial contrast enhanced computed tomography image shows low-attenuation retropharyngeal fluid *(asterisk). B,* Magnetic resonance imaging 2 days later, performed because of acute left arm weakness, confirms lack of left internal jugular vein patency on magnetic resonance venogram. *C,* Diffusion-weighted image of the brain reveals multiple small foci of bright signal infarction secondary to emboli from thrombophlebitis, vasospasm, or both. (From Lowe LH, Smith CJ. Infection and inflammation. In: *Caffey's Pediatric Diagnostic Imaging.* 12th ed. Vol 1. Philadelphia: Elsevier; 137; Figure 15.2.)

EPIGLOTTITIS AND BACTERIAL TRACHEITIS

Epiglottitis (or supraglottitis) is a life-threatening infection of the airway proximal to the vocal cords (Fig. 1.9; see also Fig. 1.6). Historically, it was an infection in 1-4 year-old children caused by *Haemophilus influenzae* type b. It presents with acute onset of fever and severe sore throat. This disease progresses rapidly to airway compromise. Patients are often drooling and leaning forward with the neck extended. Some patients may have stridor, but a muffled voice is more common. Management depends on establishing a secure airway by intubation and treating with antibiotics. When epiglottitis is suspected, the oropharynx should not be visualized or manipulated except in a controlled environment (intensive care unit or operating room) by someone with expertise in management of the airway who is prepared to immediately intubate the patient. Vaccination against *H. influenzae* type b has nearly eliminated this disease in childhood; however, epiglottitis caused by GAS, *Streptococcus pneumoniae, Staphyloccocus aureus,* and non-type b *H. influenzae* occurs occasionally.

Bacterial tracheitis (bacterial croup, bacterial laryngotracheitis) is a rare complication of viral croup. *S. aureus* is the most common superinfecting bacteria identified. Patients have a history of prolonged croup symptoms that become dramatically worse with fever and signs of airway obstruction. While sore throat may have been present at the onset of croup, it is not a prominent complaint once bacterial infection of the airway occurs. The clinical appearance of patients with bacterial tracheitis may mimic that of patients with epiglottitis.

DIPHTHERIA

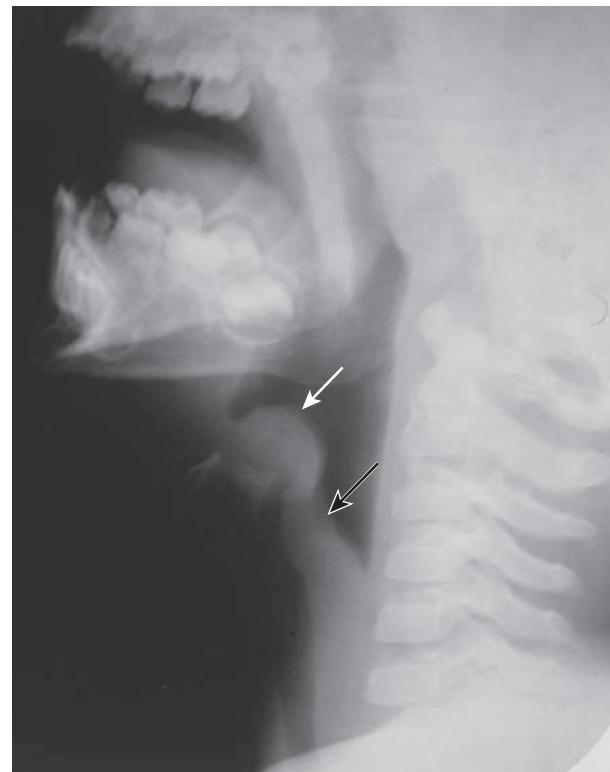
Diphtheria is a very serious disease that is caused by pharyngeal infection by toxigenic strains of *Corynebacterium diphtheriae.* It has become very rare in the United States and other developed countries as a result of immunization. The few diphtheria cases recognized annually in the United States usually occur in unimmunized individuals; the fatality rate is about 5%.


FIGURE 1.9 Epiglottis in a 5-year-old boy with respiratory distress and drooling. A lateral soft tissue neck radiograph shows a markedly thickened epiglottis *(white arrow),* which is referred to as the "thumb" sign. The aryepiglottic folds *(black arrow)* also are thickened. (From Laya BF, Lee EY. Upper airway disease. In: *Caffey's Pediatric Diagnostic Imaging.* 12th ed. Vol 1. Philadelphia: Elsevier; 529; Figure 51.2.)

(See *Nelson Textbook of Pediatrics*, p. 2035)

◆ Pathogenesis

The pathogenesis of diphtheria involves nasopharyngeal mucosal colonization by *C. diphtheriae* and toxin elaboration after an incubation period of 1-5 days. Toxin leads to local tissue inflammation and necrosis (producing an adherent grayish membrane made up of fibrin, blood, inflammatory cells, and epithelial cells) and it is absorbed into the bloodstream. Fragment B of the polypeptide toxin binds particularly well to cardiac, neural, and renal cells, and the smaller fragment A enters cells and interferes with protein synthesis. Toxin fixation by tissues may lead to fatal myocarditis (with arrhythmias) within 10-14 days and to peripheral neuritis within 3-7 weeks.

◆ Clinical Features

Acute tonsillar and pharyngeal diphtheria is characterized by sore throat, anorexia, malaise, and low-grade fever. The grayish membrane forms within 1-2 days over the tonsils and pharyngeal walls and occasionally extends into the larynx and trachea. Cervical adenopathy varies but may be severe and associated with development of a "bull neck." In mild cases, the membrane sloughs after 7-10 days, and the patient recovers. In severe cases, an increasingly toxic appearance can lead to prostration, stupor, coma, and death within 6-10 days. Distinctive features include palatal paralysis, laryngeal paralysis, ocular palsies, diaphragmatic palsy, and myocarditis. Airway obstruction (from membrane formation) may complicate the toxigenic manifestations.

◆ Diagnosis

Accurate diagnosis requires isolation of *C. diphtheriae* on culture of material from beneath the membrane, with confirmation of toxin production by the organism isolated. Laboratories must be forewarned that diphtheria is suspected. Other tests are of little value.

GONOCOCCAL PHARYNGITIS

Acute symptomatic pharyngitis caused by *Neisseria gonorrhoeae* occurs occasionally in sexually active individuals as a consequence of oral-genital contact. In cases involving young children, sexual abuse must be suspected. The infection usually manifests as an ulcerative, exudative tonsillopharyngitis but may be asymptomatic and resolve spontaneously. Gonococcal pharyngitis occurs after fellatio in homosexual men and heterosexual women and is less readily acquired after cunnilingus. Gonorrhea rarely is transmitted from the pharynx to a sex partner, but pharyngitis can serve as a source for gonococcemia. Diagnosis requires culture on appropriate selective media (e.g., Thayer-Martin medium). Nucleic acid amplification tests (NAAT) may also detect the organism from pharyngeal and other sites. Examination and testing for other sexually transmitted infections and pregnancy are recommended.

CHLAMYDIAL AND MYCOPLASMAL INFECTIONS

Chlamydia species and *Mycoplasma pneumoniae* may cause pharyngitis, although the frequency of these infections is unclear. *Chlamydia trachomatis* has been implicated serologically as a cause of pharyngitis in as many as 20% of adults with pharyngitis, but isolation of the organism from the pharynx has proved more difficult. *Chlamydia pneumoniae* has also been identified as a cause of pharyngitis. Because antibodies to this organism show some cross reaction with *C. trachomatis*, it is possible that infections formerly attributed to *C. trachomatis* were really caused by *C. pneumoniae*. Diagnosis of chlamydial pharyngitis is difficult, whether by culture or serologically, and neither method is readily available to the clinician.

M. pneumoniae most likely causes pharyngitis. Serologic (positive mycoplasma IgM) or, less often, culture methods can be used to identify this infectious agent, which was found in 33% of college students with pharyngitis in one study. PCR is diagnostic but there is no need to seek evidence of these organisms routinely in pharyngitis patients in the absence of ongoing research studies of nonstreptococcal pharyngitis. The efficacy of antibiotic treatment for *M. pneumoniae* and chlamydial pharyngitis is not known, but these illnesses appear to be self-limited.

■ SUMMARY AND RED FLAGS

Sore throat is a common complaint. Most children with acute sore throat have a viral illness. Accurate diagnosis of acute streptococcal pharyngitis is essential because appropriate therapy ensures prevention of serious suppurative and nonsuppurative complications. Life-threatening infectious complications of oropharyngeal infections may manifest with mouth pain, pharyngitis, parapharyngeal space infectious extension, and/or airway obstruction. Other red flags are prolonged fever, prolonged sore throat, drooling, trismus, and severe, unremitting pain (see Table 1.5).

Cough

Louella B. Amos

INTRODUCTION

Cough is an important defense mechanism of the lungs and is a common symptom, particularly during winter months. In most patients, it is self-limited. However, cough can be ominous, indicating serious underlying disease, because of accompanying problems (hemoptysis) or because of serious consequences of the cough itself (e.g., syncope and hemorrhage).

◆ Pathophysiology

The cough reflex serves to prevent the entry of harmful substances into the tracheobronchial tree and to expel excess secretions and retained material from the tracheobronchial tree. Cough begins with stimulation of cough receptors, located in the upper and lower airways, and in many other sites such as the ear canal, tympanic membrane, sinuses, nose, pericardium, pleura, and diaphragm. Receptors send messages via vagal, phrenic, glossopharyngeal, or trigeminal nerves to the "cough center," which is in the medulla. Because cough is not only an involuntary reflex activity but also one that can be initiated or suppressed voluntarily, "higher centers" must also be involved in the afferent limb of the responsible pathway. The neural impulses go from the medulla to the appropriate efferent pathways to the larynx, tracheobronchial tree, and expiratory muscles.

The act of coughing (Fig. 2.1) begins with an inspiration, followed by expiration against a closed glottis (compressive phase), resulting in the buildup of impressive intrathoracic pressures (50-300 cm H_2O). These pressures may be transmitted to vascular, cerebrospinal, and intraocular spaces. Finally, the glottis opens, allowing for explosive expiratory airflow (300 m/sec) and expulsion of mucus, particularly from the larger, central airways. The inability to seal the upper airway (tracheostomy) impairs, but does not abolish, the effectiveness of cough. Weak ventilatory muscles (muscular dystrophy) impair both the inspiratory and the compressive phase.

◆ History

The patient history often provides the most important body of information about a child's cough. A diagnosis can often be discerned with relative certainty from the family history, the environmental and exposure history, and the acute nature and characterization of the cough.

Demographics

The patient's age (Table 2.1) helps to focus the diagnostic possibilities. Congenital anatomic abnormalities may be symptomatic from birth, whereas toddlers, who may have incomplete neurologic control over swallowing and often put small objects in their mouths, are at risk for foreign body aspiration; adolescents may experiment with smoking or inhaled drugs. Socioeconomic factors must be considered; a family that cannot afford central heating may use a smoky wood-burning stove; spending time at a daycare center may expose an infant to respiratory viruses; and several adult smokers in a small home expose children to a high concentration of respiratory irritants.

Characteristics of the Cough

The various cough characteristics can help determine the cause of cough. The causes of acute, recurrent, and chronic coughs may be quite different from each other (Fig. 2.2; see also Table 2.1). A cough can be paroxysmal, brassy, productive, weak, volitional, and "throat-clearing," and it may occur at different times of the day (Tables 2.2 and 2.3).

The previous response or lack of response to some therapies for recurrent and chronic cough can provide important information (see Table 2.3). Furthermore, some coughs may be caused or worsened by medications (Table 2.4).

Associated Symptoms

A history of accompanying signs or symptoms, whether localized to the respiratory tract (wheeze, stridor) or elsewhere (failure to thrive, frequent malodorous stools) can give important clues (Table 2.5; see also Tables 2.2 and 2.3). It is essential to remember that the daily language of the physician is full of jargon that may be adopted by parents but with a different meaning from that understood by physicians. If a parent says that a child "wheezes" or "croups" or is "short of breath," it is important to find out what the parent means by that term.

Family and Patient's Medical History

Because many disorders of childhood have genetic or nongenetic familial components, the family history can provide helpful information:

- Are there older siblings with cystic fibrosis (CF) or asthma?
- Is there a coughing sibling whose kindergarten class has been closed because of pertussis?
- Is there an adolescent or adult with chronic cough (bronchitis) who may have pertussis or tuberculosis?
- Was the child premature, and, if so, did he or she spend a month on the ventilator, and does he or she now have chronic lung disease (bronchopulmonary dysplasia)?
- Did the toddler choke on a carrot or other food 3 months ago?
- Did the child have RSV, bronchiolitis, or rhinovirus infection as an infant?
- Did the child receive a bone marrow transplant a year ago?
- Is the child immunized?
- Did the infant have a tracheoesophageal fistula repaired in the neonatal period?

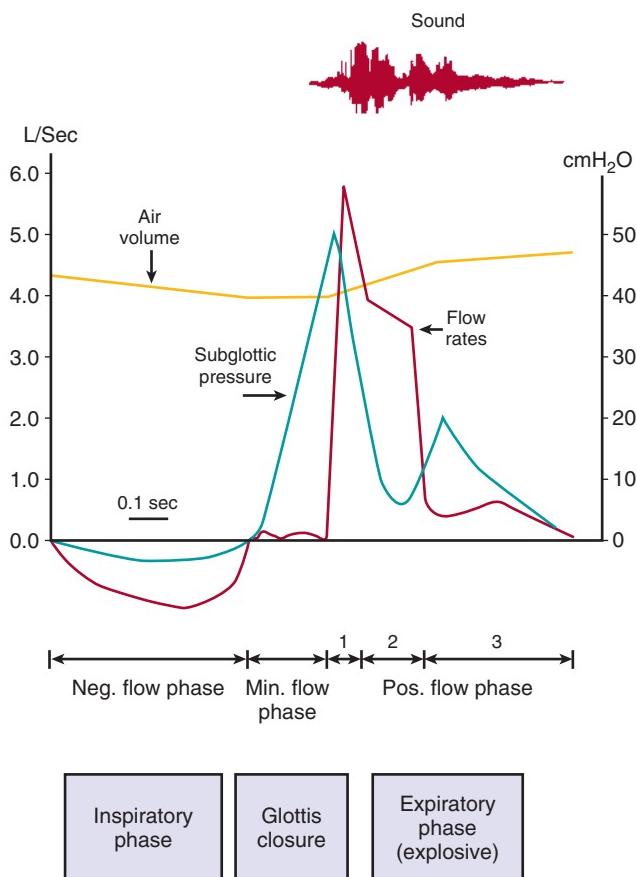
(See *Nelson Textbook of Pediatrics*, p. 2027)


FIGURE 2.1 Cough mechanics, showing changes in expiratory flow rate, air volume, subglottic pressure, and sound recording during cough. (Modified from Yanagihara N, et al. The physical parameters of cough: the larynx in a normal single cough. *Acta Otolaryngol.* 1996;61: 495-510.)

◆ Physical Examination
Inspection

Initial inspection often reveals the seriousness of an illness:
- Is the child struggling to breathe (dyspnea)?
- Does the child have an anxious look?
- Can the child be calmed or engaged in play?
- Is the child's skin blue (representing cyanosis) or ashen?
- Does the child appear wasted, with poor growth that may indicate a chronic illness?

The respiratory rate is often elevated with parenchymal lung disease or extrathoracic obstruction. Respiratory rates vary with the age of the child (Fig. 2.3) and with pulmonary infection, airway obstruction, activity, wakefulness and sleep, fever, metabolic acidosis, and anxiety.

Odors may also give helpful clues. Does the examining room or the clothing smell of stale cigarette smoke? Is there a foul odor from a diaper with a fatty stool, which may suggest pancreatic insufficiency and CF? Is the child's breath malodorous, as can be noticed in sinusitis, nasal foreign body, lung abscess, or bronchiectasis?

Fingers. Cyanotic nail beds suggest hypoxemia, poor peripheral circulation, or both. The examiner looks for the presence of **digital clubbing** (Fig. 2.4), which makes asthma or acute pneumonia extremely unlikely. The absence of digital clubbing but a history of severe chronic cough in an older child makes CF unlikely.

TABLE 2.1   Causes of Cough

Age Group	Acute	Recurrent	Chronic (>4 wk)
Infants	Infection[1]* Aspiration[2] Foreign body[3]	Asthma[1] CF[1] GER[1] Aspiration[2] Anatomic abnormality[3]† Passive smoking[3]	Asthma[1] CF[1] GER[1] Aspiration[2] Pertussis[2] Anatomic abnormality[3]† Passive smoking[3]
Toddlers	Infection[1] Foreign body[2] Aspiration[3]	Asthma[1] CF[1] GER[1] Aspiration[2] Anatomic abnormality[3] Passive smoking[3]	Asthma[1] CF[1] GER[1] Aspiration[2] Pertussis[2] Anatomic abnormality[3] Passive smoking[3]
Children	Infection[1] Foreign body[3]	Asthma[1] CF[1] GER[1] Passive smoking[3]	Asthma[1] CF[1] GER[2] Pertussis[2] *Mycoplasma*[3] Psychogenic[3] Anatomic abnormality[3] Passive smoking[3]
Adolescents	Infection[1]	Asthma[1] CF[1] GER[1] Aspiration[2] Anatomic abnormality[3]	Asthma[1] CF[1] GER[2] Smoking[2] Tuberculosis[3] Psychogenic[2] Pertussis[3] Aspiration[3] Anatomic abnormality[3] Tumor[3]

*Infections include upper (pharyngitis, sinusitis, tracheitis, rhinitis, otitis) and lower (pneumonia, abscess, empyema) respiratory tract disease.
†Anatomic abnormality includes tracheobronchomalacia, tracheoesophageal fistula, vascular ring, abnormal position or take-off of large bronchi.
[1]Common; [2]less common; [3]much less common.
CF, cystic fibrosis; GER, gastroesophageal reflux.

Chest, abdomen, and spine. The shape of the chest gives information. Is the anteroposterior (AP) diameter increased, which indicates hyperinflation of the lungs from obstruction of small airways (asthma, bronchiolitis, CF)? Is this diameter small, as can be seen with some restrictive lung diseases with small lung volumes (muscular dystrophy, spinal muscular atrophy)? The normal infant has a "round" chest configuration, with the AP diameter of the chest about 84% of the transverse (lateral) diameter. With growth, the chest becomes more flattened in the AP dimension, and the AP-to-transverse ratio is between 70% and 75%. Although obstetric calipers can be used to give an objective assessment of the AP diameter of the chest, most clinicians rely on their

Workdays with clearing on days off	Occupational exposure

subjective assessment of whether the diameter is increased: Does the patient look "barrel-chested"?

Intercostal, subcostal, suprasternal, and supraclavicular retractions (inspiratory sinking in of the soft tissues) indicate increased effort of breathing and reflect both the contraction of the accessory muscles of respiration and the resulting difference between intrapleural and extra-thoracic pressure. Retractions occur most commonly with obstructed airways (upper or lower), but they may occur with any condition leading to the use of the accessory muscles. Any retractions other than the mild normal depressions seen between an infant's lower ribs indicate a greater than normal work of breathing.

Less easy to notice than intercostal retractions is their bulging out with expiration in a child with expiratory obstruction (asthma). Contraction of the abdominal muscles with expiration is easier to notice and is another indication that a child is working harder than normal to push air out through obstructed airways.

Inspection of the spine may reveal kyphosis or scoliosis. There is a risk of restrictive lung disease if the curvature is severe.

Palpation

Palpating the trachea, particularly in infants, may reveal a shift to one side, which suggests loss of volume of the lung on that side or extra-pulmonary gas (pneumothorax) on the other side. Placing one hand on each side of the chest while the patient breathes may enable the examiner to detect asymmetry of chest wall movement, either in timing or in degree of expansion. The former indicates a partial bronchial obstruction, and the latter suggests a smaller lung volume, voluntary guarding, or diminished muscle function on one side. Palpating the abdomen gently during expiration may allow the examiner to feel the contraction of the abdominal muscles in cases of expiratory obstruction. Hyperinflation may push the liver down making it palpable below the costal margin.

Palpation for tactile fremitus, the transmitted vibrations of the spoken word ("ninety-nine" is the word often used to accentuate these

TABLE 2.3   Cough: Some Aspects of Differential Diagnosis

Cause	Abrupt Onset	Only When Awake	Yellow Sputum	Responds to Inhaled Bronchodilator (by History)	Responds to Antibiotics (by History)	Responds to Steroids (by History)	Failure to Thrive	Wheeze	Digital Clubbing
Asthma	+	++	++	+++	+	+++	+	+++	−
Cystic fibrosis	+	++	++	+	+++	+	++	++	+++
Infection	+	+	++	−	++	−	+	+	−
Aspiration	+	+	+	+	+	+	++	++	+

Foreign body	+++	+	++	+	++	+	+	++	+
Habit	−	+++	−	−	−	−	−	−	−

+++, very common and suggests the diagnosis; ++, common; +, uncommon; −, almost never and makes examiner question the diagnosis.

TABLE 2.4   Drugs Causing Cough

Drug	Mechanism
Tobacco, marijuana	Direct irritants
β-Adrenergic blockers	Potentiate asthma
ACE inhibitors	(?) Possibly potentiate asthma
Bethanechol	Potentiates asthma
Nitrofurantoin	(?) Via oxygen radicals vs via autoimmunity
Antineoplastic agents	Various (including pneumonitis/fibrosis, hypersensitivity, noncardiogenic pulmonary edema)
Sulfasalazine	(?) Causes bronchiolitis obliterans
Penicillamine	(?) Causes bronchiolitis obliterans
Diphenylhydantoin	Hypersensitivity pneumonitis
Gold	(?) Causes interstitial fibrosis
Aspirin, NSAIDs	Potentiate asthma
Nebulized antibiotics	(?) Direct irritant
Inhaled/nebulized bronchodilators	Increases tracheal/bronchial wall instability in airway malacia; or via reaction to vehicle
Theophylline, caffeine	Indirect, via worsened gastroesophageal reflux (relaxation of lower esophageal sphincter)
Metabisulfite	Induces allergic asthma
Cholinesterase inhibitors	Induce mucus production (bronchorrhea)

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 2.5   Nonpulmonary History Suggesting Cystic Fibrosis

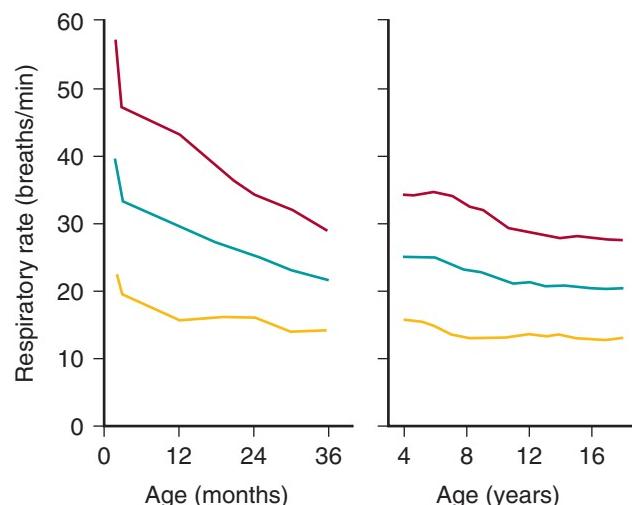
Maldigestion, malabsorption, steatorrhea (in 80–90%)
Poor weight gain
Family history of cystic fibrosis
Salty taste to skin
Rectal prolapse (up to 20% of patients)
Digital clubbing
Meconium ileus (in 10–15%)
Intestinal atresia
Neonatal cholestatic jaundice
Male sterility


FIGURE 2.3 Mean values *(blue line)* ±2 standard deviations *(red and yellow lines)* of the normal respiratory rate at rest (during sleep in children younger than 3 years). There is no significant difference between the genders. (Data from Pasterkamp H. The history and physical examination. In: Chernick V, ed. *Kendig's Disorders of the Respiratory Tract in Children*. 6th ed. Philadelphia: WB Saunders; 1998:88.)

vibrations), helps determine areas of increased parenchymal density and hence increased fremitus (as in pneumonic consolidation) or decreased fremitus (as in pneumothorax or pleural effusion).

Percussion

The percussion note determined by the examiner's tapping of one middle finger on the middle finger of the other hand, which is firmly placed over the patient's thorax, may be dull over an area of consolidation or effusion and hyperresonant with air trapping. Percussion can also be used to determine diaphragmatic excursion. The lowest level

NORMAL   CLUBBING

Phalangeal depth ratio

IPD>DPD   DPD>IPD

Hyponychial angle

abc<180°   abc>195°

Schamroth sign

FIGURE 2.4 Measurement of digital clubbing. The ratio of the distal phalangeal depth (DPD) to the interphalangeal depth (IPD), or the phalangeal depth ratio, is normally less than 1 but increases to more than 1 with finger clubbing. The DPD/IPD ratio can be measured with calipers or, more accurately, with finger casts. The hyponychial angle is measured from lateral projections of the finger contour on a magnifying screen and is normally less than 180 degrees but greater than 195 degrees with finger clubbing. Schamroth sign is useful for bedside assessment. The dorsal surfaces of the terminal phalanges of similar fingers are placed together. With clubbing, the normal diamond-shaped aperture or "window" at the bases of the nail beds disappears, and a prominent distal angle forms between the end of the nails. In normal subjects, this angle is minimal or nonexistent. (From Pasterkamp H. The history and physical examination. In: Chernick V, ed. *Kendig's Disorders of the Respiratory Tract in Children.* 6th ed. Philadelphia: WB Saunders; 1998.)

of resonance at inspiration and expiration determines diaphragmatic motion.

Auscultation

Because lung sounds tend to be higher-pitched than heart sounds, the diaphragm of the stethoscope is better suited to pulmonary auscultation than is the bell, whose target is primarily the lower-pitched heart sounds (Table 2.6). The adult-sized stethoscope generally is superior to the smaller pediatric or neonatal diaphragms, even for listening to small chests, because its acoustics are better (Figs. 2.5 and 2.6).

Adventitious sounds come in a few varieties, namely, stridor, crackles, rhonchi, and wheezes. Other sounds should be described in clear, everyday language.
- **Stridor** is a continuous musical sound usually heard on inspiration and is caused by narrowing in the extrathoracic airway, as with croup or laryngomalacia.
- **Crackles** are discontinuous, representing the popping open of air-fluid menisci as the airways dilate with inspiration. Fluid in larger airways causes crackles early in inspiration (congestive heart failure). Crackles that tend to be a bit lower in pitch ("coarse" crackles) than the early, higher-pitched ("fine") crackles are associated with fluid in small airways (pneumonia). Although crackles usually signal the presence of excess airway fluid (pneumonia, pulmonary edema), they may also be produced by the popping open of noninfected fibrotic or atelectatic airways. Fine crackles are not audible at the mouth, whereas coarse crackles may be. Crackles is the preferred term, rather than the previously popular "rales."
- **Rhonchi**, or "large airway sounds," are continuous gurgling or bubbling sounds typically heard during both inhalation and exhalation. These sounds are caused by movement of fluid and secretions in larger airways (asthma, viral URI). Rhonchi, unlike other sounds, may clear with coughing.

TABLE 2.6 Physical Signs of Pulmonary Disease

Disease Process	Mediastinal Deviation	Chest Motion	Fremitus	Percussion	Breath Sounds	Adventitious Sounds	Voice Signs
Consolidation (pneumonia)	No	Reduced over area, splinting	Increased	Dull	Bronchial or reduced	Crackles	Egophony,* whispering pectoriloquy increased†
Bronchospasm	No	Hyperexpansion with limited motion	Normal or decreased	Hyperresonant	Normal to decreased	Wheezes, crackles	Normal to decreased
Atelectasis	Shift toward lesion	Reduced over area	Decreased	Dull	Reduced or absent	None or crackles	None
Pneumothorax	Tension deviates trachea and PMI to opposite side	Reduced over area	None	Resonant, tympanitic	None	None	None
Pleural effusion	Deviation to opposite side	Reduced over area	None	Dull	None	Friction rub; splash, if hemopneumothorax	None

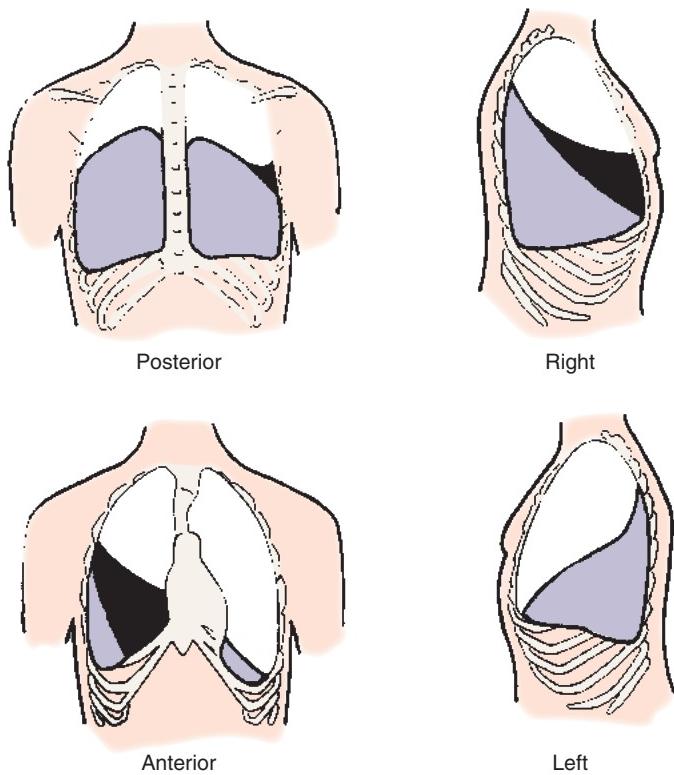
*Egophony is present when *e* sounds like *a.*
†Whispering pectoriloquy produces clearer sounding whispered words (e.g., "ninety-nine").
PMI, point of maximal impulse.
Modified from Dantzker D, Tobin M, Whatley R. Respiratory diseases. In: Andreoli TE, Carpenter CJ, Plum F, Smith LH, eds. *Cecil Essentials of Medicine.* Philadelphia: WB Saunders; 1986:126-180.


FIGURE 2.5 Projections of the pulmonary lobes on the chest surface. The upper lobes are *white*, the right-middle lobe is *black*, and the lower lobes are *purple*. (From Pasterkamp H. The history and physical examination. In: Chernick V, ed. *Kendig's Disorders of the Respiratory Tract in Children*. 6th ed. Philadelphia: WB Saunders; 1998.)

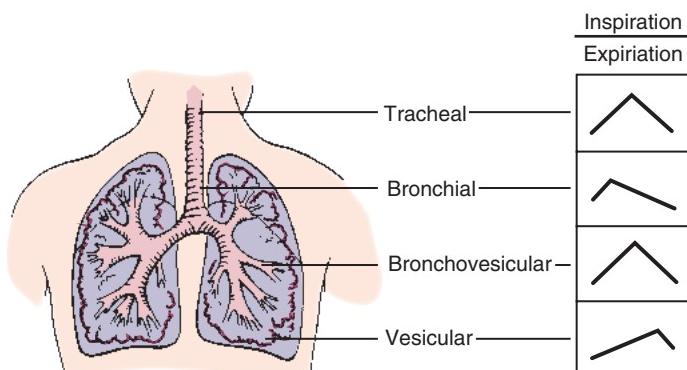
- **Wheezes** are continuous musical sounds (lasting longer than 200 msec), caused by vibration of narrowed airway walls, as with asthma, and perhaps vibration of material within airway lumens. These sounds are much more commonly heard during expiration than inspiration.

◆ Diagnostic Studies
Radiography
The chest radiograph is often the most useful diagnostic test in the evaluation of the child with cough. Table 2.7 highlights some of the radiographic features of the most common causes of cough in pediatric patients. Radiographic findings are often similar for a number of disorders, and thus these studies may not indicate a definitive diagnosis. Chest radiographs are normal in children with psychogenic (habit) cough and in children with sinusitis or gastroesophageal reflux (GER) as the primary cause of cough. A normal chest radiograph indicates the unlikelihood of pneumonia caused by respiratory syncytial virus (RSV), influenza, parainfluenza, adenovirus, *Chlamydia* species, or bacteria. Although children with cough resulting from cystic fibrosis (CF), *Mycoplasma* species, tuberculosis, aspiration, a bronchial foreign body, or an anatomic abnormality usually have abnormal chest radiographs, a normal radiograph does not exclude these diagnoses. Hyperinflation of the lungs is commonly seen on chest radiographs of infants with RSV bronchiolitis or *Chlamydia* pneumonia, and a lobar or round (coin lesion) infiltrate is the radiographic hallmark of bacterial pneumonia. The diagnosis of sinusitis cannot be sustained with normal sinuses on radiograph or computed tomography (CT) scan.

Hematology/Immunology
The white blood cell (WBC) count may help exclude or include certain entities for a differential diagnosis. For example, a WBC count of


Characteristic	Tracheal	Bronchial	Bronchovesicular	Vesicular
Intensity	Very loud	Loud	Moderate	Soft
Pitch	Very high	High	Moderate	Low
I:E ratio*	1:1	1:3	1:1	3:1
Description	Harsh	Tubular	Rustling, but tubular	Gentle rustling
Normal locations	Extrathoracic trachea	Manubrium	Over mainstem bronchi	Most of peripheral lung

*Ratio of duration of inspiration to expiration.

FIGURE 2.6 Characteristics of breath sounds. Tracheal breath sounds are very harsh, loud, and high-pitched; they are heard over the extrathoracic portion of the trachea. Bronchial breath sounds are loud and high-pitched; normally, they are heard over the lower sternum and sound like air rushing through a tube. The expiratory component is louder and longer than the inspiratory component; a definite pause is heard between the two phases. Bronchovesicular breath sounds are a mixture of bronchial and vesicular sounds. The inspiratory (I) and expiratory (E) components are equal in length. They are usually heard only in the first and second interspaces anteriorly and between the scapulae posteriorly, near the carina and mainstem bronchi. Vesicular breath sounds are soft and low-pitched; they are heard over most of the lung fields. The inspiratory component is much longer than the expiratory component; the latter is softer and often inaudible. (From Swartz MH, ed. The chest. In: *Textbook of Physical Diagnosis: History and Examination*. Philadelphia: WB Saunders; 1989.)

[1] Positive response to bronchodilators, either as a home therapeutic trial or in a pulmonary function test in the laboratory.
[2] "Steeple" sign: narrowing of upper tracheal air column.
[3] "Swollen thumb": sign of thickened epiglottis.
[4] Low yield in paroxysmal stage.
[5] Pleural effusion relatively common.
[6] Blood culture positive in 10%; needle aspiration of pleural fluid or lung fluid may yield organism; bacterial antigen in urine. In older infants and children, common pathogens include pneumococci and group A streptococci; *Staphylococcus aureus* is rare and may be associated with pneumatoceles or empyema.
[7] Localized hyperinflation is common; localized atelectasis is common; inspiratory-expiratory radiographs may show ball-valve obstruction.
[8] Esophageal biopsy specimen shows esophagitis.
[9] Multilobular or multisegmental, dependent lobes.
[10] (?) Lipid-laden macrophages from bronchoscopy or gastric washings; barium swallow or radionuclide study showing aspiration.
[11] Right-sided arch, mass effect on airways, mass identified; magnetic resonance imaging (MRI).
[12] Bronchoscopy; computed tomography; MRI.

+++, almost always—if not present, must question diagnosis; ++, common; +, less common; −, seldom—if present, must question diagnosis. +Bld cult, blood culture may be positive; Bronch, bronchoscopy can reveal the foreign body; Diff, diffuse or scattered; ↑EOS, increased eosinophil count; Esoph pH, prolonged esophageal pH probe monitoring; GE, gastroesophageal; Hyper, hyperinflated; Ig, immunoglobulin; Infil, infiltrates; ↑LY, increased lymphocyte count; +NP aspirate PCR, nasopharyngeal positive for specific organism; Paraflu, parainfluenza virus; PCR, polymerase chain reaction; ↑PMN, increased polymorphonuclear neutrophil count; PPD, purified protein derivative (TB); RAD, reactive airways disease; RSV, respiratory syncytial virus; TB, tuberculosis; ↑WBC, increased white blood cell count.

35,000 with 85% lymphocytes strongly suggests pertussis, but not every child with pertussis presents such a clear hematologic picture. The presence of a high number or large proportions of immature forms of WBCs suggests an acute process, such as a bacterial infection. Immunoglobulins provide supportive evidence for a few diagnoses, such as chlamydial infection, which rarely occurs without elevated serum concentrations of immunoglobulins G and M.

Bacteriology/Virology

Specific bacteriologic or virologic diagnoses can be made in a number of disorders causing cough, including RSV, influenza, parainfluenza, adenovirus, and *Chlamydia* pneumonia. In most cases, the viruses can be rapidly identified with amplification of the viral genome through polymerase chain reaction (PCR). In bacterial pneumonia, the offending organism can be cultured from the blood in a small proportion (10%) of patients. A positive culture provides definitive diagnosis, but a negative culture specimen is not helpful. Throat cultures are seldom helpful (except in CF) in identifying lower respiratory tract bacterial organisms. Sputum cultures and Gram stains may help guide initial empirical therapy in older children with pneumonia or purulent bronchitis, but their ability to identify specific causative organisms with certainty (with the exception of CF) has not been shown clearly.

Infants and young children usually do not expectorate but rather swallow their sputum. Specimens obtained via bronchoscopy may be contaminated by mouth flora, but heavy growth of a single organism in the presence of polymorphonuclear neutrophils certainly supports the organism's role in disease. If pleural fluid or fluid obtained directly from the lung via needle aspiration is cultured, the same rules apply: Positive cultures are definitive, but negative cultures are not.

Other Tests

A number of specific tests can help to establish diagnoses in a child with cough (see Table 2.7). These include a positive response to bronchodilators in a child with asthma; visualizing the red, swollen epiglottis in epiglottitis (to be done only under very controlled conditions); the bronchoscopic visualization of the peanut, plastic toy, or other offender in foreign body aspiration; a positive purified protein derivative (PPD) or Quantiferon assay in tuberculosis; and several studies of the esophagus in GER. Several imaging techniques, such as CT or magnetic resonance imaging (MRI), can help to delineate various intrathoracic anatomic abnormalities, pulmonary embolism, and bronchiectasis. Multiple tests can be employed to confirm the diagnosis of CF (Table 2.8).

◆ Differential Diagnosis and Treatment

Infection

Infections are the most common cause of acute cough in all age groups and are responsible for some chronic coughs. The age of the patient has a large impact on the frequency of the type of infection.

Infections in infants. Viral upper respiratory infections (common cold); croup (laryngotracheobronchitis); viral bronchiolitis, particularly with RSV or human metapneumovirus; and viral pneumonia are the most frequently encountered respiratory tract infections and hence the most common causes of cough in infancy. Viral illness may predispose to bacterial superinfection (croup and *Staphylococcus aureus* tracheitis or influenza and *H. influenzae* or *S. aureus* pneumonia).

Viral upper respiratory infections (URI). Viral URI symptoms and signs usually include stuffy nose with nasal discharge, sore throat, and sneezing. There may be fever, constitutional signs (irritability, myalgias, and headache), or both. Cough is common and may persist for 5-7 days. The mechanism by which URIs cause cough in children is undetermined. In adults, it is generally thought that "postnasal drip"—that is, nasal or sinus secretions draining into the posterior nasopharynx—causes cough and, in fact, may be one of the most frequent causes of cough. Indeed, sinus CT in older patients with URIs often reveals unexpected involvement of the sinus mucosa. Other authorities believe that cough in a child with a URI indicates involvement (inflammation or bronchospasm) of the lower respiratory tract. Over-the-counter cough and cold medications are commonly used. Evidence of efficacy of these medications for children with URI is lacking. Because of the known risk for unintentional overdose from these medications, their use is not recommended in children under age 4 years.

TABLE 2.8	**Laboratory Tests for Cystic Fibrosis**				
Usefulness	**Test**	**Sensitivity**	**Specificity**	**Cost**
Definitive	Sweat chloride test	.99+	.95+	$96
	DNA analysis	.85–.90	.99	$962
Suggestive	Throat or sputum culture* positive for mucoid *Pseudomonas aeruginosa*	.70-.80	.85	$183
	Sinus radiographs			$179
	Pansinusitis	.95	.90	
	Positive IRT newborn screen	.98	.25	$1
Supportive	Fecal elastase			$587
	Pulmonary function tests:			$100–$800
	Obstructive pattern, especially small airways and especially if patient is poorly responsive to bronchodilator	.70+	?	
	Chest radiograph:			$160
	Hyperinflation, ± other findings; especially with right upper lobe infiltrate/atelectasis	.70+	?	
	Throat or sputum culture*:			$183
	Positive for *Staphylococcus aureus*	.20	.20	
	Positive for *Haemophilus influenzae*	.05-.20	.15	

*Throat is usually deep pharyngeal culture.
IRT, immunoreactive trypsinogen.

Common viral pathogens include rhinovirus, RSV, coronaviruses, and parainfluenza viruses. The differential diagnosis includes allergic rhinitis, which often demonstrates clear nasal secretions with eosinophils and pale nasal mucosa, and sinusitis, which presents with mucopurulent nasal secretions containing neutrophils and erythematous mucosa.

Croup (laryngotracheobronchitis). Infectious croup (see Chapter 3) is most common in the first 2 years of life. Its most dramatic components are the barking ("croupy") cough and inspiratory stridor, which appear a few days after the onset of a cold. In most cases, the patient has a low-grade fever, and the disease resolves within a day or two. In severe cases, the child can be extremely ill and is at risk for complete laryngeal obstruction. There may be marked intercostal and suprasternal retractions and cyanosis. *Stridor at rest signifies significant obstruction.* Diminishing stridor in a child who is becoming more comfortable is a good sign, but diminishing stridor in and of itself is not necessarily good: If the child becomes fatigued because of the tremendous work of breathing through an obstructed airway and can no longer breathe effectively, smaller-than-needed tidal volumes make less noise.

It is important to distinguish croup from epiglottitis in the child with harsh, barking cough and inspiratory stridor because the natural histories of the two diseases are quite different (see Table 2.7). Epiglottitis occurs more commonly in unimmunized toddlers than in infants (see Chapter 3).

Treatment of mild croup is usually not needed. For decades, pediatricians have recommended putting a child with croup in a steamy bathroom or driving to the office or emergency department with the car windows rolled down. It is likely that these remedies are effective because of the heat exchange properties of the upper airway; air that is cooler or more humid than the airway mucosa will serve to cool the mucosa, thus causing local vasoconstriction and probably decreasing local edema.

In a child who has stridor at rest, evaluation is indicated. Symptomatic, often dramatic relief through decreased laryngeal edema can usually be achieved with aerosolized racemic epinephrine (2.25% solution, 0.25 to 0.5 mL/dose). It is essential to remember that the effects of the epinephrine are transient, lasting only a few hours, although the course of the illness is often longer. The result is that when the racemic epinephrine's effect has worn off, the child's cough and stridor will probably be as bad or even worse than before the aerosol was administered. This is not a "rebound" effect: The symptoms are not worse because of the treatment but, rather, because of the natural progression of the viral illness. Repeating the aerosol will probably again have a beneficial effect. A child who responds favorably to such an aerosol needs to be observed for several hours because further treatment may be needed. A single dose of dexamethasone (0.6 mg/kg orally, intramuscularly, or intravenously) reduces the severity and hastens recovery. Aerosolized steroids (budesonide) may also be effective in patients with mild to moderately severe croup.

Bronchiolitis. Bronchiolitis is a common and potentially serious lower respiratory tract disorder in infants (see Chapter 3). It is caused usually by RSV but on occasion by parainfluenza, influenza, human metapneumovirus, adenovirus, enterovirus, and human rhinovirus. It mostly occurs in the winter months, often in epidemics. RSV bronchiolitis is seen uncommonly in children older than 4 years. Typically, "cold-like" symptoms of rhinorrhea precede the harsh cough, increased respiratory rate, and retractions. Respiratory distress and cyanosis can be severe. The child's temperature is seldom elevated above 38°C.

The chest is hyperinflated, widespread crackles are audible on inspiration, and wheezing marks expiration. The chest radiograph invariably reveals hyperinflation, as depicted by a depressed diaphragm, with an enlarged retrosternal air space in as many as 60% of patients, peribronchial thickening in approximately 50%, and consolidation and/or atelectasis in 10-25%.

The diagnosis is confirmed with demonstration of RSV by PCR of nasopharyngeal secretions. In most cases, no treatment is needed because the disease does not interfere with the infant's eating or breathing. Apnea is a common complication of RSV bronchiolitis in neonates and may necessitate close monitoring. In severe cases, often those in which there is underlying chronic heart, lung, or immunodeficiency disease, RSV can be life-threatening. In severe cases, hospital care with supplemental oxygen and intravenous fluids is indicated. Suctioning of secretions is an essential part of the treatment. Many other treatment modalities have been tried for hospitalized infants with bronchiolitis. Aerosolized bronchodilators and systemic glucocorticoids do not seem to alter clinical outcome and are not recommended in most patients. Nebulized saline may reduce the length of hospitalization. Use of high-flow nasal cannula may reduce the need for more invasive forms of respiratory support in infants with impending respiratory failure.

Viral pneumonia. Viral pneumonia can be similar to bronchiolitis in its manifestation, with cough and tachypnea, after a few days of apparent URI. There can be variable degrees of fever and of overall illness. Infants and children with viral pneumonia may appear relatively well or, particularly with adenovirus or influenza, may have a rapidly progressive course. Frequent symptoms include poor feeding, cough, cyanosis, fever (some patients may be afebrile), apnea, and rhinorrhea. Frequent signs include tachypnea, retractions, crackles, and cough. Cyanosis is less common.

The most common agents causing viral pneumonia in infancy and childhood are RSV, influenza, and parainfluenza. Adenovirus is less common, but it is important because it can be severe and leave residua, including bronchiectasis and bronchiolitis obliterans. Adenovirus pneumonia is often accompanied by conjunctivitis and pharyngitis, in addition to leukocytosis and an elevated erythrocyte sedimentation rate (ESR); the ESR and leukocyte count are usually not elevated in other types of viral pneumonia. Additional viral agents include enteroviruses, human metapneumovirus and rhinovirus. Radiographs most often reveal diffuse, bilateral peribronchial infiltrates, with a predilection for the perihilar regions, but occasionally lobar infiltrates are present. Pleural effusions are not common. On occasion, if an infant is extremely ill, bronchoscopy with bronchoalveolar lavage may be indicated to isolate the virus responsible for the pneumonia.

Treatment is largely supportive, with oxygen and intravenous fluids. Mechanical ventilation may be necessary in a small minority of infants.

In young infants, the **afebrile pneumonia syndrome** may be caused by *Chlamydia*, *Ureaplasma*, or *Mycoplasma* species; cytomegalovirus; or *Pneumocystis jiroveci*. In this syndrome, cough and tachypnea are common. Severe pneumonia may develop in neonates as a result of herpes simplex.

Pertussis (whooping cough). Pertussis is a relatively common cause of lower respiratory tract infection in infants, children, adolescents, and adults, especially in those who are underimmunized or not immunized. The causative organism, *Bordetella pertussis*, has a tropism for tracheal and bronchial ciliated epithelial cells; thus the disease is primarily bronchitis, but spread of the organism to alveoli, or secondary invasion by other bacteria, can cause pneumonia. The disease can occur at any age, from early infancy onward, although its manifestations in young infants and in those who have been partially immunized may be atypical.

Most commonly, pertussis has three stages:

- Catarrhal, in which symptoms are indistinguishable from a viral URI

(See *Nelson Textbook of Pediatrics*, p. 2032.)

(See *Nelson Textbook of Pediatrics*, p. 2091.)

- Paroxysmal, dominated by repeated forceful, paroxysmal coughing spells; spells may be punctuated by an inspiratory "whoop," post-tussive emesis, or both
- Convalescent, in which the intensity and frequency of coughing spells gradually diminish

Each stage typically lasts 1-2 weeks, except the paroxysmal stage, which lasts many weeks. (Pertussis is known as the "100 day cough" in China.) Most children are entirely well between coughing spells, when physical findings are remarkably benign. Infants younger than 6 months of age are at highest risk for complications. The majority of infants with pertussis need to be hospitalized.

Diagnosis can be difficult because the definitive result—namely, culturing the organism from nasopharyngeal secretions—requires special culture medium (Bordet-Gengou, which must be prepared fresh for each collection). Culture specimens are much less likely to be positive during the paroxysmal stage than during the catarrhal stage, when the diagnosis is not being considered. PCR assay of an adequate nasopharyngeal (NP) specimen is the most commonly used test because of improved sensitivity and faster turnaround time compared to culture. An elevated WBC count, as high as 20,000-50,000, with lymphocytes predominating is suggestive of pertussis in infants and children but often absent in adolescents. Chest radiographic findings are nonspecific. Infants with severe disease may require hospitalization.

Treatment is largely supportive, with oxygen, fluids, and small frequent feedings for patients who do not tolerate their normal feedings. Treatment with azithromycin decreases infectivity and may ameliorate the course of the disease if given during the catarrhal stage.

Complications include those related to severe coughing (Table 2.9) and those specific to pertussis, such as seizures and encephalopathy. The risk of acquiring pertussis is markedly reduced by immunizations (three primary immunizations and regular booster immunizations). Neither pertussis infection nor immunization produces lifelong immunity.

Chlamydial infection. *Chlamydia trachomatis* can cause pneumonia in young infants, particularly those aged 3-12 weeks. Cough, nasal congestion, low-grade or no fever, and tachypnea are common. Conjunctivitis is an important clue to chlamydial disease but is present in only 50% of infants with chlamydial pneumonia at the time of presentation. Affected infants may have a paroxysmal cough similar to that of pertussis, but post-tussive emesis is less common. Crackles are commonly heard on auscultation, but wheezing is much less common than the overinflated appearance of the lungs on radiographs would suggest. The organism may be recovered from the nasopharynx by culture or antigen testing. The complete blood cell count may reveal eosinophilia. Chlamydial infection responds to oral erythromycin therapy.

Ureaplasmal infection. *Ureaplasma urealyticum* pneumonia is difficult to diagnose but causes cough in some infants. There are no particularly outstanding features to distinguish this relatively uncommon infection from viral pneumonias.

Bacterial pneumonia. Bacterial pneumonia is relatively less common in infants than is viral pneumonia but can cause severe illness, with cough, respiratory distress, and fever. Chest radiographs are abnormal, and the WBC count is elevated.

Treatment is with antibiotics effective against pneumococci, group A streptococci, and, if illness is severe, *S. aureus*.

Infections in toddlers and children

Viral URIs. In early childhood, as children attend daycare and nursery schools, they are constantly exposed to respiratory viruses to which they have little or no immunity (e.g., RSV, rhinoviruses, adenoviruses, parainfluenza, and enteroviruses). Young children may have as many as 6-8 or even more URIs in a year. The remarks concerning colds and cough in infants (see previous discussion) apply to this older age group. The differential diagnosis of rhinorrhea is noted in Table 2.10.

Sinusitis. The sinuses may become the site for viral and subsequent secondary bacterial infection spreading from the nasopharynx (Fig. 2.7). The signs and symptoms are usually localized, including nasal congestion, a feeling of "fullness" or pain in the face (Fig. 2.8), headache, sinus tenderness, day or night cough, and fever. Maxillary toothache, purulent nasal discharge for more than 10 days, and a positive transillumination (opacification) are important clues. Sinus radiographs or (more accurate) CT scan may facilitate the diagnosis of sinusitis by demonstrating opacification of the sinus with mucosal thickening. Sinusitis is thought to be a cause of cough in adults and can probably be listed, with lower certainty, as a cause of cough in children.

Sinusitis is frequently seen in other conditions known to cause cough, especially CF, asthma, ciliary dyskinesia, and granulomatosis with polyangiitis with or without eosinophilia. It may be difficult to ascertain whether the cough is a direct result of the sinus infection or the underlying problem (purulent bronchitis in the child with CF or ciliary dyskinesia, exacerbation of asthma). In the first two situations, it may not matter because treatment is the same. In the case of the child with asthma, it is important to treat the asthma with broncho-dilating and antiinflammatory agents, as well as to treat the infected sinuses with antibiotics.

TABLE 2.9	**Potential Complications of Cough**
Musculoskeletal	Rib fractures Vertebral fractures Rupture of rectus abdominis muscle Asymptomatic elevation of serum creatine phosphokinase
Pulmonary	Chest wall pain* Bronchoconstriction Pneumomediastinum Pneumothorax Mild hemoptysis Subcutaneous emphysema Irritation of larynx and trachea
Cardiovascular	Rupture of subconjunctival,* nasal,* and anal veins Bradycardia, heart block Transient hypertension

(See *Nelson Textbook of Pediatrics*, p. 2014.)

TABLE 2.10 Differential Diagnosis of Rhinorrhea

| Etiology	Frequency	Duration*	Discharge	Comment
Viral	Common	Acute	Purulent	Polymorphonuclear neutrophils in smear
Allergic	Common	Acute/Chronic	Clear	Eosinophils in smear, seasonal
Vasomotor	Common	Chronic	Variable	? Environmental triggers
Sinusitis	Common	Chronic	Purulent	Sinus tenderness
Rhinitis medicamentosusa	Common	Chronic	Variable	Medication use
Response to stimuli	Common	Acute	Clear	Odors, exercise, cold air, pollution
Nasal polyps	Uncommon	Chronic	Variable	Consider cystic fibrosis
Granulomatous disease	Uncommon	Chronic	Bloody	Sarcoid, Granulomatosis with polyangiitis, midline granuloma
Cerebrospinal fluid fistula	Uncommon	Chronic	Watery	Trauma, encephalocele
Foreign body	Uncommon	Chronic	Purulent	Often malodorous
Tumor	Uncommon	Chronic	Clear to bloody	Angiofibroma, hemangioma, rhabdomyosarcoma, lymphoma, nasopharyngeal carcinoma, neuroblastoma
Choanal atresia, stenosis	Uncommon	Chronic	Clear to purulent	Congenital
Nonallergic eosinophilic rhinitis syndrome	Uncommon	Chronic	Clear	Eosinophils in smear
Septal deviation	Unknown	Chronic	Clear	Congenital, trauma
Drugs	Uncommon	Chronic	Variable	Cocaine, glue and organic solvents, angiotensin-converting enzyme inhibitors, β blockers
Hypothyroidism	Uncommon	Chronic	Clear	
Cluster headache	Uncommon	Intermittent	Clear	Associated tearing, headache
Horner syndrome	Uncommon	Chronic	Clear	Ptosis, miosis, anhidrosis

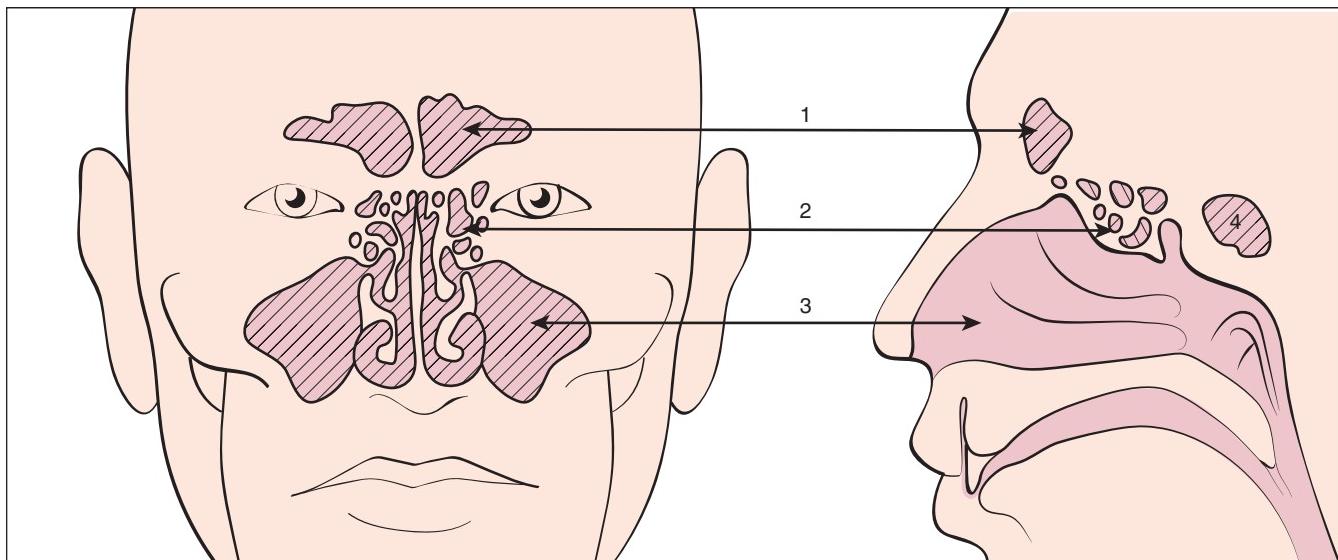
*Less than 1 week is considered acute.


FIGURE 2.7 The paranasal sinuses. *1,* Frontal. *2,* Ethmoid. *3,* Maxillary. *4,* Sphenoid. (From Smith RP. Common upper respiratory tract infections. In: Reilly B, ed. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991.)

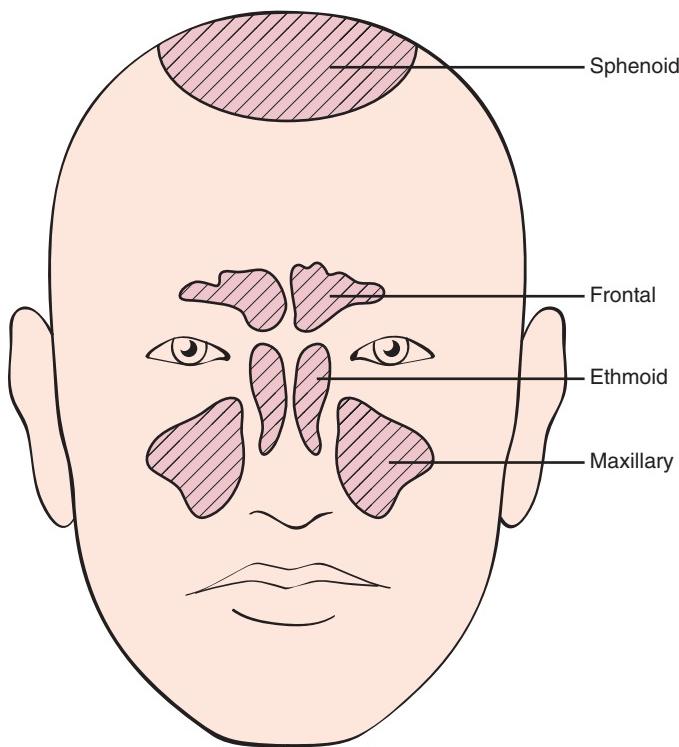
The treatment of sinusitis involves the use of oral antibiotics active against the common pathogens (i.e., *Streptococcus pneumoniae*, nontypable *H. influenzae*, *Moraxella catarrhalis*, and, in rare cases, anaerobic bacteria or *Streptococcus pyogenes*). Treatment regimens include the use of amoxicillin, amoxicillin-clavulanate, cefuroxime, cefpodoxime, or cefdinir. *Amoxicillin is considered the initial agent of choice.* Oral (pseudoephedrine, phenylephrine) or topical (phenylephrine, oxymetazoline) decongestants may be of benefit by increasing the patency of the sinus ostia, which permits drainage of the infected and obstructed sinuses. Oral antihistamines may benefit patients with an allergic history. Treatment with antimicrobial agents should continue for at least 7 days after the patient has responded. This may require 14-21 days of therapy. Many patients with presumed sinusitis recover without antibiotic therapy.


FIGURE 2.8 Typical pain locations in patients with various anatomic sites of acute sinusitis. (From Smith RP. Common upper respiratory tract infections. In: Reilly B, ed. *Practical Strategies in Outpatient Medicine*. 2nd ed. Philadelphia: WB Saunders; 1991.)

Complications of acute sinusitis include orbital cellulitis, abscesses (orbital, cerebral), cranial (frontal) osteomyelitis (Pott puffy tumor), empyema (subdural, epidural), and thrombosis (sagittal or cavernous sinus).

Pneumonia. The features discussed for viral pneumonia in infants are relevant for viral pneumonia in older children. The differentiation of viral or atypical pneumonia from classical bacterial pneumonia is noted in Table 2.11. Adenovirus and influenza pneumonia may present similar to bacterial pneumonia in severity and acuteness.

Bacterial pneumonia is more common in toddlers and older children than in infants. The most common pathogen is *S. pneumoniae*. (Table 2.12). Cough may not be as prominent a presenting symptom or sign as tachypnea and grunting. Raised respiratory rates (>50 in infants 2-12 months old, >40 in children 1-5 years old) plus retractions and grunting with or without hypoxia (oxygen saturation <90%) have a high specificity and sensitivity for pneumonia. Chest pain, abdominal pain, headache, or any combination of these symptoms may occur. Upper lobe pneumonia may produce meningeal signs, and lower lobe involvement may cause abdominal pain and an ileus.

Examination of the chest shows tachypnea but may be otherwise surprisingly normal. In older children, there may be localized dullness to percussion, with crackles or amphoric (bronchial) breath sounds over a consolidated lobe. The chest radiograph may be normal in the first hours of the illness, inasmuch as the radiographic findings often lag behind the clinical manifestations. Nonetheless, both anterior-posterior and lateral views are the main diagnostic tools; lobar consolidation is usual, with or without pleural effusion. In infants, the pattern may be more diffuse and extensive.

TABLE 2.11   Differentiation of Classical Bacterial Pneumonia from Viral and Atypical Pneumonias*

	Bacterial	**Viral/Atypical**
History	Precedent URI	Headache, malaise, URI, myalgias
Course	Often biphasic illness	Often monophasic
Onset	Sudden	Gradual
Temperature	High fever	Low-grade fever
Rigors	Common	Uncommon
Vital signs	Tachypnea, tachycardia	Usually normal
Pain	Pleuritic	Unusual
Chest examination	Crackles, signs of consolidation	Consolidation unusual
Pleural effusion	Common	Uncommon
Sputum	Productive, purulent, many PMNs, one dominant organism on Gram stain	Scant, no organisms; PMNs or mononuclear cells
ESR	Elevated	Usually normal
WBC count	Elevated; left shift	Often normal; predominant lymphocytes
Chest radiography	Lobar consolidation, round infiltrate, parapneumonic effusion; may be "bronchopneumonia"	Diffuse, bilateral, patchy, interstitial or bronchopneumonia; lower lobe involvement common; chest radiograph may look worse than patient's condition
Progression	May be rapid	Rapid if *Legionella* species, hantavirus, SARS, herpesvirus, adenovirus
Diagnosis	Blood, sputum, and pleural fluid specimens for culture; antigen detection possible; BAL if progressive	Viral, chlamydial culture or PCR detection; acute and convalescent titers; BAL if progressive

*Atypical pneumonias include *Chlamydia pneumoniae, Mycoplasma pneumoniae*, Legionella species *(L. pneumophila, L. micdadei)*, Q fever, psittacosis.
BAL, bronchoalveolar lavage; ESR, erythrocyte sedimentation rate; PMNs, polymorphonuclear neutrophils; SARS, severe acute respiratory syndrome; URI, upper respiratory tract infection; WBC, white blood cell.

TABLE 2.12 Causes of Infectious Pneumonia

Bacterial			Uncommon	
Common			Enterovirus	Neonates
Streptococcus pneumoniae	See Table 2.11		Herpes simplex	Neonates
Group B streptococci	Neonates		Cytomegalovirus	Infants, immunosuppressed persons
Group A streptococci	See Table 2.11		Measles	Rash, coryza, conjunctivitis
*Mycoplasma pneumoniae**	Adolescents; summer-fall epidemics		Varicella	Adolescents
*Chlamydia pneumoniae**	Adolescents (see Table 2.11)		Hantavirus	Southwestern United States
Chlamydia trachomatis	Infants		SARS agent	Asia
Mixed anaerobes	Aspiration pneumonia			
Gram-negative enteric	Nosocomial pneumonia		**Fungal**	
			Histoplasma capsulatum	Geographic region; bird, bat contact
Uncommon			*Cryptococcus neoformans*	Bird contact
Haemophilus influenzae type B	See Table 2.11		*Aspergillus* species	Immunosuppressed
Staphylococcus aureus	Pneumatoceles; infants		Mucormycosis	Immunosuppressed
Moraxella catarrhalis			*Coccidioides immitis*	Geographic region
Neisseria meningitidis			*Blastomyces dermatitidis*	Geographic region
Francisella tularensis	Animal, tick, fly contact			
Nocardia species	Immunosuppressed persons		**Rickettsial**	
*Chlamydia psittaci**	Bird contact		*Coxiella burnetii**	Q fever, animal (goat, sheep, cattle) exposure
Yersinia pestis	Plague		*Rickettsia rickettsiae*	Tick bite
Legionella species*	Exposure to contaminated water; nosocomial			
			Mycobacterial	
Viral			*Mycobacterium tuberculosis*	See Table 2.14
Common			*Mycobacterim avium–intracellulare*	Immunosuppressed persons
Respiratory syncytial virus	See Table 2.11			
Parainfluenza types 1-4	Croup, Type 3 and 4 seen in the summer		**Parasitic**	
			Pneumocystis jiroveci	Immunosuppressed, steroids
Influenza A, B	High fever; winter months		Eosinophilic	Various parasites (e.g., *Ascaris, Strongyloides* species)
Adenovirus	Can be severe; occurs all year round			
Human metapneumovirus	Similar to RSV			
Rhinovirus	Rhinorrhea			

*Atypical pneumonia syndrome (see Table 2.11); atypical in terms of extrapulmonary manifestations, low-grade fever, patchy diffuse infiltrates, poor response to penicillin-type antibiotics, and negative sputum Gram stain.
SARS, severe acute respiratory syndrome.

Some clinical and radiographic features may be suggestive of the bacterial cause of pneumonia. Children (especially infants) with staphylococcal pneumonia are more likely to have a rapid overwhelming course. Staphylococcal pneumonia may be accompanied by more extensive radiographic abnormalities, including multilobar consolidation, pneumatocele formation, and extensive pleural (empyema) fluid. The presence of a pleural effusion is not helpful in indicating the specific bacterial diagnosis because other bacterial pneumonias may be accompanied by pleural effusion. Pleural effusions may represent a reactive parapneumonic effusion or an empyema. Pleural fluid may be characterized as transudate, exudate, or empyema (Table 2.13). If the effusion is of sufficient size, as demonstrated by a lateral decubitus radiograph or ultrasonography, a thoracentesis may be indicated to differentiate the nature of the effusion and to identify possible pathogens. For young children who require sedation for thoracentesis and who have an effusion needing drainage, a primary chest tube placement is preferred over thoracentesis to decrease the risks from multiple procedures with sedation.

Differentiating among the causes of bacterial pneumonia can be done with certainty only with positive cultures from blood, pleural fluid, fluid obtained by direct lung tap, or, in rare cases, sputum. Current or previous antibiotic treatment diminishes the yield of such cultures. Bronchoscopy with or without lavage may yield helpful specimens from the progressively ill child or the child who has not responded promptly to empirical antibiotics.

Treatment of uncomplicated presumed bacterial pneumonia is with antibiotics. Ampicillin is the drug of choice for the previously healthy child who requires hospitalization with lobar pneumonia who is fully immunized. If the child is not fully immunized, either cefotaxime or ceftriaxone is indicated. For the critically ill child, vancomycin and cefotaxime/ceftriaxone may be considered for possible drug-resistant *S. pneumoniae* and methicillin-resistant *S aureus* (MRSA). Many children with pneumonia do well with oral antibiotics and respond within hours to the first dose. Repeated or follow-up chest radiographs may remain abnormal for 4-6 weeks after appropriate treatment and are not indicated for a single episode of uncomplicated pneumonia (i.e.,

TABLE 2.13 Differentiation of Pleural Fluid

	Transudate	Exudate	Complicated Empyema
Appearance	Clear	Cloudy	Purulent
Cell count	<1000	>1000	>5000
Cell type	Lymphocytes, monocytes	PMNs	PMNs
LDH	<200 U/L	>200 U/L	>1000 U/L
Pleural/serum LDH ratio	<0.6	>0.6	>0.6
Protein >3 g	Unusual	Common	Common
Pleural/serum protein ratio	<0.5	>0.5	>0.5
Glucose*	Normal	Low	Very low* (<40 mg/dL)
pH*	Normal (7.40–7.60)	7.20–7.40	<7.20
Gram stain	Negative	Usually positive	>85% positive unless patient received prior antibiotics

*Low glucose or pH may be seen in malignant effusion, tuberculosis, esophageal rupture, pancreatitis (positive pleural amylase), and rheumatologic diseases (e.g., systemic lupus erythematosus).
LDH, lactate dehydrogenase; PMNs, polymorphonuclear neutrophils.

no effusion, no abscess, and good response to treatment). *Mycoplasma pneumoniae* is a common cause of pneumonia among school-aged children. The disease often occurs in community outbreaks in the fall. The illness typically begins with extrapulmonary symptoms (i.e., sore throat, myalgias, headache, fever), which then progress to include cough, which can be paroxysmal at times. Patients do not often appear acutely ill, but cough may persist for weeks. There may be no specific abnormalities on the chest examination, although a few crackles may be heard, and about one third of younger patients wheeze.

The radiographic findings in mycoplasmal pneumonia can mimic almost any intrathoracic disease; scattered infiltrates with nonspecific "dirty" lung fields, predominantly perihilar or lower lobes, are common, and lobar infiltrates and pleural effusion are occasionally seen. Laboratory data (complete blood cell count, ESR, sputum culture) may not be helpful. A rise in antimycoplasma immunoglobulin G over 1-2 weeks may be demonstrated but is seldom helpful in guiding therapy. A positive immunoglobulin M response may be useful, although it can persist in serum for several months and, consequently, may not indicate current infection. *PCR is helpful.* The cold agglutinin test yields positive results in about 70% of patients with mycoplasmal pneumonia, but they are also positive in other conditions, including adenovirus infection. The more severe the illness is, the greater is the frequency of positive cold agglutinins. The diagnosis is often made from the history of an older child who has a lingering coughing illness in the setting of a community outbreak, unresponsive to most (nonerythromycin) antibiotic regimens.

Treatment with azithromycin, clarithromycin, or erythromycin in children <8 years old or tetracycline or doxycycline in children ≥8 years old usually shortens the course of illness. Extrapulmonary complications of mycoplasmal infection include aseptic meningitis, transverse myelitis, peripheral neuropathy, erythema multiforme, myocarditis, pericarditis, hemolytic anemia, and bullous otitis media (myringitis). In patients with sickle cell anemia, severe respiratory failure and acute chest syndrome may develop. Infection with *Chlamydia pneumoniae* mimics respiratory disease resulting from *M. pneumoniae*, inasmuch as it occurs in epidemics, is seen in older children, and produces an atypical pneumonia syndrome and pharyngitis.

Tuberculosis. Tuberculosis is uncommon in developed countries; 95% of the disease burden worldwide is in developing countries. Tuberculosis must be considered in the child with chest disease that is not easily explained by other diagnoses, especially if the child lives in or has migrated from an endemic area of the world or has been exposed

TABLE 2.14 Definitions of Positive Tuberculosis (TB) by Mantoux Skin Test (5 TU)*

Cutaneous Induration ≥5 mm
- Close exposure to known or suspected active TB
- Chest radiograph consistent with TB (old or active)
- Clinical evidence of TB
- Children receiving immunosuppresive therapy or with immunosuppressive conditions

Cutaneous Induration ≥10 mm
Children at increased risk
- Age < 4 yr of age
- Medical *high risks* (chronic renal failure, malnutrition, diabetes mellitus, lymphoma)

Children with likelihood of increased exposure
- Children born in high-prevalence regions of the world
- Children who travel to high-prevalence regions of the world
- Children frequently exposed to adults who are HIV infected, homeless, users of illicit drugs, residents of nursing homes, incarcerated, or institutionalized

Cutaneous Induration ≥15 mm
- All children ≥4 yr of age without any identifiable risk

*BCG vaccination status not relevant.
BCG, bacille Calmette-Guérin; HIV, human immunodeficiency virus; TU, tuberculin units.
Data from American Academy of Pediatrics. Tuberculosis. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *2015 Red Book: Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:806.

to an adult with active tuberculosis. Nonetheless, tuberculosis is an infrequent cause of cough in children, even in those with active disease.

The diagnosis is made primarily by skin testing (purified protein derivative [PPD]) or a positive Quantiferon test; a history of contact with a person who has tuberculosis; and recovery of the organism from sputum, bronchoalveolar lavage, pleural fluid or biopsy, or morning gastric aspirates (Table 2.14). The yield from these procedures is relatively low, even from children with active pulmonary tuberculosis.

The patterns of disease in normal hosts include primary pulmonary tuberculosis, with subsequent inactivation usually noted in young children and reactivation pulmonary disease among adolescents. **Primary pulmonary disease** is often noted as a lower or middle lobe infiltrate during the period of T lymphocyte reaction to the initial infection. Before resolution, the *Mycobacterium tuberculosis* infection may disseminate to the better oxygenated upper lobes and extrathoracic sites, such as bone, or the central nervous system. If the immune response contains the initial infection, the radiographic findings may be indistinguishable from those of any other pneumonic process. With altered immune function, however, there may be progressive local disease, dissemination to miliary pulmonary disease, or early reactivation (months to 5 years) at distal sites, which produces tuberculous meningitis or osteomyelitis. **Reactivation** of upper lobe pulmonary disease may produce cavities that are similar to the disease among adults. Cavitary and endobronchial lymph node involvement are highly infectious, in contrast to the much less contagious nature of the hypersensitivity reaction noted in primary pulmonary disease.

Aspiration

Inhaling food, mouth or gastric secretions, or foreign bodies into the tracheobronchial tree causes acute, recurrent, or chronic cough. Interference with normal swallowing disrupts the coordination of swallowing and breathing that prevents aspiration. Structural causes of disordered swallowing include esophageal atresia (in neonates), strictures, webs, or congenital stenoses. Mediastinal lesions (tumors, lymph nodes), including vascular rings, may compromise the esophageal lumen and esophageal peristalsis, increasing the likelihood of aspiration. Functional disorders include central nervous system dysfunction or immaturity, dysautonomia, achalasia, and diffuse esophageal spasm. Prior neck surgery, including tracheostomy, may alter normal swallowing. Tracheoesophageal fistula and laryngeal clefts are congenital malformations with direct physical connections between the tracheobronchial tree and the upper gastrointestinal tract; thus oral contents enter the lungs directly.

Making the diagnosis of aspiration as the cause of cough may be difficult. Barium contrast studies during swallowing may help characterize these disorders if barium enters the trachea. Because most patients aspirate sporadically, a normal barium swallow does not rule out aspiration. Radionuclide studies can be helpful if ingested radiolabeled milk or formula is demonstrated over the lung fields at several-hour intervals after the meal. Bronchoscopy and bronchoalveolar lavage that recover large numbers of lipid-laden macrophages suggest that aspiration has taken place; however, the finding is neither sensitive nor specific for aspiration.

Treatment depends largely on the cause of aspiration. Because many patients who aspirate do so because of lack of neurologic control of swallowing and breathing, it is often difficult to prevent. Even gastrostomy feedings cannot prevent aspiration of oral secretions. In extreme cases, tracheostomy with ligation of the proximal trachea has been employed. This not only prevents aspiration but also prevents phonation, and it must be considered only in unusual situations. Aspiration pneumonia is often treated with intravenous ampicillin-sulbactam or clindamycin to cover mouth flora of predominant anaerobes. Additional coverage against gram-negative organisms may be indicated if the aspiration is nosocomial.

Foreign Body

Any child with cough of abrupt onset should be suspected of having inhaled a foreign body into the airway. Toddlers, who by nature put all types of things into their mouths and who have incompletely matured swallowing and airway protective mechanisms, are at high risk. Infants with toddlers or young children in the household who may "feed" the baby are also at risk. In older children, it is usually possible to obtain an accurate history of the aspiration event. These events are described as choking, gagging, and coughing while something (e.g., peanuts, popcorn, small toys, sunflower seeds) is in the mouth. The child may come to the physician with cough and wheeze immediately after the event, with a clear history and a straightforward diagnosis. In many children with a tracheobronchial foreign body, however, the initial episode is not recognized; these children may not come to medical attention for days, weeks, or even months. The initial episode may be followed by a relatively symptom-free period lasting days or even weeks, until infection develops behind an obstructed segmental or lobar bronchus. At this point, cough, perhaps with hemoptysis, with or without wheeze, recurs.

On physical examination early after an aspiration episode, there is cough, wheeze, or both, often with asymmetry of auscultatory findings. There may be locally diminished breath sounds. Later, localized wheeze or crackles may be detected. The triad of wheezing, coughing, and decreased breath sounds is present in fewer than 50% of patients. The presence of laryngotracheal foreign bodies often manifests with stridor, retractions, aphonia, cough, and normal radiographs.

Chest radiographs may be normal in 15% of patients with intrathoracic foreign bodies but should be obtained in both inspiration and expiration because in some cases the only abnormality is unilateral or unilobar air trapping, which is occasionally more clearly identified with an expiratory radiograph. In this view, an overdistended lung that had appeared normal on the inspiratory view does not empty, but the normal, unobstructed lung empties normally. This phenomenon causes a shift of the mediastinum toward the emptying lung, away from the side with the obstructing foreign body (Fig. 2.9). In other patients, localized infiltrate or atelectasis may be present behind the obstructing object. In a few patients, it may be possible to identify the foreign body itself; nonetheless, most inhaled food particles are not radiopaque and cannot be seen on radiographs. Aspiration is usually unilateral (80%); 50-60% of the objects are in the right lung (the lobe depends on body position—supine versus standing—but is often the right middle lobe). The definitive diagnostic and therapeutic maneuver is bronchoscopy; either the flexible or rigid open-tube bronchoscope enables direct visualization of the object; the rigid instrument also enables its removal.

Gastroesophageal Reflux

GER is a common cause of cough in all age groups (see Chapter 12). The typical patient is an infant in the first 6 months of life who spits up small amounts of milk frequently after feedings. This "regurgitant reflux" most commonly resolves by 1 year of age. However, many toddlers and children continue to have reflux, although it may be "silent" or nonregurgitant (without spitting up).

In most people with GER, it is merely a nuisance or not noticed. In some there are sequelae, and this condition is designated gastroesophageal reflux disease (GERD). One manifestation is cough; the mechanisms for the cough are not fully understood. Aspiration of refluxed material is one mechanism for cough but is probably not very common in neurologically intact children. A major mechanism for GERD with cough is mediated by vagal esophagobronchial reflexes (bronchoconstriction), stimulated by acid in the esophagus. Whether acid in the esophagus is sufficient stimulus to cause bronchoconstriction by itself or whether it merely heightens bronchial reactivity to other stimuli is not yet clear. Many children with reactive airways disease have cough or wheeze that is difficult to control until their concurrent GER is also treated. Many episodes of cough caused by GERD occur in children with asthma that is difficult to control.

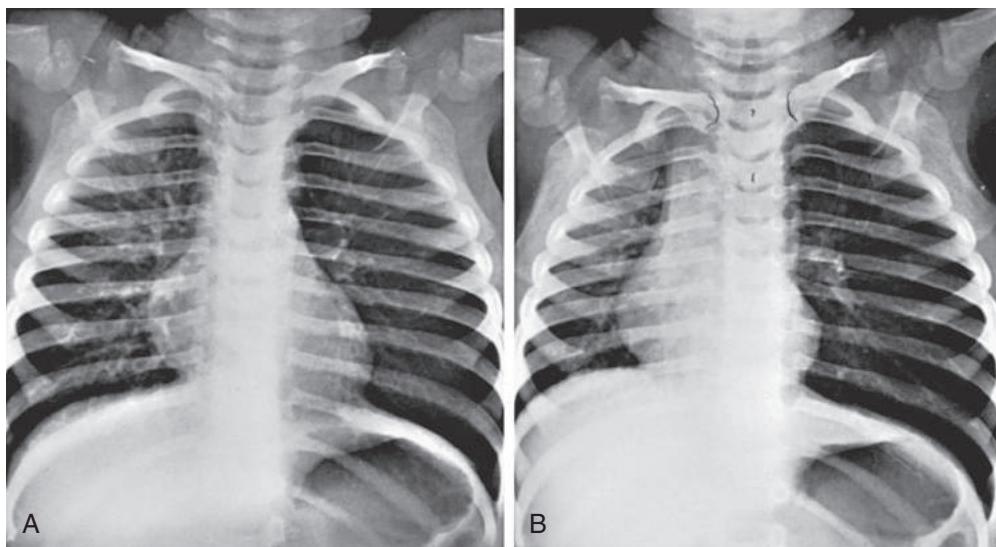
(See *Nelson Textbook of Pediatrics*, p. 1787.)


FIGURE 2.9 *A,* Normal inspiratory chest radiograph in a toddler with a peanut fragment in the left main bronchus. *B,* Expiratory radiograph of the same child showing the classic air trapping on the involved side. (From Schroeder JW Jr, Holinger LD. Foreign bodies in the airway. In: Kliegman RM, Stanton BF, St Geme JW III, Schor N, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:2040, Fig. 387.2.)

The diagnosis of GERD must also be considered in the child with chronic or recurrent cough with no other obvious explanation. The child who coughs after meals or at night, when the supine position may provoke GER, should be evaluated for GER. If GER is confirmed, the next step is a therapeutic trial of antireflux therapy.

Treatment in a child whose cough is related to GER may be accomplished by treating the reflux (see Chapter 12) or by a combination of antireflux and antiasthma treatment (see Chapter 3). On occasion, the cough may be abolished by stopping all antiasthma medications. In such cases, the cough was a manifestation of reactive airways with esophageal acidification as the trigger for bronchospasm; the esophageal acidification was caused by the bronchodilator effects on the lower esophageal sphincter.

Asthma

Cough is frequently the sole or most prominent manifestation of asthma; wheezing may be entirely absent. In fact, asthma is almost certainly the most common cause of recurrent and chronic cough in childhood (see Chapter 3). Some of the features that characterize the cough of a child with asthma are listed in Table 2.15. Treatment for asthma manifesting as cough is the same as the treatment for asthma.

Cystic Fibrosis

Cystic fibrosis (CF) is a common cause of recurrent or chronic cough in infancy and childhood. CF occurs in 1 in 2000-3000 live births among white persons, is far less common among African Americans (1 in 15,000), and is rare among Native Americans and Asians. Early diagnosis improves the prognosis for untreated CF; if untreated, many patients die in infancy or early childhood. With current state-of-the-art care, median length of survival is upper 30s.

CF is a genetic disorder, inherited as an autosomal recessive trait. The CF gene is on the long arm of chromosome 7; more than 1900 mutations have been identified at the CF locus. Of these mutations, one (ΔF508, indicating a deletion, Δ, of a single phenylalanine, F, at position 508 of the protein product) is the most common, responsible for 70-75% of all CF chromosomes. The mutation affects the gene's protein product, termed cystic fibrosis transmembrane regulator

TABLE 2.15. **Asthma as a Cause of Cough: History**
Any age (even infants)
Coexistence of allergy increases likelihood, but absence of allergy does not decrease likelihood
Wheeze need not be present
↑Cough with upper respiratory infections
↑Cough with (and especially after) exercise
↑Cough with hard laughing or crying
↑Cough with exposure to cold
↑Cough with exposure to cigarette smoke
Usually a history of dramatic response to inhaled β-agonists

(CFTR), which acts as a chloride channel and affects other aspects of membrane transport of ions and water. Not all the consequences of the defective gene and protein have been determined. In general, however, the defective gene product results in the long-observed clinical manifestations of the disease, including thick, viscid mucus in the tracheobronchial tree, leading to purulent bronchiolitis and bronchitis with subsequent bronchiectasis, pulmonary fibrosis, and respiratory failure; pancreatic duct obstruction, leading to pancreatic insufficiency with steatorrhea and failure to thrive; and abnormally high sweat chloride and sodium concentrations. The airway disease in CF is characterized by infection, inflammation, and endobronchial obstruction. The infection begins with *S. aureus, H. influenzae, Escherichia coli, Klebsiella* species, or combinations of these organisms but eventually is dominated by nonmucoid or mucoid *Pseudomonas aeruginosa.* Other organisms, such as *Burkholderia cepacia, Stenotrophomonas maltophilia, Alcaligenes xylosoxidans, Aspergillus fumigatus,* or nontuberculous mycobacteria may also appear; their significance remains undetermined. In some patients, *B. cepacia* has been associated with rapid deterioration and death, and in others, *Aspergillus* species has caused allergic bronchopulmonary aspergillosis (ABPA). The airway inflammation in all patients with CF appears to be the result of toxic substances, including elastase, released by neutrophils as they respond

to the endobronchial infection and by similar enzymes released by the invading organisms.

CF may manifest at birth with meconium ileus (10-15% of patients), or later, with steatorrhea and failure to thrive despite a voracious appetite, in an apparent effort to make up for the calories that are lost in the stool (see Chapter 11). The most common presenting symptom is cough, which may appear within the first weeks of life or may be delayed for decades. The cough can be dry, productive, or paroxysmal. Cough may respond to antibiotics or perhaps steroids, but it is less likely to improve with bronchodilators (see Tables 2.3 and 2.5). Although CF is a genetic disease, there is often no family history. Furthermore, in atypical cases, patients may not have pancreatic insufficiency (~10% of patients) and thus may not demonstrate steatorrhea and failure to thrive. In addition, malabsorption may not be evident in the neonatal period.

There is no such thing as a child who looks "too good" to have CF; common abnormalities found on physical examination are noted in Table 2.16. One of the most important physical findings is digital clubbing. In most patients with CF, clubbing develops within the first few years of life. Although the list of conditions associated with digital clubbing (Table 2.17) is long, they are less common than CF, or the incidence of digital clubbing with these conditions is low. There is some relationship between the degree of pulmonary disease severity and the degree of digital clubbing. A child who has had years of severe respiratory symptoms without digital clubbing is not likely to have CF.

The diagnosis is confirmed by a positive sweat test or confirming the presence of two CF mutations on chromosome 7. The sweat test, if not performed correctly in a laboratory with extensive experience with the technique (as, for example, in an accredited CF center), yields many false-positive and false-negative results. The proper technique is to use quantitative analysis of the concentration of chloride in the sweat produced after pilocarpine iontophoretic stimulation. Chloride concentrations higher than 60 mmol/L are considered positive, and those lower than 40 mmol/L are negative (normal). Healthy adults have slightly higher sweat chloride concentrations than do children, but the same guidelines hold for positive tests in adults. The non-CF conditions yielding elevated sweat chloride concentrations are listed in Table 2.18. False-negative results of sweat tests can be seen in CF children presenting with edema or hypoproteinemia and in samples from

children with an inadequate sweat rate. Sweat testing can be performed at any age. Newborns within the first few weeks of life may not produce a large enough volume of sweat to analyze (75 mg minimum), but in those who do (the majority), the results are accurate. Indications for sweat testing are noted in Table 2.19.

In patients for whom sweat testing is difficult (e.g., because of distance from an experienced laboratory, small infants who have not produced enough sweat, patients with extreme dermatitis, or patients with intermediate-range sweat chloride concentrations), DNA mutation testing can be useful. Demonstration of two known CF mutations confirms the diagnosis. Finding one or no known mutation makes the diagnosis less likely but is not exclusive, inasmuch as there are patients

TABLE 2.16 Physical Examination Features of Cystic Fibrosis

General
  Low weight for height (>50% of patients)
Head, eyes, ears, nose, and throat
  Nasal polyps (20%)
Chest
  Cough
  Barrel chest (↑anteroposterior diameter)
  Intercostal, suprasternal retractions
  Crackles, especially upper lobes
  Wheeze
Abdomen
  Hepatomegaly (10%)
  Right lower quadrant fecal mass (5-10%)
Extremities
  Digital clubbing (80%)
Reproductive tract
  Bilateral atresia or absence of vas deferens (>95% of males)

TABLE 2.17 Causes of Digital Clubbing in Children

Pulmonary
- Cystic fibrosis ++
- Non–cystic fibrosis bronchiectasis +
- Ciliary dyskinesia
- Bronchiolitis obliterans
- Interstitial lung diseases
- Empyema
- Lung abscess
- Malignancy
- Tuberculosis
- Pulmonary arteriovenous fistula

Cardiac
- Cyanotic congenital heart disease ++
- Bacterial endocarditis +
- Chronic congestive heart failure

Gastrointestinal
- Crohn disease
- Ulcerative colitis
- Celiac disease +
- Severe gastrointestinal hemorrhage
- Small bowel lymphoma

Mucopolysaccharidosis
Glycogen storage disease (type I)
Fucosidosis
Hereditary nephrogenic diabetes insipidus
Mauriac syndrome
Pseudohypoaldosteronism
Familial cholestasis
Nephrosis with edema

TABLE 2.19 Indications for Sweat Testing

Pulmonary Indications
- Chronic or recurrent cough
- Chronic or recurrent pneumonia (especially RUL)
- Recurrent bronchiolitis
- Atelectasis
- Hemoptysis
- Staphylococcal pneumonia
- *Pseudomonas aeruginosa* in the respiratory tract (in the absence of such circumstances as tracheostomy or prolonged intubation)
- Mucoid *P. aeruginosa* in the respiratory tract

Gastrointestinal Indications
- Meconium ileus
- Neonatal intestinal obstruction (meconium plug, atresia)
- Steatorrhea, malabsorption
- Hepatic cirrhosis in childhood (including any manifestations such as esophageal varices or portal hypertension)
- Pancreatitis
- Rectal prolapse
- Vitamin K deficiency states (hypoprothrombinemia)

Miscellaneous Indications
- Digital clubbing
- Failure to thrive
- Family history of cystic fibrosis (sibling or cousin)
- Salty taste when kissed; salt crystals on skin after evaporation of sweat
- Heat prostration, especially under seemingly inappropriate circumstances
- Hyponatremic hypochloremic alkalosis in infants
- Nasal polyps
- Pansinusitis
- Aspermia

RUL, right upper lobe.
From Kercsmar CM. The respiratory system. In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics*. 2nd ed. Philadelphia: WB Saunders; 1994:451.

with not-yet-characterized mutations. Furthermore, commercial laboratories do not identify all of the mutations.

Recovery of mucoid *Pseudomonas aeruginosa* from respiratory tract secretions is strongly suggestive of CF. Similarly pansinusitis is nearly universal among CF patients but is quite uncommon in other children.

All 50 states are using a neonatal screen for CF. The CF screen assays include measuring serum immunoreactive trypsinogen (IRT) levels, which are elevated in most infants with CF for the first several weeks of life, and DNA analysis for CFTR mutations. The main drawback of the IRT assay is that it has relatively poor specificity; as many as 90% of the positive results on the initial screen are false-positive results. If an infant's IRT screen is positive, the test should be repeated, or DNA analysis for the 23 most common CFTR mutations should be performed. At 2-3 weeks of age, which is when the IRT is repeated, the false-positive rate has fallen dramatically but is still quite high (25%). Definitive testing with the sweat chloride test needs to be carried out on infants with positive screening results.

Laboratory data that may support the diagnosis of CF include low levels of fecal elastase. This suggests pancreatic insufficiency, which occurs most commonly in CF but can be seen in other diseases. The test is not perfect for confirming CF as some CF patients have sufficient pancreatic function. Pulmonary function test findings with an obstructive pattern, incompletely responsive to bronchodilators, are consistent with CF but, of course, can be seen in other conditions. Conversely, some patients with CF also have asthma and may show a marked response to a bronchodilator. Complications of CF that should suggest the diagnosis are noted in Table 2.20.

The treatment of patients with CF requires a comprehensive approach, best performed in, or in conjunction with, an approved CF center. Several studies have shown survival to be significantly better in center-based care than in non–center-based care.

Anatomic Abnormalities

Table 2.21 lists the main anatomic abnormalities that cause cough.

Vascular rings and slings. Vascular rings and slings are often associated with inspiratory stridor because the abnormal vessels compress central airways, most commonly the trachea (see Chapter 3). The patient may also have difficulty swallowing if the esophagus is compressed.

The diagnosis may be suspected from plain radiographs of the chest, especially those showing tracheal deviation and a right-sided aortic arch. Further support for the diagnosis can be found at bronchoscopy (which shows extrinsic compression of the trachea or a main stem bronchus), barium esophagram (which shows esophageal compression), or both. The definitive diagnosis is made with computed tomographic angiography or magnetic resonance angiography. Treatment is surgical.

Pulmonary sequestration. Pulmonary sequestration is relatively unusual, occurring in 1 in 60,000 children. It occurs most commonly in the left lower lobe and can manifest in several ways (Fig. 2.10; see also Table 2.21). The chest radiograph usually shows a density in the left lower lobe; this density often appears to contain cysts (Fig. 2.11). The feature distinguishing a sequestered lobe from a complicated pneumonia is that the blood supply arises from the aorta and not the pulmonary circulation. Doppler ultrasonography and CT angiography provide the definitive diagnosis. The treatment is surgical removal.

Congenital pulmonary airway malformation (CPAM). Congenital pulmonary airway malformations (formerly known as congenital cystadenomatoid malformations or CCAMs) are rare. They manifest in infancy with respiratory distress in nearly 50% of cases; the other half may manifest as cough with recurrent infection later in childhood or even adulthood. The chest radiograph reveals multiple cysts, separated by dense areas. Chest CT scans can help make the diagnosis with near certainty. Surgical removal is the treatment of choice if the lesion is symptomatic.

Congenital lobar emphysema. Congenital lobar emphysema occurs in one of 50,000 live births. It can manifest dramatically with

TABLE 2.20 Complications of Cystic Fibrosis

Pulmonary Complications
- Bronchiectasis, bronchitis, bronchiolitis, pneumonia
- Atelectasis
- Hemoptysis
- Pneumothorax
- Nasal polyps
- Sinusitis
- Reactive airways disease
- Cor pulmonale
- Respiratory failure
- Mucoid impaction of the bronchi
- Allergic bronchopulmonary aspergillosis

Gastrointestinal Complications
- Meconium ileus
- Meconium peritonitis
- Distal intestinal obstruction syndrome (meconium ileus equivalent) (nonneonatal obstruction)
- Rectal prolapse
- Intussusception
- Volvulus
- Appendicitis
- Intestinal atresia
- Pancreatitis
- Biliary cirrhosis (portal hypertension: esophageal varices, hypersplenism)
- Neonatal obstructive jaundice
- Hepatic steatosis
- Gastroesophageal reflux
- Cholelithiasis
- Inguinal hernia
- Growth failure
- Vitamin deficiency states (vitamins A, D, E, K)
- Insulin deficiency, symptomatic hyperglycemia, diabetes

Other Complications
- Infertility
- Edema/hypoproteinemia
- Dehydration/heat exhaustion
- Hypertrophic osteoarthropathy/arthritis
- Delayed puberty
- Amyloidosis

respiratory distress in the neonatal period or later (Fig. 2.12), with cough or wheeze, or as an incidental finding on a chest radiograph. Radiography shows localized overinflation, often dramatic, with compression of adjacent lung tissue and occasionally atelectasis of the contralateral lung because of mediastinal shift away from the involved side. The appearance on chest CT scan is typical, with widely spaced blood vessels (as opposed to congenital cysts, for example, which have no blood vessels within the overinflated area). Bronchoscopy can document patent bronchi and should probably be performed in older children in whom congenital lobar emphysema can be confused with acquired overinflation of a lobe as the result of bronchial obstruction, as with a foreign body. If the disease is symptomatic, treatment is surgical.

Tracheoesophageal fistula. Tracheoesophageal fistula is common, with an incidence of about one in 5000 live births. Of these fistulas, the large majority (85%) are associated with esophageal atresia; only 3% are the isolated, H-type fistula (a patent esophagus with fistulous tract connecting the esophagus and trachea). A neonate with esophageal atresia experiences respiratory distress, excessive drooling, and choking and gagging with feeding. The H-type fistula causes more subtle signs and may be undiagnosed for months or even years. The child may have only intermittent feeding trouble, especially with liquids. There may be recurrent lower respiratory tract infections.

The diagnosis is not challenging in the infant with esophageal atresia; a nasogastric tube cannot be passed, and swallowed barium outlines the trachea. In the older child with H-type fistula, a barium esophagogram may or may not reveal the fistula. Bronchoscopy and esophagoscopy should permit direct visualization of the fistula; however, the opening may be hidden in mucosal folds.

Treatment is surgical. Many children born with tracheoesophageal fistula have recurrent cough and lower respiratory tract infection for many years, even after successful surgical correction. The cough is characteristically the harsh cough of tracheomalacia, which is present at the site of the fistula. The infections result from several causes, including GER, with or without aspiration, and altered mucociliary transport. Treatment involves regular chest physiotherapy and early and aggressive use of antibiotics whenever there is evidence of increased pulmonary symptoms.

Hemangiomas. Hemangiomas may be present within the airway and can cause cough, rarely with hemoptysis. Stridor (if the hemangioma is high in the airway) and respiratory distress (if the hemangioma is large) may also occur. In rare cases, with very large airway hemangiomas, there may even be dysphagia from extrinsic compression. Children with cutaneous hemangiomas in the mandibular or neck region ("beard" distribution) are at risk for an airway hemangioma.

The diagnosis is made with bronchoscopy. These lesions may resolve spontaneously over the first year or so. However, if they cause symptoms, it may not be advisable or possible to wait for them to resolve.

Many airway hemangiomas regress with steroid treatment; however, due to the side effect profile, propranolol is considered the treatment of choice. Asthma is a contraindication for propranolol treatment due to its beta-blocking effect and potential to worsen asthma. Laser ablation may be indicated in some refractory cases that do not respond to first-line treatment. In the case of a large subglottic hemangioma, a tracheostomy is performed and maintained until the mass regresses.

Enlarged lymph nodes. Enlarged mediastinal lymph nodes, such as those resulting from tuberculosis, leukemia, other hematologic malignancies, or other infections, are occasionally a cause of cough in children (Table 2.22; see also Table 2.21). These nodes are usually seen on

TABLE 2.21 Anatomic Abnormalities Causing Cough			
Condition	**Other Symptoms**	**Diagnostic Evidence**	**Treatment**
Vascular ring/sling	Stridor; dysphagia, emesis	Radiographic: deviated trachea, right-sided arch Barium swallow: esophageal indentation Bronchoscopy: extrinsic compression MRI/angiography: definitive	Surgical
Pulmonary sequestration	Fever, dyspnea; may be asymptomatic	Radiographic: left lower lobe density, usually with cysts Angiography: blood supply from aorta	Surgical
Congenital pulmonary airway malformation	Respiratory distress; recurrent infection	Radiographic: multiple cysts alternating with solid areas	Surgical
Congenital lobar emphysema	Respiratory distress; wheeze; may be asymptomatic	Radiographic: localized overinflation, other lobes (even other lung) collapsed Bronchoscopy to rule out foreign body	Surgical (if symptomatic)
Tracheoesophageal fistula, cleft	Gagging, choking with feeds; respiratory distress (especially with esophageal atresia)	Barium esophagram: barium in tracheobronchial tree Bronchoscopy: direct visualization	Surgical
Airway hemangioma	Stridor; wheeze; dysphagia; hemoptysis	Bronchoscopy	Propranolol, steroids; laser; occasionally tracheostomy required
Mediastinal lymph nodes	Stridor	Radiographic: hilar nodes; compressed tracheal air column	Treat cause
Bronchial stenosis	Wheeze; recurrent pneumonia	Bronchoscopy	Balloon dilatation; surgery
Bronchogenic cysts	Wheeze, stridor	Radiographic: hyperinflation of one lung; visible mass (carina, posterior mediastinum) Bronchoscopy: extrinsic compression CT: often definitive	Surgical

CT, computed tomography; MRI, magnetic resonance imaging.

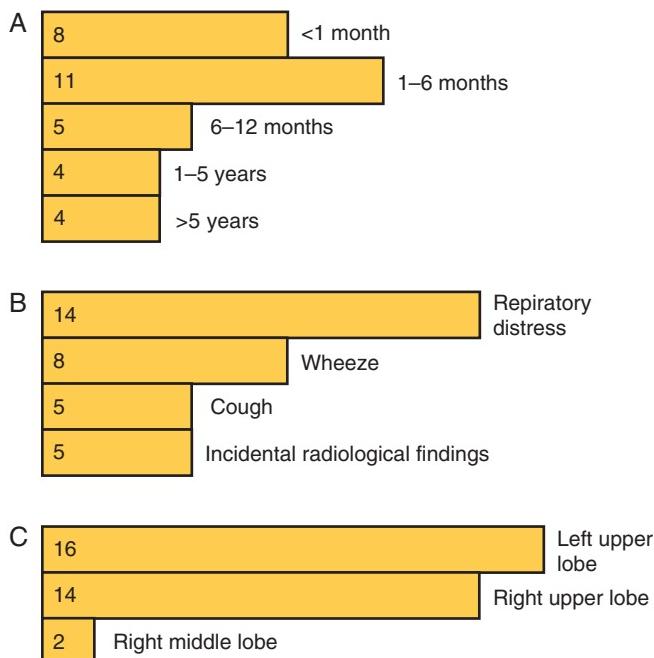

FIGURE 2.12 Different modes of presentation of congenital lobar emphysema. *A,* Age at presentation. *B,* Symptoms at presentation. *C,* Involved lobe. Numbers refer to the number of children in each category. (From Phelan PD, Olinsky A, eds. *Respiratory Illness in Children.* Oxford: Wiley-Blackwell; 1994.)

plain radiographs of the chest. The x-ray study or bronchoscopy may show extrinsic compression of the trachea. Treatment is directed at the underlying cause.

Bronchial stenosis. Occasionally bronchial stenosis, either congenital or acquired, may cause cough. The diagnosis is made with bronchoscopy, after suspicion has been raised by the child having recurrent infiltrates in the same lobe, especially with localized wheeze.

Treatment may be difficult. In some cases, endoscopic balloon dilatation or airway stent placement is successful; in others, surgical resection of stenotic areas may be necessary.

Bronchogenic cysts. Bronchogenic cysts are uncommon, but they can cause cough, wheeze, stridor, or any combination of these. They may also cause recurrent or persistent pneumonia if they block a bronchus sufficiently to interfere with normal drainage of the segment or lobe. Radiography may show localized overinflation if the cyst causes a ball-valve–type obstruction. The cyst itself may or may not be seen on plain radiographs. Bronchoscopy reveals extrinsic compression of the airway. CT studies often definitively show the lesion. Surgical removal is indicated.

Habit (Psychogenic) Cough

On occasion, a school-aged child may develop a cough that lasts for weeks, often after a fairly typical cold. This cough occurs only during wakefulness, never during sleep. In many cases, the cough is harsh and foghorn-like. It often disrupts the classroom, and the child is asked to leave. The child is otherwise well and may seem rather unbothered by the spectacle created. There is no response to medications. It seems that this type of cough, previously termed "psychogenic," or "psychogenic cough tic," but now called habit cough, has given the child valuable attention. This attention then serves as the sustaining force, and the cough persists beyond the original airway inflammation. In the small minority of cases, there may be deep-seated emotional problems of which the cough is the physical expression.

During the history or physical examination, the child appears completely well and may cough when attention is drawn to the child or when the word "cough" is uttered. The physical examination findings are otherwise completely normal, as are laboratory values. Because this may occur in any child, evidence of mild reactive airways disease (history or pulmonary function testing) does not rule out the diagnosis. Once a physician has seen a child with this problem, it is usually possible to make the diagnosis with certainty on entering the examining room or, indeed, from the hallway outside the room.

Treatment can prove more difficult. The child and family should be reassured that the child is well. Suggestion therapy empowers and encourages the patient to suppress the cough for short increments of time. The goal is for them to gradually lengthen the cough-free intervals. Speech therapy may be helpful (Table 2.23).

TABLE 2.23   **Speech Therapy Techniques for Treating Habit Cough**
Increase abdominal breathing
Reduce muscle tension in neck, chest, and shoulders
Interrupt early cough sensation by swallowing
Substitute gentle cough for racking cough
Interrupt cough sequence with diaphragm breathing and tightly pursed lips
Increase the patient's awareness of initial sensations that would trigger cough

Other Causes of Cough

Table 2.24 lists several miscellaneous causes of cough in children.

Bronchiectasis. Bronchiectasis is defined as an abnormal dilation of the subsegmental bronchi and is usually associated with chronic cough and purulent sputum production. It occasionally occurs after severe pneumonias (bacterial or viral); it eventually develops in nearly all patients with CF. Diagnosis may, on occasion, be made with plain-chest radiographs, but high-resolution CT scanning is the diagnostic procedure of choice. Treatment of bronchiectasis consists of airway clearance with chest physiotherapy with postural drainage or high-frequency chest wall oscillation, occasionally bronchodilators and mucolytic agents, and antibiotic therapy during exacerbations. Surgical resection may be indicated in cases that are progressive and localized when medical therapy has failed. The prognosis of bronchiectasis depends on the underlying cause. CF-associated bronchiectasis is a major cause of CF-related morbidity and mortality; whereas, non-CF bronchiectasis may remain stable or even regress with therapy.

Ciliary dyskinesia. Conditions in which the cilia do not function properly (immotile cilia or ciliary dyskinesia) lead to cough, usually because infection (and bronchiectasis) occurs in the absence of normal mucociliary transport. Treatment is similar to that for CF, with regular chest physiotherapy and frequent and aggressive use of antibiotics at the first sign of airways infection, most commonly increased cough.

Interstitial lung disease. Interstitial lung diseases are now classified based on those that occur during the neonatal period and those that are not as prevalent in infancy. Interstitial lung diseases that manifest with cough include aspiration (chronic and recurrent) pneumonitis, hypersensitivity pneumonitis, bronchiolitis obliterans, and cryptogenic organizing pneumonia (formerly known as bronchiolitis obliterans organizing pneumonia or BOOP). Lung biopsy may be required for a diagnosis.

Pulmonary hemosiderosis. Pulmonary hemosiderosis is a rare, and often fatal, condition of bleeding into the lung that can manifest with cough. If sputum is produced, it is often frothy and blood-tinged. There may be frank hemoptysis. However, the cough may be nonproductive, or the sputum may be swallowed. Some cases are associated with milk hypersensitivity (Heiner syndrome), and affected children may have upper airway obstruction. Some cases are associated with collagen vascular disorders. Radiographs usually show diffuse fluffy infiltrates, and there is invariably iron deficiency anemia. The diagnosis is based on lung biopsy findings.

Tumors. Tumors causing cough are rare in childhood. Cough occurs because of bronchial blockage, either extrinsic or endobronchial (see Table 2.22). The diagnosis is usually made from bronchoscopy, chest CT, or both. Treatment depends on the cell type, but it usually involves at least some surgical removal. Chemotherapy or radiation may be used in some cases.

Tracheomalacia and bronchomalacia. Isolated tracheomalacia or bronchomalacia is uncommon but can cause cough in some children. The cough of tracheomalacia is typically harsh and brassy. Treatment is difficult but, fortunately, is seldom needed.

Spasmodic croup. Some children, usually preschoolers, may episodically awaken at night with stridor and a harsh, barking cough indistinguishable from that of viral croup. This entity is termed spasmodic croup and is of unclear origin. Viral and allergic causes have been postulated. GER may be the cause in some patients.

Treatment with cool mist or racemic epinephrine is effective in most patients. If GER is the underlying cause, antireflux treatment is beneficial.

Obliterative bronchiolitis. Obliterative bronchiolitis is very rare except in lung transplant recipients. In other instances, it may arise after adenovirus, measles, or influenza pneumonia; after exposure to certain toxins; or in other rare circumstances. Children may exhibit cough, respiratory distress, and exercise intolerance.

The diagnosis is suggested by the pulmonary function test or radiographic evidence of small airways obstruction; however, these findings are not always present. Not all chest radiographs show overinflated lungs, and not all pulmonary function tests show decreased small airways function.

The definitive diagnosis is histologic via open or transbronchial biopsy. No specific treatment is available. Most children with obliterative bronchiolitis recover, but many progress to chronic disability or death.

Hemoptysis

The child who coughs out blood or bloody mucus presents special diagnostic and therapeutic challenges. Although hemoptysis is relatively uncommon in children, particularly among those without CF, many conditions can cause it (Table 2.25). It is important (and not always easy) to distinguish cases in which blood has originated in the tracheobronchial tree (true hemoptysis), the nose (epistaxis), and the gastrointestinal tract (hematemesis). Table 2.26 gives some guidelines to help localize sites of origin of blood that has been reported or suspected as hemoptysis. None of these guidelines is foolproof, partly because blood that has originated in one of these sites might well end up in another before being expelled from the body; for instance, blood from the nose can be swallowed and vomited or aspirated and expectorated.

Infection is among the most common causes of hemoptysis. Lung abscess and tuberculosis need to be considered. Bronchiectasis can readily cause erosion into bronchial vessels, often made tortuous by years of local inflammation, and produce hemoptysis. Other infectious causes are less common and include necrotizing pneumonias and fungal and parasitic lung invasion.

Foreign bodies in the airway can cause hemoptysis by direct irritation, by erosion of airway mucosa, or by secondary infection.

Pulmonary embolus is uncommon in children and adolescents, but it needs to be considered in the differential diagnosis of an adolescent with hemoptysis of unclear origin. Clues to the diagnosis of pulmonary embolus include a positive family history, severe dyspnea, chest pain, hypoxia, a normal chest radiograph, an accentuated second

Bronchodilators for presumed reactive airways

heart sound, an abnormal compression ultrasonographic study of the leg veins, a positive Homans sign, a positive helical CT scan, and a high-probability lung ventilation-perfusion scan.

The diagnosis of several causes of hemoptysis is straightforward. For example, hemoptysis that occurs immediately after a surgical or invasive diagnostic procedure in the chest should suggest an iatrogenic problem. The chest radiograph can help suggest lung abscess, pulmonary sequestration, bronchogenic cyst, or tumor. Chest CT can help with cases of arteriovenous malformations, and additional laboratory values can support the diagnosis of collagen vascular disease.

Bronchoscopy can sometimes localize a bleeding site, identify a cause (e.g., a foreign body or endobronchial tumor), or recover an offending bacterial, fungal, or parasitic pathogen. In many instances, bronchoscopy does not help except by excluding some possibilities, because either no blood or blood throughout the tracheobronchial tree is found. Bronchial artery angiography may help to identify the involved vessel or vessels.

Treatment of hemoptysis depends on the underlying cause. It can be a terrifying symptom to children and their parents, and a calm, reassuring approach is essential. Because hemoptysis is seldom fatal in children, reassurance is usually warranted. Furthermore, hemoptysis most often resolves, and treatment of the bleeding itself is not often needed. What is required is treatment of the underlying cause of the hemoptysis, such as therapy for infection, removal of a foreign body, or control of collagen vascular disease. When death occurs from hemoptysis, it is more likely to be from suffocation than from exsanguination. In cases of massive bleeding, the rigid open-tube bronchoscope may help suction large amounts of blood while ventilating and keeping unaffected portions of lung clear of blood. Interventional radiologists treat as well as localize a bleeding site by injecting the offending vessel with occlusive substances (embolization). In extremely rare instances, emergency lobectomy may be indicated.

WHEN COUGH ITSELF IS A PROBLEM

Cough itself seldom necessitates specific treatment. Nonetheless, cough is not always completely benign (see Table 2.9). Most complications are uncommon, and most accompany only very severe cough, but some are serious enough to justify treatment of the cough itself.

Cough suppressants include codeine and hydrocodone (two narcotics) and dextromethorphan (a nonnarcotic D-isomer of the codeine analog of levorphanol). Such agents should be used only for severe cough that may produce significant complications (see Table 2.9). For most diseases, suppressing the cough offers no advantage. Disadvantages include narcotic addiction and loss of the protective cough reflex with subsequent mucous retention and possible superinfection. Demulcent preparations (sugar-containing, bland soothing agents or honey) temporarily suppress the cough response from pharyngeal sources, and decongestant-antihistamine combinations may reduce postnasal drip.

SUMMARY AND RED FLAGS

Cough is important because it is a symptom and sign of underlying disease that frequently merits treatment. In the acute setting, severe disease, including massive hemoptysis or profound dyspnea or hypoxemia, warrants immediate attention, rapid diagnosis, and rapid management. Certain chronic conditions, including those that suggest CF and those in which symptoms have persisted and interfere with a child's daily activities and quality of life, warrant further evaluation and treatment. Finally, a child whose cough fails to respond to what should have been reasonable treatment should be referred to a pulmonary specialist (Table 2.27).

Respiratory Distress

Anjali Sharma

INTRODUCTION

The main function of the respiratory system is to supply oxygen to meet the body's demands and remove excess carbon dioxide. Many processes are involved in ensuring that this occurs, including ventilation (gas delivery to and from the lungs), perfusion (blood supply to the lungs) and diffusion (the exchange of gases along the alveoli). Respiratory distress arises when there is impaired air exchange that leads to decreased ventilation and oxygenation, and can be caused by problems in any of these pathways. It is essential to identify and treat the cause of respiratory distress to prevent respiratory failure, which ensues if the respiratory effort is inadequate to provide appropriate tissue oxygenation and maintenance of blood pH.

Respiratory distress occurs for a variety of reasons and with many levels of severity. It can be caused by a change in respiratory drive, impaired neuromuscular reserve, or increased ventilatory demand (Tables 3.1 and 3.2).

◆ Diagnostic Approach

Signs and symptoms of respiratory distress vary, depending on the severity and cause. The initial approach to a patient includes determining the severity of illness then determining if immediate treatment is needed by first ensuring that airway, breathing, and circulation are intact. After these steps are completed, further work-up into the cause of respiratory distress may be done. A careful history and physical examination is often sufficient to elucidate the cause of respiratory distress. Not all causes of respiratory distress arise within the respiratory tract. Heart failure, pulmonary edema, neuromuscular disorders, toxic ingestion, and central nervous system disorders may all manifest with respiratory signs and symptoms. In severe respiratory distress or suspicion of airway obstruction, a feeding trial should not be done as this may increase the risk of aspiration or further respiratory compromise.

◆ History

An appropriate medical history is important in the child with acute respiratory distress. The chief complaint provides insight into the nature of the distress (i.e., cough, wheezing, stridor, dyspnea, and/or chest pain). The onset, duration, and chronicity of symptoms should also be obtained. It is important to obtain data regarding any prodrome, exacerbating or ameliorating factors, history of trauma, previous occurrence of similar symptoms, and response to any therapy. Questions should also be directed toward any change in voice or cry, change with positioning, feeding problems, or any choking episode. The possibility of a foreign body should be raised, although this is often not observed. Past medical history of neonatal events (prematurity), previous endotracheal intubation, recurrent infections,

hospitalizations, noisy breathing, and prior gagging or choking episodes may also provide valuable information. A family history of asthma and allergies, travel, and environmental exposure (i.e., smoking, pets, or irritants) may also uncover etiologic clues. A review of systems with regard to systemic signs and symptoms associated with respiratory disease, such as fever, weight loss, night sweats, or dysphagia, is useful (Table 3.3).

◆ Physical Examination

Pulmonary Physical Examination

The physical examination begins with measurement of vital signs, with attention paid to respiratory rate, pulse oximetry, heart rate, and blood pressure. Tachypnea is often the most prominent manifestation of respiratory distress. A respiratory rate of more than 50 breaths/min in infants 2-12 months of age, 40 breaths/min in children 1-5 years, and 30 breaths/min in children older than 5 years is abnormal. The physical examination should be performed in a warm, well-lit room, preferably with the child in the parent's lap and the child's chest exposed. It is essential to observe the child's general appearance, sense of well-being, degree of dyspnea or cyanosis, and respiratory pattern, including nasal flaring, retractions, and accessory muscle use. **Central cyanosis** (lips, tongue, sublingual tissue as well as hands and feet), which is an abnormal blue discoloration, is related both to the degree of oxygen desaturation and the hemoglobin level (Table 3.4). Cyanosis is detected when the average amount of deoxygenated hemoglobin is 5 g/dL. Any posture assumed in an effort to minimize the airway difficulties should be determined. The degree and location of retractions should be noted. Retractions may be intercostal, subcostal, or suprasternal, and often signify worsening respiratory distress, particularly in the older child. Infants have a particularly compliant chest wall, and are therefore more predisposed to intercostal and sternal retractions; in older children, these features may be less prominent. Nasal flaring and accessory muscle use signify significant respiratory distress; and, as fatigue sets in, head bobbing and/or grunting can be noted, which requires prompt management as this may be a sign of impending respiratory failure. Altered mental status (either agitation or somnolence) may be indicative of severe respiratory distress, hypoxemia, hypercapnia, and impending respiratory failure. Palpation of the chest wall and cervical region may enable the examiner to detect the presence of subcutaneous emphysema indicative of pulmonary air leak. On percussion of the chest and back, a hyperresonant note during percussion of the chest wall indicates hyperinflation; whereas, dullness to percussion suggests atelectasis, pulmonary consolidation, or pleural effusion.

Auscultation of the chest should focus on identifying the degree of air exchange and the presence, timing, and symmetry of adventitious breath sounds. Air entry should be evaluated over all discrete anatomic

(See *Nelson Textbook of Pediatrics,* p. 529.)

TABLE 3.1   Age-Related Causes of Respiratory Distress

Cause	Full-Term Neonate	Infant-Toddler	Child	Adolescent
Common	Meconium aspiration pneumonia Congenital heart disease Transient tachypnea Persistent fetal circulation Congenital pneumonia	Viral pneumonia[†] Bacterial pneumonia[‡] Aspiration[§] Croup (infectious, spasmodic) Bronchiolitis Cystic fibrosis Laryngomalacia Asthma	Pneumonia[‖] Asthma Cystic fibrosis Sickle cell acute chest crisis Aspiration[§] Tonsillitis	Pneumonia[#] Asthma Sickle cell acute chest crisis Tonsillitis Peritonsillar abscess Cystic fibrosis Panic attack
Uncommon	Pneumothorax Congenital anomalies* Pneumopericardium Polycythemia Vocal cord paralysis Pleural effusions Severe anemia Pulmonary hypoplasia Surfactant protein deficiency Pulmonary lymphangiectasia	Congenital anomalies Epiglottitis Near drowning Pulmonary hemosiderosis Pulmonary hemorrhage Retropharyngeal abscess Trauma Hydrocarbon aspiration Smoke inhalation (burn) Airway hemangioma Papilloma of vocal cords Bacterial tracheitis Heart failure HIV associated[‖]	ARDS Anaphylaxis Interstitial lung disease[¶] Hemoptysis Retropharyngeal abscess Near drowning Hydrocarbon aspiration Trauma Pulmonary fibrosis Desquamating interstitial pneumonia Pulmonary alveolar proteinosis Smoke inhalation (burn) HIV associated[‖]	ARDS Spontaneous pneumothorax Pulmonary embolism Drug-induced** Interstitial lung disease[¶] Collagen vascular disease[††] Hypersensitivity pneumonitis[‡‡] Allergic bronchopulmonary aspergillosis Alveolar proteinosis Trauma Anaphylaxis Smoke inhalation (burn) Scoliosis Bronchiectasis Mediastinal mass[§§] Hemoptysis HIV associated[‖]

*Congenital anomalies = tracheoesophageal fistula; choanal atresia; tracheal web-stenosis-atresia-cleft; diaphragmatic hernia; eventration of the diaphragm; congenital pulmonary airway malformation (previously called cystic adenomatoid malformation); lobar emphysema; cleft palate–macroglossia (Pierre Robin syndrome); thyroid goiter; pulmonary hypoplasia, including Potter syndrome (renal agenesis, oligohydramnios, pulmonary hypoplasia); lung cysts; chylothorax; pulmonary lymphangiectasia; asphyxiating thoracic dystrophy; vascular rings and slings; arteriovenous malformation; subglottic stenosis.

[†]Viral pneumonia: see Table 3.12 for common causes.

[‡]Pneumonia (infant–toddler): see Table 3.12 for common causes.

[§]Aspiration = gastric fluid or formula aspiration in gastroesophageal reflux, foreign body aspiration.

[‖]Pneumonia (child): see Table 3.12 for common causes.

[¶]Interstitial lung disease = idiopathic, rheumatoid, infection *(P. carinii)*, Langerhans cell histiocytosis, hypereosinophilia syndromes, Goodpasture syndrome, LIP, alveolar proteinosis, familial fibrosis, chronic active hepatitis, inflammatory bowel disease, vasculitis (granulomatosis with polyangiitis with or without eosiniphilia, hypersensitivity), graft-versus-host disease, pulmonary venoocclusive disease, sarcoidosis, leukemia, lymphoma, neurofibromatosis, tuberous sclerosis, Gaucher disease, Niemann-Pick disease, Weber-Christian disease, organic dusts (e.g., farmer's lung, humidifier/air-conditioner lung, bird feeder, pancreatic extract, rodent handler, cheese worker), inorganic dusts (pneumoconiosis), irradiation.

[#]Pneumonia (adolescent): see Table 3.12 for common causes.

**Drugs = azathioprine, bleomycin, cyclophosphamide, methotrexate, nitrosoureas, busulfan, nitrofurantoin, penicillin, sulfonamides, erythromycin, isoniazid, hydralazine, phenytoin, carbamazepine, imipramine, naproxen, penicillamine, cromolyn sodium, mineral oil, paraquat, inhaled drugs (cocaine, hydrocarbons), talc, shoe spray.

[††]Collagen vascular disease = rheumatoid arthritis, progressive systemic sclerosis, systemic lupus erythematosus, dermatomyositis, mixed connective tissue disease.

[‡‡]Hypersensitivity pneumonia (also called extrinsic allergic alveolitis): see[¶] above for some specific organic dusts (antigens).

[§§]Mediastinal masses = anterior (teratoma, T-cell lymphoma, thymus, thyroid), middle (lymph nodes–infection–tumor–sarcoidosis, cysts), posterior (neuroenteric cysts–duplication, meningocele, neural tumors–neuroblastoma, ganglioneuroblastoma, neurofibroma, pheochromocytoma), and parenchymal tumors (hamartoma, arteriovenous malformation, carcinoid, adenoma; metastatic–osteogenic sarcoma, Wilms tumor).

[‖]HIV associated = *P. jiroveci*, LIP, CMV, *Mycobacterium tuberculosis*, atypical mycobacteria, measles, common bacterial pathogens.

ARDS, acute respiratory distress syndrome; BPD, bronchopulmonary dysplasia; CMV, cytomegalovirus; HIV, human immunodeficiency virus; LIP, lymphocytic interstitial pneumonia; RDS, respiratory distress syndrome; RSV, respiratory syncytial virus.

TABLE 3.2 Causes of Respiratory Distress

Extrathoracic	Intrathoracic
Nervous System–Metabolic	**Pulmonary**
Intracranial hemorrhage	Airway obstruction
Acidosis	Parenchymal lesions:
Ingestion (aspirin)	pneumonia, hemorrhage,
Ketoacidosis (diabetes)	malformation
Meningitis	Air leaks:
Shock/sepsis	pneumomediastinum,
Neuromuscular disease	pneumothorax
Diaphragmatic paralysis, paresis	Pleural effusion, empyema
Psychologic (anxiety)	Acute respiratory distress syndrome
Vocal cord dysfunction	Chest wall trauma
Panic attack	Pulmonary embolus
	Foreign body (airway or esophagus)
	Tumor (cyst, adenoma)
	Cystic fibrosis
Lesions of Upper Airway	**Cardiac**
Malacia	Myocarditis
Web	Cardiomyopathy
Cyst	Shunt (left to right)
Hemangioma	Congestive heart failure
Stenosis (glottic or choanal)	Pulmonary edema
Papillamatosis	Pericardial effusion
Miscellaneous	
Abdominal masses, distention	
Ascites	
Anemia	

locations bilaterally. Homologous segments of each lung should be examined sequentially to compare similar areas. The presence of adventitious sounds should be determined next. The most commonly encountered sounds are wheezing, stridor, crackles, and rhonchi (Table 3.5).

Crackles (previously called "rales") are intermittent, nonmusical low or higher pitched, largely inspiratory noises that are produced by the opening of airways closed during the previous expiration.

Wheezing is a continuous, high-pitched musical noise, similar to a hiss or whistle.

Rhonchi are continuous sounds that are lower pitched and more rumbling or sonorous.

Stridor is a high-pitched musical noise generated by turbulent flow of air through the large upper airways.

Determination of the timing (inspiration, expiration, or biphasic) and distribution of the adventitious sounds offers clues as to the site of airway and lung involvement. Wheezing that is continuous and heard equally over both lung fields is associated with diffuse airway narrowing and limitation of airflow, whereas unilateral or very localized wheezing or decreased breath sounds suggest segmental airway obstruction, such as that found with retained foreign body aspiration, mucus plugging, or atelectasis. Additionally, inspiratory stridor is characteristic of partial airway obstruction at or above the vocal cords, whereas biphasic or expiratory stridor is characteristic of airway obstruction in the subglottic space or trachea (Fig. 3.1).

Other Parts of the Physical Examination

Other elements of the physical examination may have direct bearing on the respiratory system. Pulsus paradoxus, the difference between the systolic blood pressure obtained during inspiration and during exhalation, is exaggerated by airway obstruction and pulmonary hyperinflation. As pulmonary overinflation gets worse, pulsus paradoxus values increase and correlate well with the degree of airway obstruction. It is difficult to measure pulsus paradoxus in young children with rapid heart rates. A method that allows a reasonable approximation of the pulsus paradoxus can be obtained by using a sphygmomanometer and noting the difference between the pressure at which the first sporadic faint pulse sounds and the pressure at which all sounds are heard. Values greater than 10 mm Hg are abnormal, and values greater than 20 mm Hg are consistent with severe airway obstruction. Although digital clubbing is occasionally seen as a normal and familial variant, its presence in a child with respiratory distress suggests an acute illness superimposed on an underlying chronic condition. The most common pulmonary causes of digital clubbing in pediatric patients are cystic fibrosis, bronchiectasis, and other destructive pulmonary diseases. Digital clubbing is rarely seen in children with asthma. Other physical findings to observe include mouth breathing and morphologic features suggestive of craniofacial anomalies, such as maxillary hypoplasia, nasal septal deflection, micrognathia, retrognathia, absent nasal airflow (choanal obstructions), platybasia, or macroglossia.

◆ Laboratory Tests

The arterial blood gas analysis, obtained while the patient is breathing a known fraction of inspired oxygen (FIO_2), is the "gold standard" for assessing oxygenation, ventilation, and acid-base status. In lieu of an arterial blood gas determination, capillary or venous blood gases may be utilized, but these are less helpful for evaluating oxygenation. Noninvasive measurement of oxygenation by pulse oximetry can provide valuable information. Oximetry measures the degree of hemoglobin saturation with oxygen and should not be confused with partial pressure of oxygen in the blood, as measured by blood gas analysis or estimated by transcutaneous measures. At or near sea level, hemoglobin oxygen saturation lower than 93% indicates that significant hypoxemia may be present, and saturations of 90% or lower are clearly abnormal. A blood gas analysis may be necessary to confirm the presence and degree of hypoxemia, as well as information on acid-base status (pH) and ventilation ($PaCO_2$). Hemoglobin oxygen saturation, measured by pulse oximetry, cannot detect significant hypoxia, but it is relatively accurate at oxygen saturations of 70% or more. Various conditions, such as poor circulation, presence of carboxyhemoglobin or methemoglobin, nail polish, and improper sensor alignment and motion, can result in inaccurate oximetry measures.

◆ Imaging
Radiography

A plain radiograph of the chest, taken in the posterior-anterior and lateral projections, should be obtained in any patient with respiratory distress in which an etiology has not been determined from the history and physical examination. Important information regarding the presence of parenchymal infiltrates, effusion, airway obstruction, cardiac size, pulmonary vascular markings, extrapulmonary air leaks, and the presence of radiopaque foreign bodies may be obtained from this test. Radiopaque foreign bodies are generally seen easily on a radiograph. If there is a possibility of a radiolucent foreign body, inspiratory and expiratory chest radiographic studies must be performed. Demonstration of unilateral hyperinflation or a mediastinal shift during

TABLE 3.3 Focused History for a Patient with Respiratory Distress

Component	Comments and Examples
Onset, duration, and chronicity	Abrupt onset: suggests upper airway conditions such as foreign body, allergy, anaphylaxis, irritant exposure or pulmonary embolism Gradual onset: more consistent with process such as infection or heart failure
Alleviating and provoking factors	A child with respiratory distress caused by upper airway obstruction may have some degree of relief by assuming the "sniffing position" to maximize airway patency
Treatment attempted	A child with wheezing secondary to asthma may respond readily to inhaled bronchodilators, but a child with wheezing caused by foreign body aspiration may continue to show symptoms after treatment
Respiratory symptoms	Cold symptoms: may indicate viral upper respiratory infection Cough: "seal-like" or "barky" cough is commonly heard in patients with croup Eliciting descriptions of the difficulty breathing may provide clues to the underlying cause (e.g., supraclavicular or suprasternal retractions point to upper airway obstruction) Color change: Pallor may indicate anemia; cyanosis is indicative of decreased oxygen content in the blood, as seen in some forms of congenital heart disease and in methemoglobinemia Respiratory effort: Poor effort may be seen in patients with underlying muscular dystrophies Change in voice: Whereas muffled or hoarse voice points to upper airway pathology, lower airway disease does not typically change the character of the voice
Systemic or associated symptoms	Fever: Presence suggests an infectious cause Hydration status, including intake and output (urine, emesis, diarrhea, excessive perspiration, or high respiratory rate) Weight loss or failure to gain weight: may indicate systemic process (e.g., inborn error of metabolism) or the severity of respiratory distress is impairing growth (as seen in congestive heart failure) Abdominal pain: may suggest abdominal pathology such as obstruction or appendicitis or may represent referred pain from diaphragmatic irritation (as in basilar pneumonia)
Past medical history	Underlying disorders may predispose patients to certain conditions: For example, a patient with sickle cell disease and respiratory distress may be exhibiting signs of acute chest syndrome; a patient with known gastroesophageal reflux and coarse lung findings on examination could have an aspiration pneumonia
Exposures or environmental factors	For example, a patient involved in a fire may not only be affected by thermal injury to the airways but also systemic toxins such as carbon monoxide and cyanide A patient with allergy and a potential exposure to the allergen could be showing signs of anaphylaxis
Trauma	History of trauma suggests diagnoses such as pneumothorax, flail chest, cardiac tamponade, or abdominal injury
Immunization status	Children with incomplete or lack of immunization against *Haemophilus influenzae* type B are at increased risk for epiglottitis
Last oral intake	If advanced airway management becomes necessary (e.g., positive-pressure ventilation), the presence of stomach contents may increase the risk of pulmonary aspiration

expiration suggests localized bronchial obstruction, such as a retained foreign body. Lateral decubitus positioning of the patient during the radiographic procedure can reveal a pleural effusion in the lower dependent lung. Ultrasonography of the chest is also useful in detecting pleural fluid and loculations within pleural effusions.

In patients with stridor, anteroposterior and lateral soft tissue radiographic studies of the neck and chest are frequently needed. These should be obtained during inspiration, because the soft tissues of the pharynx may bulge with expiration, causing a false-positive finding of a soft tissue mass that may mimic a retropharyngeal infection.

Computed Tomography

Computed tomography (CT) of the upper airway and chest can help detect the relationship of the vasculature to the airways (trachea and large central airways); pulmonary parenchymal lesions (infiltrates, abscesses, cysts) or lesions (abscesses, inflammation) in the airway; and central airway caliber. Rapid, fine-cut CT is a technique of high resolution and short duration, which increases its acceptability for pediatric patients. It is the method of choice for noninvasive detection and evaluation of bronchiectasis and interstitial lung disease. Helical CT is a valuable method of detecting pulmonary embolism.

TABLE 3.5	Classification of Common Lung Sounds		
	Acoustic Characteristics	**American Thoracic Society Nomenclature**	**Common Synonyms**
Normal	200-600 Hz Decreasing power with increasing Hz	Normal	Vesicular
	75-1600 Hz Flat until sharp decrease in power (900 Hz)	Bronchial	Bronchial Tracheal
Adventitious		Adventitious	Abnormal
	Discontinuous, interrupted explosive sounds (loud, low in pitch), early inspiratory or expiratory	Coarse crackles	Coarse crackles
	Discontinuous, interrupted explosive sounds (less loud than above and of shorter duration; higher in pitch than coarse crackles or crackles), mid- to late inspiratory	Fine crackles	Fine crackles, crepitation
	Continuous sounds (>250 msec, high-pitched; dominant frequency of 400 Hz or more, a hissing sound)	Wheezes	Sibilant rhonchus, high-pitched wheeze
	Continuous sounds (>250 msec, low-pitched; dominant frequency <200 Hz, a snoring sound)	Rhonchi	Sonorous rhonchus, low-pitched wheeze

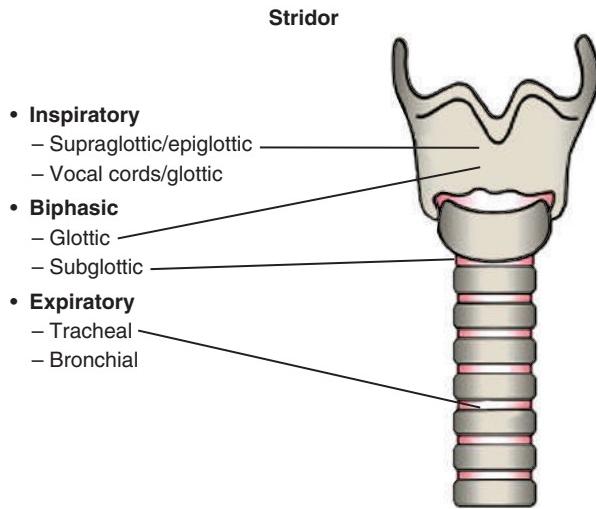
  - Subglottic
- **Expiratory**
  - Tracheal
  - Bronchial


FIGURE 3.1 Stridor. Inspiratory stridor is characteristic of partial airway obstruction at or above the vocal cords (supraglottic/epiglottic and glottis areas). Biphasic stridor is characteristic at the glottis or subglottic areas, and is typically caused by a fixed obstruction. Expiratory stridor is characteristic of a high tracheal lesion as there is a decrease in airway diameter with expiration. (From Ida JB, Thompson DM. Pediatric stridor. *Otolaryngol Clin North Am.* 2014;47:795-819.)

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the pulmonary system may also be useful in elucidating the relationship of the great vessels to the airways and may be superior to CT for this purpose. MRI is less useful for imaging the lung parenchyma. The need for long imaging times often means sedation for young children, and this limits the utility of MRI imaging of the chest for some pediatric patients. Sedatives must be used very carefully, particularly in patients with respiratory distress, and only in monitored situations with the availability of experienced personnel and equipment to provide possible resuscitation.

Fluoroscopy

Fluoroscopic examination of the chest may be useful in determining the cause of respiratory distress. Real-time visualization of the

diaphragm can determine whether paralysis or paresis of this major muscle of respiration is contributing to respiratory distress. Asymmetric chest wall motion or unilateral hyperinflation during the respiratory cycle suggests bronchial obstruction, such as that seen with a retained foreign body in the airways. An upper gastrointestinal (GI) series is useful to assess for abnormalities of swallowing causing aspiration, presence of tracheoesophageal fistula, or presence of a vascular ring.

Endoscopy

Endoscopy can provide direct visualization of the cause of the airway obstruction and lung lesions; its use involves manipulation of the airway, which should not be undertaken unless the personnel and equipment are present to manage possible worsening airway compromise. Flexible, direct laryngoscopy is widely used to visualize the upper airway without the need for sedation. Rigid bronchoscopy provides visualization of both the upper and lower airways; cardiopulmonary monitoring and intravenous access for sedative administration are required. In cases of significant upper airway obstruction necessitating intervention, or if there is any likelihood of a foreign body, direct laryngoscopy and rigid bronchoscopy in the operating room are the safest procedures that can secure the airway, provide a diagnosis, and accomplish treatment.

CAUSES OF RESPIRATORY DISTRESS

Wheezing

Wheezing is best characterized as a continuous, musical sound most often heard on expiration, but it may occur in both phases of respiration. The most common cause of acute wheezing in children is asthma. However, it is critical to rule out other causes of wheezing that necessitate different therapy (Table 3.6). Anatomic abnormalities of the airway, such as vascular ring, tracheobronchomalacia, ciliary dyskinesia, and foreign body aspiration, may cause airway obstruction and wheezing, especially in infants and young children. Viral infections, notably those of respiratory syncytial virus (RSV), human metapneumovirus, adenovirus, parainfluenza, and influenza, are also common causes of wheezing in infants and young children. Infection with *Mycoplasma* species may produce airway hyperactivity in older

TABLE 3.6 **Causes of Wheezing in Childhood**	
Acute	**Airway Compression by Mass or Blood Vessel**
Reactive Airways Disease	Vascular ring/sling
Asthma*	Anomalous innominate artery
Exercise-induced asthma*	Pulmonary artery dilation (absent pulmonary valve)
Hypersensitivity reactions	Bronchial or pulmonary cysts
Anaphylaxis	Lymph nodes or tumors
Bronchial Edema	**Aspiration**
Infection* (bronchiolitis, ILD, pneumonia)	Foreign body
Inhalation of irritant gases or particulates	Gastroesophageal reflux*
Increased pulmonary venous pressure	Tracheoesophageal fistula (repaired or unrepaired)
Bronchial Hypersecretion	**Bronchial Hypersecretion or Failure to Clear Secretions**
Infection	Bronchitis, bronchiectasis
Inhalation of irritant gases or particulates	Cystic fibrosis*
Cholinergic drugs	Dyskinetic (immotile) cilia syndrome

children. Other entities to consider are cystic fibrosis, interstitial lung disease, or vocal cord dysfunction. In comparison with asthma, one key distinguishing feature of these diagnoses is that the wheezing does not respond to treatment with bronchodilators.

Asthma

Asthma is defined as airway obstruction that is reversible either spontaneously or with the use of medication. Chronic airway inflammation and bronchial hyperresponsiveness are the likely causes of the airway obstruction. The airways of patients with even mild asthma demonstrate inflammation, manifested as mucosal edema, hypersecretion of mucus, smooth muscle constriction, and inflammatory cell infiltrate. Even when asthma symptoms are not present, airway inflammation may be demonstrated. Furthermore, bronchial hyperresponsiveness, the tendency of airway smooth muscle to constrict in response to a variety of environmental stimuli, is present in virtually all children with asthma and may be exacerbated by airway inflammation. Airway remodeling, the deposition of collagen in the subepithelial basement membrane area, occurs in some but not all asthmatic patients. Fixed airway obstruction is a long-term complication that may occur as a result of airway remodeling.

The diagnosis of asthma is made by a combination of history, physical examination and spirometry testing. For the child with acute wheezing and respiratory distress, a therapeutic trial of an inhaled ß-agonist is the best "diagnostic test" for reversible airway obstruction. Once the acute symptoms have improved, other diagnostic studies can be undertaken. Spirometry, particularly measurement of the forced expiratory volume in 1 second (FEV_1) and mid-maximal forced expiratory flow rates ($FEF_{25-75\%}$), provides a good indication of airflow obstruction in the larger and smaller airways, respectively. If airway obstruction is detected in the resting state, a bronchodilator (typically albuterol) is administered, and spirometry is repeated. An improvement of ≥12% and ≥200 mL in FEV_1 above baseline is considered significant and indicative of reversible airway obstruction (Fig. 3.2). If the baseline spirometry is normal, an inhalation challenge test, with either increasing doses of methacholine or hyperventilation of cold, dry air can provoke a statistically (but usually not clinically) significant decrease in FEV_1; a fall in FEV_1 of 10% or greater is considered diagnostic of airway hyperresponsiveness and asthma. In children too young to perform spirometry (typically under the age of 5 years), the repeated nature of wheezing episodes and the improvement in symptoms after treatment with antiinflammatory agents and

FEF, forced expiratory flow rate; FVC, forced vital capacity; PEF, peak expiratory flow rate; PIF, peak inspiratory flow rate. (From South M, Isaacs D: *Practical Paediatrics.* 7th ed. Oxford: Churchill Livingstone; 2013.)

bronchodilators, peripheral blood eosinophilia (>4%), a family history of atopy, and/or a personal history of atopy (eczema, food allergy, or allergic rhinitis) are strongly suggestive of the diagnosis of asthma. Other studies include measurement of total serum immunoglobulin E (IgE) levels. This immunoglobulin is often elevated in individuals with asthma and/or allergy, as well as in those predisposed to asthma.

Patients with acute asthma typically present with shortness of breath, wheezing, cough, and increased work of breathing. Persistent cough may be the most prominent or even sole feature of acute asthma (see Chapter 2). Many asthma episodes are misdiagnosed as bronchitis (which is rare in children). Chest wall retractions and the use of accessory muscles indicate significant airway obstruction. Acute asthma exacerbations that are unresponsive to aggressive bronchodilator administration are termed **status asthmaticus**. The severity of asthma exacerbation may be assessed with the parameters presented in Table 3.7. Common triggers of acute episodes include upper respiratory tract infections, exposure to cold air, exercise, allergens, pollutants, strong odors, and tobacco smoke.

A brief history should be obtained for every child with acute asthma to determine the duration of symptoms, the character of previous episodes (severity, need for hospitalization, and need for intensive care, including mechanical ventilation), antecedent illness, symptoms, exposures, and both chronic and acute use of medications, including dose and time of last administration. History should also focus on identifying risk factors for severe asthma (Table 3.8) and classification of asthma type, which are based on age (Figs. 3.3, 3.4, and 3.5). It is also important to assess the degree of asthma control. The physical examination should focus on respiratory rate, air exchange, degree and

localization of wheezing, other adventitious lung sounds, mental status, presence of cyanosis, and degree of fatigue. A chest radiograph should be obtained for all patients with a first episode of wheezing to evaluate for other causes of wheezing. Patients with recurrent asthma should have a chest radiograph if there is evidence for a foreign body or pneumonia, or concern for a pneumothorax. Chest radiograph findings in asthma are nonspecific, but they usually show symmetric hyperinflation and increased peribronchial thickening. Spirometry has limited efficacy in the emergency management of status asthmaticus. Although peak expiratory flow rates are often measured, this test is a measure of large airway function only, is effort dependent, and may be unreliable in an anxious, untrained patient. The major value of peak flow measurements in acute asthma is to provide an objective trend indicative of improvement (or lack thereof) in airway caliber if frequent and scheduled treatments are needed.

A complete blood cell count is not of use unless other complicating conditions (i.e., bacterial infection, anemia, hemoglobinopathy) are suspected. Serum electrolyte measurements are of little value unless dehydration is suspected. Hypokalemia is associated with the frequent administration of ß-agonists.

Treatment of acute asthma should be instituted in any child with wheezing, dyspnea, cough, and no other immediately discernible cause of the symptoms. Patients with moderate to severe airway obstruction have significant hypoxemia as a result of ventilation-perfusion mismatch. Consequently, supplemental humidified oxygen should be administered to any child who has significant wheezing, accessory muscle use, or an oxygen saturation of <93%. The mainstay of treatment for an asthma exacerbation is the administration of an inhaled

TABLE 3.7	**Severity of Asthma Exacerbations**			
	Mild	**Moderate**	**Severe**	**Respiratory Arrest Imminent**
Symptoms				
Breathlessness	While walking	While at rest (infant—softer, shorter cry; difficulty feeding)	While at rest (infant—stops feeding)	
	Can lie down	Prefers sitting	Sits upright	
Talks in	Sentences	Phrases	Words	
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
Signs				
Respiratory rate	Increased	Increased Guide to rates of breathing in awake children: *Age* *Normal rate* <2 mo <60/min 2-12 mo <50/min 1-5 yr <40/min 6-8 yr <30/min	Often >30/min	
Use of accessory muscles; suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate, often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absence of wheeze
Pulse/minute	<100	100-120 Guide to normal pulse rates in children: *Age* *Normal rate* 2-12 mo <160/min 1-2 yr <120/min 2-8 yr <110/min	>120	Bradycardia
Pulsus paradoxus	Absent <10 mm Hg	May be present 10-25 mm Hg	Often present >25 mm Hg (adult) 20-40 mm Hg (child)	Absence suggests respiratory muscle fatigue
Functional Assessment				
PEF percent predicted or percent personal best	≥70%	~40-69% or response lasts <2 hr	<40%	<25% Note: PEF testing may not be needed in very severe attacks
Pa_{O_2} (on air)	Normal (test not necessary)	≥60 mm Hg (test not usually necessary)	<60 mm Hg: possible cyanosis	
and/or P_{CO_2}	<42 mm Hg (test not usually necessary)	<42 mm Hg (test not usually necessary)	≥42 mm Hg: possible respiratory failure	
Sa_{O_2} (on air) at sea level	>95% (test not usually necessary)	90-95% (test not usually necessary)	<90%	
	Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.			

Pa_{O_2}, arterial oxygen pressure; P_{CO_2}, partial pressure of carbon dioxide; PEF, peak expiratory flow; Sa_{O_2}, oxygen saturation.

ß-adrenergic agonist and systemic corticosteroids. Inhalation of ß-agonist by nebulizer or metered-dose inhaler is the route of choice because the onset of action is rapid, sustained, and relatively free of significant side effects even in the most severely affected patients. Anticholinergic agents (ipratropium bromide), when combined with a ß-agonist as inhaled treatment, can provide additional bronchodilation. The effect is most marked in children who present to the emergency department with significant airway obstruction. With few exceptions, any patient who presents with wheezing responsive to bronchodilator therapy or any patient requiring hospital admission should receive corticosteroids. In severe respiratory distress, intravenous (IV) magnesium or theophylline (or the intravenous formulation aminophylline) may be of benefit. A small percentage of children with acute asthma progresses to severe status asthmaticus and respiratory failure. A number of clinical signs and symptoms define respiratory failure in such severely affected patients: a Pa_{O_2} less than 60 mm in room air or cyanosis in 40% F_{IO_2}, a Pa_{CO_2} of 40 mm or higher or rising and accompanied by respiratory distress, deterioration in clinical status in spite of aggressive treatment, a change in mental status, and fatigue. Patients meeting any of these criteria should be admitted to an intensive care unit.

TABLE 3.8 Risk Factors for Death from Asthma

Asthma History
Previous severe exacerbation (e.g., intubation or ICU admission for asthma)
Two or more hospitalizations for asthma in the past year
Three or more ED visits for asthma in the past year
Hospitalization or ED visit for asthma in the past month
Using >2 canisters of SABA per month
Difficulty perceiving asthma symptoms or severity of exacerbations by patient, family, and physician
Other risk factors: lack of a written asthma action plan, sensitivity to *Alternaria*

Social History
Low socioeconomic status or inner-city residence
Illicit drug use
Major psychosocial problems

Comorbidities
Cardiovascular disease
Other chronic lung disease
Chronic psychiatric disease

From National Heart, Lung and Blood Institute. Expert Panel Report 3 [EPR 3]. Guidelines for the Diagnosis and Management of Asthma. Available at: http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm

Identification and treatment of chronic asthma requires careful assessment of the severity of the disease, according to frequency and intensity of symptoms, and subsequent grading into mild, moderate, and severe categories (see Figs. 3.3, 3.4, and 3.5). All patients except those with mild intermittent disease are best managed with chronic administration of an inhaled antiinflammatory agent (corticosteroids) and the intermittent use of an inhaled ß-agonist for treatment of acute wheezing episodes. Leukotriene receptor antagonists may be considered as an alternative preventive therapy for mild asthma. Oral corticosteroids are administered for short intervals to control more severe exacerbations. Avoidance of environmental triggers (allergens, tobacco smoke) is also paramount to successful management.

Bronchiolitis

Bronchiolitis is a common, acute viral infection of the distal lower respiratory tract, and is characterized as lower airway obstruction secondary to airway edema, mucous and cellular debris. Impaired gas exchange can occur as a result of airway obstruction and ventilation-perfusion inequalities. RSV is the most important respiratory pathogen in infants and young children. It has been identified as the etiologic agent in 5%-40% of pneumonias in young children. Other viruses, such as adenovirus, influenza, human metapneumovirus, and parainfluenza, can also cause bronchiolitis. The most severe disease occurs in infants younger than 6 months. By 5 years of age, 95% of all children have serologic evidence of RSV infection. Reinfections are common in older children and adults, because immunity to RSV is short lived and incomplete. In older children and adolescents, infections with RSV are often limited to the upper respiratory tract. In temperate climates, RSV epidemics occur yearly, beginning in midwinter and persisting through early spring.

In infected infants, upper respiratory tract symptoms usually precede the lower respiratory tract involvement by 3-7 days. Low-grade fever, rhinitis, and pharyngitis are common signs in the initial phase of the disease. This then progresses to cough, increased work of breathing, and wheezing (see Chapter 2). Apnea may also occur, particularly in infants less than 3 months of age. Chest wall retractions and dyspnea are frequently observed, and adventitious sounds (wheezing, crackles) are appreciated on auscultation of the chest. Most children with bronchiolitis demonstrate clinical improvement after 5-7 days, but the duration of illness can be as long as 21 days. *Bacterial superinfection of the lower respiratory tract is rare.* Approximately 30% of infants with bronchiolitis caused by RSV have recurrent episodes of wheezing caused by bronchial hyperactivity and are diagnosed with asthma. This is in part due to persistent inflammation of the distal respiratory tract produced by the viral infection.

The clinical determination of the severity of the lower respiratory tract involvement in infants infected with bronchiolitis can be difficult. Physical findings often associated with respiratory distress, such as tachypnea, intercostal retractions, and wheezing, are not necessarily correlated with the level of hypoxemia. Carbon dioxide retention secondary to alveolar hypoventilation is not a common finding in otherwise normal children, but hypercapnia and acute respiratory acidosis can be serious problems in infants with chronic pulmonary disease or congenital heart disease. Chest radiograph findings include a diffuse interstitial pneumonitis and bilateral lung overinflation; alveolar infiltrates or consolidation are present in approximately 20% of children. Infants with congenital heart disease, pulmonary hypertension, prematurity, and young age (<12 weeks) have an increased rate of severe disease and mortality; the course of illness is usually prolonged, and intensive care and mechanical ventilation are frequently needed.

The diagnosis of bronchiolitis is usually made on clinical grounds. Bronchiolitis is most common in children under 2 years of age and should be suspected in the wheezing child who has current or antecedent upper respiratory tract infection symptoms in the late fall or winter months. The definitive diagnosis of RSV or other viral infection is based on the presence of the viral genome in respiratory secretions. This testing is often not needed if the clinical findings are consistent with bronchiolitis. Polymerase chain reaction (PCR) testing is specific, accurate, and has a short turnaround time in identifying the virus from nasopharyngeal swabs.

Suctioning and supplemental oxygen remain the cornerstone of treatment for bronchiolitis. Unlike asthma, the wheezing accompanying bronchiolitis is often less responsive to bronchodilators. Nonetheless, patients with significant hypoxia and hypercapnia may receive a *trial treatment* with aerosol bronchodilators to determine if this may improve symptoms, which may be continued if infants do show improvement. Infants with bronchiolitis do not respond to treatment with antiinflammatory agents, such as corticosteroids, so these are not recommended. Severely ill patients may require mechanical ventilation; heated, humidified, high-flow nasal cannula oxygen has been shown to decrease intubation rates and can be used in children with severe respiratory distress. Other modalities, such as hypertonic or normal saline aerosols, PEP (positive expiratory pressure) therapy, and chest physiotherapy have shown mixed results, but may be of benefit for patients who are hospitalized. Treatment with exogenous surfactant or helium-oxygen mixtures for severely ill infants requiring intubation and mechanical ventilation has yielded mixed results and remains experimental.

Monthly administration (intramuscularly) of a humanized monoclonal antibody (palivizumab) against RSV can reduce morbidity from bronchiolitis but does not completely prevent infection. Infants at high risk (infants who are premature, those with bronchopulmonary dysplasia or other forms of chronic obstructive pulmonary disease, those

(See *Nelson Textbook of Pediatrics,* p. 2053.)

Components of Severity		Classification of Asthma Severity (0–4 years of age)			
			Persistent		
		Intermittent	Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/week	≥2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	0	1–2x/month	3–4x/month	>1x/week
	Short-acting beta$_2$-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year	≥2 exacerbations in 6 months requiring oral systemic corticosteroids, or ≥4 wheezing episodes/1 year lasting >1 day AND risk factors for persistent asthma		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. ◄──────────────► Exacerbations of any severity may occur in patients in any severity category.			
Recommended Step for Initiating Therapy		Step 1	Step 2	Step 3 and consider short course of oral systemic corticosteroids	
		In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. If no clear benefit is observed in 4–6 weeks, consider adjusting therapy or alternative diagnoses.			

Key: EIB, exercise-induced bronchospasm

Notes

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.

- Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit. Assign severity to the most severe category in which any feature occurs.

- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past 6 months, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

FIGURE 3.3 Classifying asthma severity ages 0-4. (From NHLBI/National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. NIH Publication; 2007.)

with complex congenital heart disease) who are younger than 2 years are most likely to benefit.

Mycoplasma pneumoniae Infections

One of the basic tenets regarding respiratory infections in children is that "bacteria do not make you wheeze." *Mycoplasma pneumoniae* is an exception to that rule and should be considered in an older child who presents with new-onset wheezing. In addition, infections with *M. pneumoniae* can precipitate exacerbations in patients with asthma. Other clinical manifestations of *M. pneumoniae* infections include cough, fever/chills, rhinorrhea, and otitis media (see Chapter 2). Extrapulmonary manifestations, such as hemolytic anemia, rash, cardiac disease, polyarthritis, transverse myelitis, and central nervous system (CNS) disease, may also be present. The incidence of *M. pneumoniae* infection peaks between the ages of 5 and 19 years; the organism usually does not produce disease in children younger than age 2. Infections with *M. pneumoniae* tend to be seasonal, occurring most frequently during autumn and early winter.

The findings of *M. pneumonia* on chest radiographs are variable. A diffuse, bilateral, reticular infiltrate is the classic appearance. However, lobar, alveolar, and interstitial infiltrates have also been described. Enlargement of hilar or peritracheal lymph nodes may also be evident.

Pleural effusions (usually small) are found in 14% of patients with *M. pneumoniae*. Atypical pneumonia (diffuse infiltrates with nonlobar pattern; fever, malaise, myalgias) is often caused by *M. pneumoniae* but may also be caused by *Chlamydia pneumoniae*, *Legionella* species, and other related pathogens. PCR may help to confirm a diagnosis. Treatment is with azithromycin. Doxycycline or fluoroquinolones may also be used in older children.

Vocal Cord Dysfunction

A functional disorder that mimics asthma, vocal cord dysfunction is typically manifested as wheezing, dyspnea, and shortness of breath refractory to treatment with inhaled bronchodilators. Vocal cord dysfunction should be considered in patients with wheezing who present with atypical findings or those who are difficult to treat. The wheezing is produced by adduction of the vocal cords during inspiration and expiration. The resultant high-pitched inspiratory and expiratory noises are transmitted to the chest, although the sounds are best appreciated over the larynx. Despite the patient's apparent dyspnea, gas exchange is usually unaffected. Spirometry shows variable flattening of the inspiratory flow loop. The diagnosis is established by direct laryngoscopy, which demonstrates paradoxical motion of the vocal cords. Speech therapy is the treatment of choice.

Components of Severity		Classification of Asthma Severity (5–11 years of age)			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but nightly	Often 7x/week
	Short-acting beta$_2$-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV$_1$ between exacerbations • FEV$_1$ >80% predicted • FEV$_1$/FVC >85%	• FEV$_1$ = >80% predicted • FEV$_1$/FVC >80%	• FEV$_1$ = 60–80% predicted • FEV$_1$/FVC = 75–80%	• FEV$_1$ <60% predicted • FEV$_1$/FVC <75%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year (see note)	≥2/year (see note) ⟶		
		⟵ Consider severity and interval since last exacerbation. ⟶ Frequency and severity may fluctuate over time for patients in any severity category.			
		Relative annual risk of exacerbations may be related to FEV$_1$.			
Recommended Step for Initiating Therapy		Step 1	Step 2	Step 3, medium-dose ICS option and consider short course of oral systemic corticosteroids	Step 3, medium-dose ICS option, or step 4
		In 2–6 weeks, evaluate level of asthma control that is achieved, and adjust therapy accordingly.			

Key: EIB, exercise-induced bronchospasm; FEV$_1$, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids

Notes

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.

- Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of the previous 2–4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.

- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

FIGURE 3.4 Classifying asthma severity ages 5-11. (From NHLBI/National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. NIH Publication; 2007.)

Foreign Body Aspiration

Aspiration of a foreign body into the intrathoracic airways must be considered in the differential diagnosis of a child with the sudden onset of respiratory distress or wheezing. If both main stem bronchi or the trachea are obstructed (typically by larger foreign bodies), the patient may have asphyxia and sudden death; aspiration of foreign bodies in the distal airways often takes a more indolent course. Aspiration of foreign bodies is most common in children between 1 and 4 years of age, particularly in boys or in children with neurologic disorders or delayed development. It is rare in children younger than 6 months. The most common objects aspirated by children are small toy parts, coins, marbles, balloons, and food products (e.g., hot dogs, popcorn, seeds, nuts, grapes, carrots, and beans). Endobronchial aspiration of peanuts, raisins, popcorn kernels, or seeds tends to produce more difficulties than other kinds of foreign bodies (metallic or plastic objects) because, in addition to causing physical obstruction of the airway, vegetable matter produces an intense, local inflammatory response secondary to chemical and allergic bronchitis. Larger objects, such as coins, usually lodge in the esophagus. Esophageal foreign bodies can produce significant respiratory symptoms as a result of extrinsic compression of the posterior trachea. This compression can produce respiratory distress, stridor, and wheezing, especially in infants and young children. Dysphagia and vomiting can be late symptoms associated with an esophageal foreign body.

The typical clinical manifestation after the acute event is abrupt respiratory distress, characterized by choking, gagging, cyanosis, and a harsh, paroxysmal cough (see Chapter 2). However, because many aspiration events occur while children are unsupervised, the history of foreign body ingestion or aspiration is frequently not elicited. Chronic cough, dyspnea, hemoptysis, and wheezing may develop. Because the object is most frequently aspirated into the main stem or segmental bronchi (distal airway), the wheezing is typically unilateral. Physical examination may also reveal a decrease in breath sounds on the obstructed side, prolongation of the expiratory phase, and a tracheal shift. In some instances, retained foreign bodies in the airways can produce a persistent pneumonitis, and the chronic inflammatory response can result in bronchiectasis or lung abscess. Retained foreign body should be considered in a child with presumed asthma or pneumonia who is not improving with appropriate treatment.

The diagnosis of foreign body aspiration can be difficult to establish and necessitates a combination of clinical examination, radiographic

(See *Nelson Textbook of Pediatrics,* p. 2040.)

Components of Severity		Classification of Asthma Severity ≥12 years of age			
			Persistent		
		Intermittent	Mild	Moderate	Severe
Impairment Normal FEV$_1$/FVC: 8–19 yr 85% 20–39 yr 80% 40–59 yr 75% 60–80 yr 70%	Symptoms	≤2 days/week	≥2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but not nightly	Often 7x/week
	Short-acting beta$_2$-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily, and not more than 1x on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV$_1$ between exacerbations • FEV$_1$ >80% predicted • FEV$_1$ /FVC normal	• FEV$_1$ >80% predicted • FEV$_1$ /FVC normal	• FEV$_1$ >60% but <80% predicted • FEV$_1$ /FVC reduced 5%	• FEV$_1$ <60% predicted • FEV$_1$ /FVC reduced >5%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year (see note)	≥2/year (see note) ⟶		
		⟵ Consider severity and interval since last exacerbation. ⟶ Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV$_1$.			
Recommended Step for Initiating Treatment		Step 1	Step 2	Step 3	Step 4 or 5 and consider short course of oral systemic corticosteroids
		In 2–6 weeks, evaluate level of asthma control that is achieved, and adjust therapy accordingly.			

Key: FEV$_1$, forced expiratory volume in 1 second; FVC, forced vital capacity; ICU, intensive care unit

Notes:

• The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.

• Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.

• At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

FIGURE 3.5 Classifying asthma severity ages ≥12. (From NHLBI/National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. NIH Publication; 2007.)

studies, and ultimately endoscopic visualization. Radiopaque foreign bodies are generally easily visualized by radiographic studies. Radiolucent foreign bodies may become apparent on inspiratory or expiratory chest radiographs, lateral decubitus films, fluoroscopy, or barium swallow studies when an esophageal foreign body could be compressing the posterior tracheal wall. Because an occasional foreign body may not lodge in a bronchus, typical radiologic findings may not be seen. If a foreign body is likely to be present, rigid bronchoscopy for examination of the lower airway and foreign body removal is indicated. Flexible bronchoscopy provides an excellent visualization of the airway and should be reserved for when other diagnoses appear to be much more likely.

Stridor

Stridor, a harsh medium-pitched sound typically heard on inspiration, is caused by turbulent airflow in the upper airway. The phase of respiration in which stridor occurs is helpful in identifying the site of the airway obstruction (see Fig. 3.1). The relative anatomy of the upper airway in an adult versus in an infant is shown in Fig. 3.6. The most common cause of stridor of infants and young children is **laryngomalacia**. Congenital anomalies should be suspected in children with recurrent or persistent stridor. Acute respiratory stridor is most commonly caused by acute inflammation/infection, typically **croup**;

however, an acute foreign body aspiration in the upper airway may also cause acute-onset stridor. Epiglottitis is the most serious life-threatening infection in this area and must be identified quickly. A history of prior intubation in a patient with stridor and respiratory distress should raise concern for vocal cord paralysis or subglottic stenosis. An age-related differential diagnosis is noted in Table 3.9. Differentiating features of common disorders are noted in Table 3.10.

Croup

Laryngotracheal bronchitis (croup) is generally a slowly progressive, mild, self-limited viral inflammation of the subglottic larynx occurring in infants and young children. The most common causes are parainfluenza virus types 1 and 3, influenza A, respiratory syncytial virus, and adenovirus. The circumferential cricoid cartilage, which comprises the subglottic airway just below the vocal cords, is the narrowest part of the upper airway in a child (see Fig. 3.6). The inflammation associated with a viral infection in this location causes airway obstruction as edema develops within the confines of the cricoid cartilage. Most patients will develop mild rhinorrhea, cough, and low-grade fever prior to characteristic barky cough and inspiratory stridor (see Chapter 2). The cry or voice may become hoarse. Stridor typically worsens when the patient is upset or active, and improves with warm humidified air. Unless the airway obstruction is severe, the child generally has

(See *Nelson Textbook of Pediatrics,* Fig. 385-1.)

no trouble handling saliva. If a patient develops drooling or rapid progression of respiratory distress, epiglottitis or bacterial tracheitis should be considered. The diagnosis is usually apparent from the history and physical examination. If the diagnosis is not clear, obtaining a lateral neck radiograph is indicated and will show the classic "steeple" sign (Fig. 3.7).

Management varies from outpatient observation with parent education to endotracheal intubation. For mild cases, the patient must be well hydrated; the use of extra humidity is soothing to the airways and helps to keep secretions from being tenacious, so that they are less likely to become obstructive. In more severe cases (stridor at rest, retractions), nebulized epinephrine used as a mucosal vasoconstrictor may provide relief. Usually, patients being treated in this manner are observed in the hospital for a possible "rebound" effect that may occur 2-6 hours after treatment. Parenteral or oral dexamethasone is a safe and effective additional therapy for moderate to severe croup; steroid use has decreased the requirement for endotracheal intubation. Patients with severe croup are usually admitted to the hospital for observation. If intubation is needed, an endotracheal tube one-half to one size smaller than that used for a child with a normal airway of the same age and size is chosen. In atypical cases of recurrent croup or in patients in whom extubation is difficult, an endoscopic evaluation of the airway with laryngoscopy and bronchoscopy is necessary to exclude an underlying anatomic abnormality.

Bacterial Tracheitis

Bacterial tracheitis is a bacterial superinfection of a previous tracheal (croup, influenza virus) viral process and is usually caused by *Staphylococcus aureus*. A variety of other organisms, including *Moraxella*

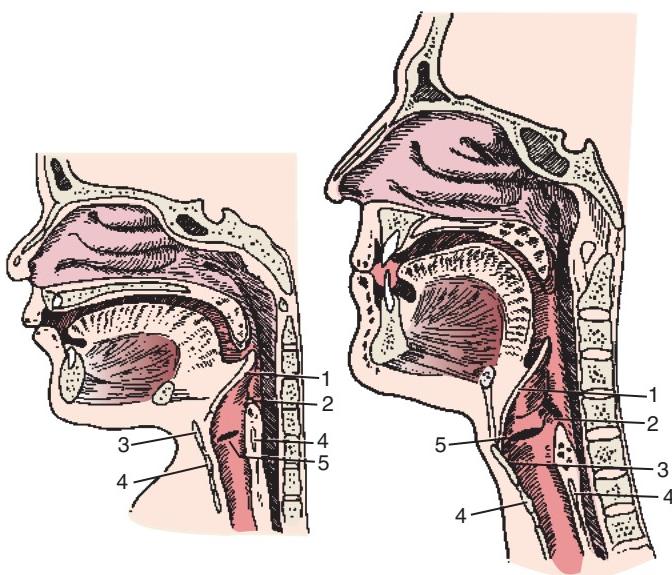

FIGURE 3.6 Anatomy of upper airway. Relative comparative anatomy of the larynx in an infant *(left)* and an adult *(right)*. Specific landmarks: *1,* epiglottis; *2,* arytenoid cartilages; *3,* thyroid cartilage; *4,* cricoid cartilage; *5,* laryngeal ventricle, the air space below the false vocal cords and above the true vocal cords. Its radiolucency is an excellent landmark on lateral radiograph. The infant larynx is situated relatively high in the cervical region. In addition, the base of the infant's tongue is close to the larynx, and the epiglottis is located near the palate. These anatomic differences partially explain the predominantly obligate nose breathing of the young infant, as well as the relative ease with which upper airway obstructions develop in infants.

TABLE 3.9 Age-Related Differential Diagnosis of Airway Obstruction

Newborn

Foreign material (meconium, amniotic fluid)
Congenital subglottic stenosis (uncommon)
Choanal atresia
Congenital cysts
Micrognathia (Pierre Robin syndrome, Treacher Collins syndrome, DiGeorge syndrome)
Macroglossia (Beckwith-Wiedemann syndrome, hypothyroidism, Pompe disease, trisomy 21, hemangioma)
Laryngeal web, clefts, atresia
Laryngospasm (intubation, aspiration, hypocalcemia, transient)
Lingual thyroid
Vocal cord paralysis (weak cry; unilateral or bilateral, with or without increased intracranial pressure from Arnold-Chiari malformation or other CNS pathology; birth trauma)
Tracheal web, stenosis, malacia, atresia
Pharyngeal collapse (cause of apnea in preterm infant)
Tumors*

Infant

Laryngomalacia (most common cause)
Subglottic stenosis (congenital; acquired after intubation)
Tumors*
Tongue tumor (dermoid, teratoma, ectopic thyroid)
Laryngeal papillomatosis
Vascular rings

Toddler

Viral croup (most common etiology in children 3 mo–4 yr of age)
Bacterial tracheitis (toxic, high fever)
Foreign body (sudden cough; airway or esophageal) (see Chapter 2)
Spasmodic (recurrent) croup (see Chapter 2)
Laryngeal papillomatosis
Retropharyngeal abscess
Diphtheria (uncommon)

Infant Older Than 2-3 Yr

Epiglottitis (epiglottis, aryepiglottic folds)
Inhalation injury (burns, toxic gas, hydrocarbons)
Foreign bodies
Angioedema (family history, cutaneous angioedema)
Anaphylaxis (allergic history, wheezing, hypotension)
Trauma (tracheal or larynx fracture)
Peritonsillar abscess (adolescents)
Ludwig angina
Diphtheria
Parapharyngeal abscess
Tumors*
Trauma

*Tumors include lymphangiomas, hemangiomas, papillomas, neuroblastoma, lymphoma, rhabdomyosarcoma, and chondrosarcomas.

TABLE 3.10 **Differential Diagnosis of Upper Airway Obstruction**

	Laryngotracheo-bronchitis (Croup)	Laryngitis	Spasmodic Croup	Epiglottitis	Membranous Croup (Bacterial Tracheitis)
Age	3 mo–3 yr	5 yr–teens	3 mo–3 yr	2–6 yr	Any age (3–10 yr)
Location	Subglottic	Subglottic	Subglottic	Supraglottic	Trachea
Etiology	Parainfluenza, influenza virus, RSV; rarely *Mycoplasma,* measles, adenovirus	As per croup	Unknown	*Haemophilus influenzae* type b	Prior croup or influenza virus with secondary bacterial infection by *Staphylococcus aureus, Moraxella catarrhalis, H. influenzae*
Prodrome onset	Insidious, URI	As per croup	Sudden onset at night; prior episodes	Rapid, short prodrome	Biphasic illness with sudden deterioration
Stridor	Yes—biphasic	No	Yes	Yes—soft inspiratory	Yes
Retractions	Yes	No	Rare	Yes	Yes
Voice	Hoarse	Hoarse; whispered	Hoarse	Muffled	Normal or hoarse
Position and appearance	Normal	Normal	Normal	Tripod sitting, leaning forward; agitation	Normal
Swallowing (dysphagia)	Normal	Normal	Normal	Drooling	Normal
Barking cough	Yes	Rare	Yes	No	Yes
Toxicity	Rare	No	No	Severe	Severe
Fever	<101°F	<101°F	None	>102°F	>102°F
Radiographic findings	Subglottic narrowing; steeple sign	Normal	Subglottic narrowing	Thumb sign of thickened epiglottis	Ragged irregular tracheal border; as per croup
WBC count	Normal	Normal	Normal	Leukocytosis with left shift	Leukocytosis with left shift
Therapy	Racemic epinephrine: aerosol, systemic steroids, aerosolized steroids, cool mist	None	Cool mist; occasionally as for croup	Endotracheal intubation, ceftriaxone	Vancomycin; ceftriaxone; intubation if needed
Prevention	None	None	None	*H. influenzae* type b conjugated vaccine	None

FFP, fresh-frozen plasma; HPV, human papillomavirus; IV, intravenous; RSV, respiratory syncytial virus; URI, upper respiratory tract infection; WBC, white blood cell.

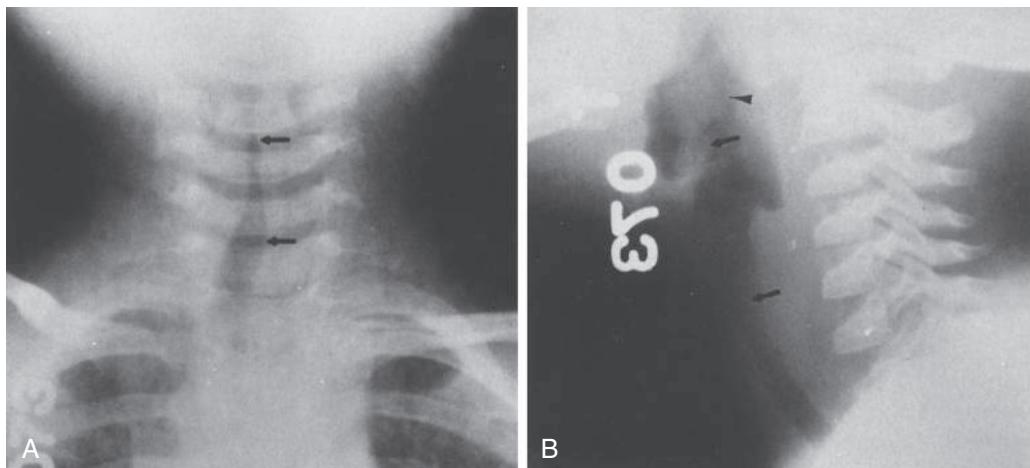
FIGURE 3.7 Croup in a 1-year-old child. *A,* Frontal radiograph of the neck shows a tapered reduction of the subglottic tracheal caliber from the level of the vocal cords *(upper arrow)* to the normal-caliber trachea below *(lower arrow)*. The right mild tracheal deviation is a normal sign resulting from the left aortic arch. *B,* Lateral view shows a normal epiglottis *(upper arrow)*, distention of the pharynx, normal palatine tonsils *(arrowhead)*, and increased density in the subglottic trachea *(lower arrow)*.


TABLE 3.10   Differential Diagnosis of Upper Airway Obstruction—cont'd

Retropharyngeal Abscess	Foreign Body	Angioedema	Peritonsillar Abscess	Laryngeal Papillomatosis
<6 yr	6 mo–5 yr	All ages	>10 yr	3 mo–3 yr
Posterior pharynx	Supraglottic, subglottic, variable	Variable	Oropharynx	Larynx, vocal cords, trachea
S. aureus, anaerobes	Small objects, vegetable, toys, coins	Congenital C-1 esterase deficiency; acquired anaphylaxis	Group A streptococci, anaerobes	HPV
Insidious to sudden	Sudden	Sudden	Biphasic with sudden worsening	Chronic
No	Yes	Yes	No	Possible
Yes	Yes (variable)	Yes	No	No
Muffled	Complete obstruction— aphonic; other variable	Hoarse, may be normal	"Hot potato," muffled	Hoarse
Arching of neck or normal	Normal	Normal; may have facial edema	Normal	Normal
Drooling	Variable; usually normal	Normal	Drooling, trismus	Normal
No	Variable; brassy if tracheal	Possible	No	Variable
Severe	No, but dyspnea	No, unless anaphylactic shock or severe anoxia	Dyspnea	None
>101°F	None	None	>101°F	None
Thickened retropharyngeal space	Radiopaque object may be seen	As per croup	None needed	May be normal
Leukocytosis with left shift	Normal	Normal	Leukocytosis with left shift	Normal
Clindamycin; ampicillin-sulbactam (or vancomycin); ceftriaxone; surgical drainage if abscess	Endoscopic removal	Anaphylaxis; epinephrine, IV fluids, steroids; C-1 esterase deficiency; replacement infusion therapy	Penicillin; aspiration	Laser therapy, repeated excision, interferon
None	Avoid small objects; supervision	Avoid allergens; FFP for hereditary angioedema	Treat group A streptococci early	Treat maternal genitourinary lesions; possible cesarean section? HPV vaccine to mother

catarrhalis, *Streptococcus pneumoniae*, and nontypable *H. influenzae* have also been identified as being occasionally involved. There is generally a virus-like mild phase, followed by a rapid deterioration, during which the patient clinically appears more ill with high fever and respiratory distress. Some patients have a two-phased illness with croup, initial recovery, followed by tracheitis. Neck and chest radiographs often show irregular scalloping of the trachea. Radiopaque densities from inspissated mucus may be seen. Close monitoring and intravenous antibiotic treatment directed toward the likely causative organisms are required. Endotracheal intubation for control of the airway is usually necessary, particularly in younger patients. Extubation is performed on the basis of clinical improvement and a resolution of excessive amounts of purulent secretions. Sometimes the exudate secondary to the tracheitis is thick and can cause airway obstruction similar to that from a foreign body.

Epiglottitis

Epiglottitis is an acute, rapidly progressive, potentially lethal infection of the epiglottis, aryepiglottic folds, and false vocal cord area. It is an emergency because of the potential for rapid airway obstruction; evaluation and treatment are directed toward establishing an airway while the physician is confirming the diagnosis and treating the infection. In the past, epiglottitis was caused by *Haemophilus influenzae* type b in nearly 100% of cases. Since the introduction of the polysaccharide conjugated *H. influenzae* type b vaccine, there has been a dramatic fall in the incidence of acute epiglottitis in the United States. However, in an internationally mobile world, patients who have not been vaccinated may acquire epiglottitis in any country. In addition, other, less common pathogens, such as *S. pneumoniae*, *S. aureus*, and ß-hemolytic streptococci, may produce epiglottitis. Unusual presentations will also become more common, with children presenting at a younger age and immunosuppressive diseases being caused by atypical organisms.

Typically, there is an abrupt onset, usually without an obvious prodrome, with rapid progression toward airway compromise. Initially, complaints of sore throat and odynophagia are common. Patients are usually febrile, and drooling is present. The typical presentation is an ill-appearing child sitting forward with her or his head hyperextended who does not want to lie down (Fig. 3.8). There is a "hot potato"

FIGURE 3.8 Child with epiglottitis. Characteristic posture in a patient with epiglottitis. The child is leaning forward and drooling, and the neck is hyperextended.

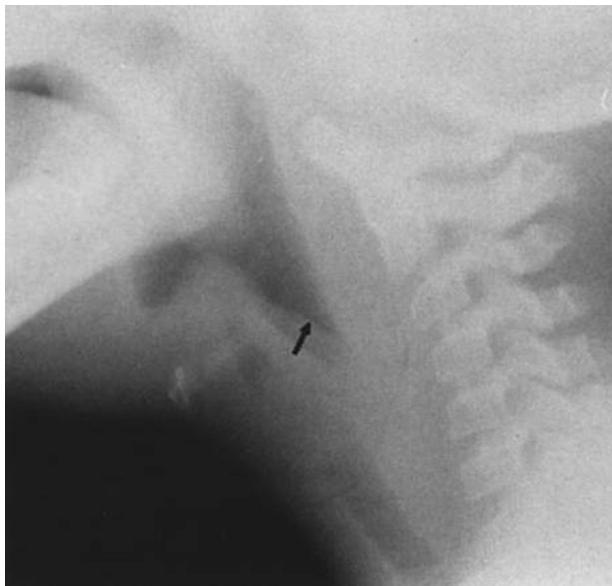

FIGURE 3.9 Epiglottitis. The patient is a 3 1/2 year old child with fever and sudden onset of stridor. Lateral radiograph shows an enlarged epiglottis ("thumb-print" sign) and aryepiglottic folds *(arrow)* and distention of the pharynx.

voice and drooling, the mouth is open, and the tongue is protruding. Mild inspiratory stridor and retractions may be present, but these are usually not obvious, because the patient generally takes short, shallow breaths. An intraoral examination is contraindicated because it may predispose to laryngospasm and airway obstruction.

If there is any question as to the diagnosis, a lateral soft tissue radiograph of the neck can be confirmatory (Fig. 3.9). Someone who has the expertise and equipment to handle sudden airway decompensation in a pediatric patient should accompany the patient to the radiology suite. When a clinical diagnosis of epiglottitis is at all likely, the patient should be taken immediately to the operating room and cared for by experienced pediatric anesthesiology and otolaryngology personnel capable of endotracheal intubation or less often tracheostomy.

Once the airway is secured and the diagnosis confirmed, blood specimens are obtained for culture and treatment is begun with ceftriaxone or cefotaxime. Patients usually require 36-48 hours of endotracheal intubation, with observation in the pediatric intensive care unit. If there is a question of safety of extubation, a second laryngoscopy is indicated.

Laryngomalacia

Laryngomalacia is the most common cause of inspiratory stridor and noisy respiration in neonates and infants. It is caused by the inspiratory collapse of the laryngeal cartilages, with prolapse of the epiglottis or arytenoid cartilages into the airway during inspiration. It typically presents with high-pitched inspiratory stridor. Stridor may occur at birth, but the onset is often delayed, occurring at 2-4 weeks of age. The condition is usually self-limited and resolves with time: often by 8-12 months of age but occasionally not until 18-24 months of age. Laryngomalacia should be suspected in infants with recurrent croup, as acute viral infections or agitation can worsen symptoms. Patients often will have associated gastroesophageal reflux disease, and some may have feeding difficulties or failure to thrive. Severe cases may cause apneic events or pulmonary hypertension.

The diagnosis is made on the basis of the clinical presentation (stridor is worse when the patient is supine or during activity, and exacerbations occur with upper respiratory tract infections) and findings on flexible laryngoscopy. Approximately 15-25% of patients with laryngomalacia may have other airway lesions. Therefore a complete airway evaluation with rigid bronchoscopy has been recommended in patients with severe respiratory distress, failure to thrive, any underlying concern for a concurrent airway lesion, and if the stridor of laryngomalacia does not follow the typical course. Unusually severe cases of laryngomalacia may necessitate operative intervention, such as a supraglottoplasty to trim redundant soft tissue or even a temporary tracheotomy. Laryngomalacia may be accompanied by tracheomalacia, a partial collapse of the tracheal cartilages with respiration. Tracheomalacia may be congenital or secondary to extrinsic compression by vascular rings or tumors. Patients with tracheomalacia manifest with wheezing, cough, stridor, dyspnea, tachypnea, or cyanosis.

Vocal Cord Paralysis

Vocal cord paralysis is a common cause of congenital neonatal laryngeal obstruction, but can also occur in older children. Vocal cord paralysis may be bilateral or unilateral, and it often can cause difficulty feeding, respiratory distress, and a weak cry. In neonates with no surgical history, it is associated with neurologic syndromes, such as the Arnold-Chiari malformation. Traction on the brainstem or increased intracranial pressure and herniation puts pressure on the vagus nerve, which is thought to cause the paralysis. It can also be iatrogenic, particularly in neonates with a history of thoracic surgery or difficult delivery. Tracheotomy is often necessary to maintain the airway in bilateral vocal cord paralysis, and neurologic and MRI evaluation should be performed to identify any central causes. Vocal cord paralysis also occurs in older children and may be caused by a polyneuropathy (Guillain-Barré syndrome), brainstem encephalitis, neck or thoracic surgery, or compression by local masses.

Vascular Rings

Vascular rings are common and can produce symptoms related to compression of the trachea and/or the esophagus (Table 3.11). Feeding often exacerbates manifestations when the obstructed esophagus acts as an additional extrinsic force on the trachea. Patients present with

TABLE 3.11   Vascular Rings

Lesion	Symptoms	Plain Film	Barium Swallow	Bronchoscopy	MRI Echocardiography	Treatment
Double arch	Stridor, respiratory distress Swallowing dysfunction Reflex apnea	AP—wider base of heart Lat.—narrowed trachea displaced forward at C3-C4	Bilateral indentation of esophagus	Bilateral tracheal compression—both pulsatile	Diagnostic	Ligate and divide smaller arch (usually left)
Right arch and ligamentum/ductus	Respiratory distress Swallowing dysfunction	AP—tracheal deviation to left (right arch)	Bilateral indentation of esophagus R > L	Bilateral tracheal compression—R pulsatile	Diagnostic	Ligate ligamentum or ductus
Anomalous innominate	Cough Stridor Reflex apnea	AP—normal Lat.—anterior tracheal compression	Normal	Pulsatile anterior tracheal compression	Unnecessary	Conservative
Aberrant right subclavian	Occasional swallowing dysfunction	Normal	AP—oblique defect upward to right Lat.—small defect on right posterior wall	Usually normal	Diagnostic	Ligate artery
Pulmonary sling	Expiratory stridor Respiratory distress	AP—low L. hilum, R emphysema/atelectasis Lat.—anterior bowing of right bronchus and trachea	±Anterior indentation above carina between esophagus and trachea	Tracheal displacement to left Compression of right main bronchus	Diagnostic	Detach and reanastomose to main pulmonary artery in front of trachea

AP, anteroposterior; L, left; Lat., lateral; MRI, magnetic resonance imaging; R, right.

cough, dysphagia, odynophagia, tachypnea, emesis, noisy breathing, stridor, and/or wheezing. Because they handle oral secretions poorly, they may develop aspiration pneumonia. They also do not tolerate neck flexion. The two most common symptomatic lesions are the right aortic arch with a left ligamentum arteriosus (or patent ductus arteriosus) and the double aortic arch. The diagnosis may be suspected on a chest radiograph by a demonstrated right-sided aortic arch or a narrow displaced trachea. An upper GI series demonstrates the indentation of the anterior and/or posterior esophagus, whereas endoscopy demonstrates the pulsatile extrinsic compressing vessels (Fig. 3.10). MRI or echocardiography is usually diagnostic; angiography is not needed to find most of these lesions.

Subglottic Stenosis

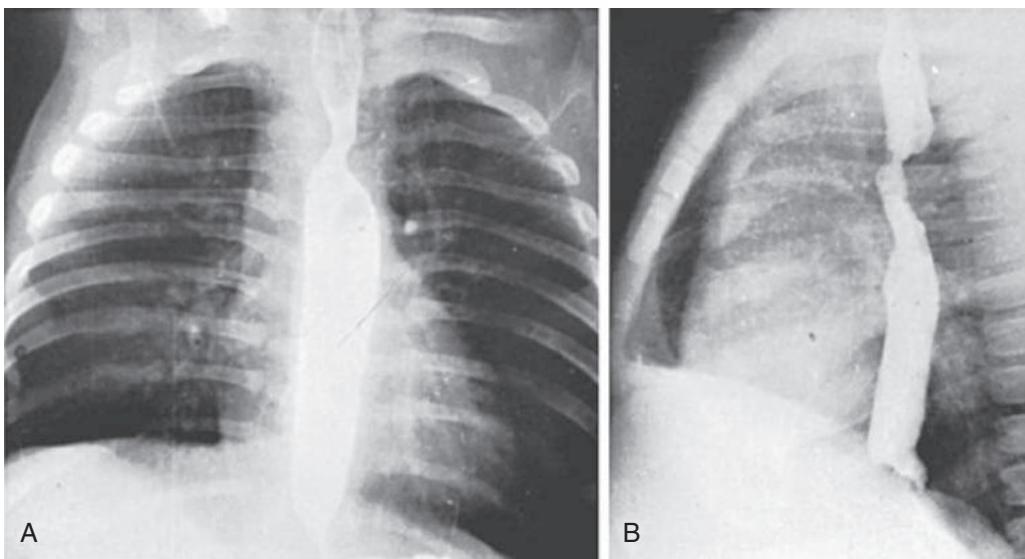
Congenital subglottic stenosis occurs when the subglottic space is narrowed, and typically presents in children younger than 3 months with respiratory distress, biphasic or inspiratory stridor, and recurrent croup. *Acquired* subglottic stenosis may develop secondary to endotracheal intubation, particularly if the intubation has been prolonged for several months, if an oversized tube was used, or if multiple intubations were required. Subglottic stenosis should be suspected in any child with these risk factors who does not tolerate extubation because of upper airway obstruction. Laryngoscopy and bronchoscopy are required for evaluation to diagnose subglottic stenosis and also evaluate for other lesions such as subglottic cysts or hemangiomas. Acquired subglottic stenosis is often more severe than the congenital type. In both types of subglottic stenosis, infection and gastroesophageal reflux may exacerbate symptoms and contribute to narrowing of the airway. A cricoid split operation, tracheotomy, or laryngotracheal reconstruction may be needed. Serial dilatations are no longer commonly used because they may continue to injure the cartilage and its overlying mucosa.


FIGURE 3.10 Double aortic arch in an infant aged 5 months. *A*, Anteroposterior view. The barium-filled esophagus is constricted on both sides. *B*, Lateral view. The esophagus is displaced forward. The anterior arch was the smaller and was divided at surgery. (From Bernstein D. Other congenital heart and vascular malformations. In: Kliegman RM, Stanton BF, St Geme JW, Schor NF, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016:2237.)

Cough

Cough is a common complaint in children (see Chapter 2). The nature of the cough is often helpful in establishing the etiology of respiratory distress. For example, a barky cough is typically associated with viral croup, whereas a more productive cough can be associated with pneumonia. Pneumonia is most commonly caused by bacteria or viruses; however, there are other common noninfectious causes of pneumonia and pneumonitis.

Viral and Bacterial Pneumonia

Pneumonia is a significant cause of mortality for children worldwide. Pneumonia is defined as acute inflammation of the lung parenchyma, and can be caused by viruses or bacteria. Clinically, it is often defined as a lower respiratory tract infection, associated with fever, respiratory symptoms, and evidence of lung parenchyma involvement, either by physical examination or chest radiograph findings. *S. pneumoniae* is the most common bacterial pathogen of community-acquired pneumonia; *H. influenzae* and *S. aureus* are less common causes. Viral pathogens are also a common cause of pneumonia in young children; it can be difficult to discern which pathogen is causing the clinical symptoms. Atypical pathogens, such as *M. pneumoniae*, are a common cause of pneumonia in school-aged children (Table 3.12). Children with immunodeficiency, sickle cell disease, cystic fibrosis, or HIV may present with more atypical pathogens.

Patients will often begin with an upper respiratory infection with rhinitis and cough (see Chapter 2). They then develop tachypnea and fever and then may develop respiratory distress with subcostal, intercostal, and suprasternal retractions, nasal flaring and use of accessory muscles, and hypoxia. Tachypnea and worsening cough are commonly noted. Patients with lower lobe pneumonias may also present with abdominal pain. Early in the course of illness, crackles, rhonchi, and wheezing are common findings. Later in the course of illness, as lungs consolidate and/or pleural effusions or empyema develop, decreased breath sounds and dullness to percussion may develop. Wheezing is more likely in viral or atypical pneumonia; however, unilateral wheezing may also correlate with a bacterial lobar pneumonia.

TABLE 3.12 Etiologic Agents of Pneumonia Grouped by Age of the Patient

Age Group	Frequent Pathogens (in Order of Frequency)
Neonates (<3 wk)	Group B streptococcus, *Escherichia coli,* other gram-negative bacilli, *Streptococcus pneumoniae, Haemophilus influenzae* (type b,* nontypable), herpes simplex
3 wk-3 mo	Respiratory syncytial virus, other respiratory viruses (rhinoviruses, parainfluenza viruses, influenza viruses, adenovirus), *S. pneumoniae, H. influenzae* (type b,* nontypable); if patient is afebrile, consider *Chlamydia trachomatis*
4 mo-4 yr	Respiratory syncytial virus, other respiratory viruses (rhinoviruses, parainfluenza viruses, influenza viruses, adenovirus), *S. pneumoniae, H. influenzae* (type b,* nontypable), *Mycoplasma pneumoniae,* group A streptococcus
≥5 yr	*M. pneumoniae, S. pneumoniae, Chlamydophila pneumoniae, H. influenzae* (type b,* nontypable), influenza viruses, adenovirus, other respiratory viruses, *Legionella pneumophila*

*__H. influenzae__ type b is uncommon with routine *H. influenzae* immunization.
From Kelly MS, Sandora TJ. Community acquired pneumonia. In: Kliegman RM, Stanton BF, St. Geme JW, Schor NF, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016:2090

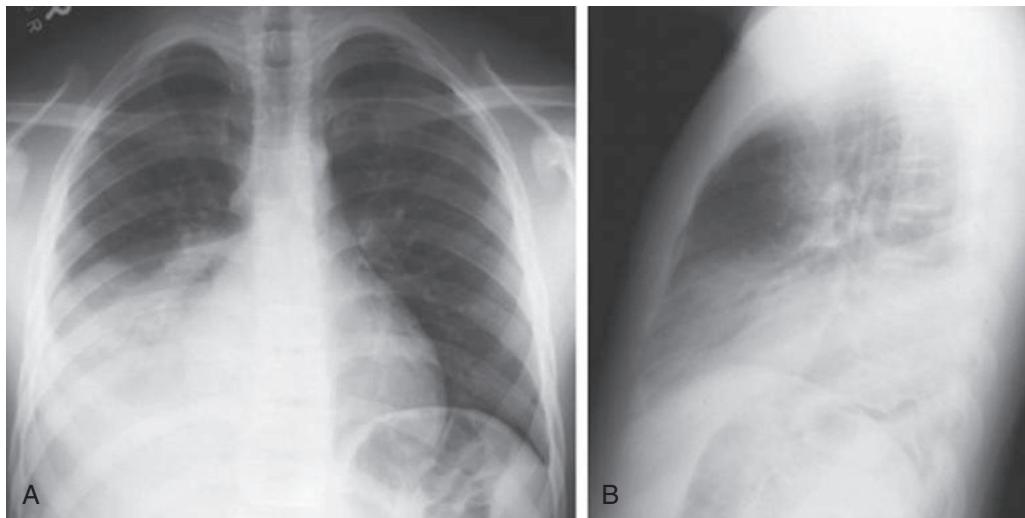
Diagnosis is made by chest radiograph, which will show a consolidation, and may show empyema or pleural effusion if present (Fig. 3.11). However, it is important to note that in children with mild lower respiratory tract disease with clinical symptoms consistent with pneumonia, a chest radiograph is not needed to make a diagnosis. Patchy infiltrates are most suggestive of atypical or viral


FIGURE 3.11 Radiographic findings characteristic of pneumococcal pneumonia in a 14-year-old boy with cough and fever. Posteroanterior *(A)* and lateral *(B)* chest radiographs reveal consolidation in the right lower lobe, strongly suggesting bacterial lobar pneumonia. (From Kelly MS, Sandora TJ: Community acquired pneumonia. In: Kliegman RM, Stanton BF, St. Geme JW, Schor NF, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016:2092, Figure 400-3.)

pneumonia. A lobar consolidation or large pleural effusion is likely from a bacterial etiology. Laboratory testing may be helpful in patients with more severe disease, but is not necessary in all patients. Peripheral white blood cell (WBC) count and acute phase reactants are likely elevated, and can be used to follow response to therapy along with clinical response. Blood cultures should be obtained for patients with moderate to severe disease, or who fail to demonstrate improvement after the initiation of antibiotics. Viral or atypical pathogen testing may be helpful as this may decrease need for additional testing or antibiotic use.

Treatment for bacterial pneumonia is antibiotics directed at suspected cause of pneumonia and supplemental care (oxygen, intravenous fluids) as indicated based on patient's clinical presentation. Hospitalization may be required for patients with hypoxia or toxic appearance, moderate to severe respiratory distress, age <6 months, or if there are concerns about observation or compliance with therapy at home. Those with complicated pneumonia (pleural effusion, empyema, abscess, or extrapulmonary infection) or suspected/documented pathogen with increased virulence are also likely to require hospitalization and further interventions.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, results from the inhalation of organic dust particles. Although numerous causes have been identified, the clinical features of the various types of hypersensitivity pneumonitis are similar and depend on the intensity and frequency of exposure to the allergen; both acute and chronic forms have been described.

In the acute form of the disease, the patient typically has fever, rigors, cough, and dyspnea several hours after exposure. The symptoms usually resolve within 24 hours of the onset once the offending material is removed. In the chronic or subacute forms of hypersensitivity pneumonitis, the affected individual may have exercise intolerance, anorexia, weight loss, and a productive cough. Diffuse crackles are the prominent finding on physical examination; the patient may be cyanotic if gas exchange is significantly impaired. Digital clubbing is an unusual finding. In acute cases, inflammation of the alveoli and pulmonary interstitium are common reactions, whereas the chronic form can result in interstitial fibrosis and noncaseating granulomas. Chronic hypersensitivity pneumonitis can insidiously lead to respiratory failure and cor pulmonale.

A number of laboratory studies may be helpful in confirming the diagnosis of hypersensitivity pneumonitis. Chest radiograph demonstrates diffuse reticulonodular infiltrate. Pulmonary function studies (spirometry) characteristically show a restrictive defect, and the carbon monoxide diffusion capacity is reduced. During the acute phase of the disease, the patient may have a peripheral leukocytosis and eosinophilia. Serologic studies looking for precipitating immunoglobulin G antibodies to specific antigens are useful in identifying the offending agent. However, these antibodies may be found in asymptomatic individuals exposed to the allergen, and thus their presence is not necessarily correlated with severity of pulmonary disease. Percutaneous or intradermal tests may also be useful, particularly if an avian hypersensitivity pneumonitis is suspected.

Removal of the specific organic dust from the patient's environment is critical to treatment. Mild episodes of hypersensitivity pneumonitis may resolve spontaneously once the offending allergen is eliminated. Severe exacerbations often necessitate treatment with systemic corticosteroids; bronchodilators may be beneficial if the patient is experiencing symptoms of bronchospasm. Hypersensitivity pneumonitis must be differentiated from other causes of interstitial or diffuse lung disease (Table 3.13).

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) is an immunologic disorder identified in patients with chronic lung disease, in which airway colonization (but not invasive infection) with *Aspergillus fumigatus* causes chronic antigen exposure and increased bronchial hyperactivity. This condition can lead to bronchiectasis, pulmonary fibrosis, and progressive respiratory insufficiency. Hypersensitivity to other fungal species that produces a clinical picture similar to that of ABPA has been reported.

It is important that the diagnosis of ABPA be made and that appropriate therapy with systemic corticosteroids be instituted, because this condition can result in irreversible lung damage. ABPA is characterized by fever, weight loss, wheezing, and productive cough yielding

TABLE 3.13 Classification of Interstitial Lung Disease (Pediatric Diffuse Lung Disease)*	

I. Disorders More Prevalent in Infancy
A. Diffuse developmental disorders
    1. Acinar dysplasia
    2. Congenital alveolar dysplasia
    3. Alveolar–capillary dysplasia with pulmonary vein misalignment
B. Growth abnormalities
    1. Pulmonary hypoplasia
    2. Chronic neonatal lung disease
C. Prematurity-related chronic lung disease (bronchopulmonary dysplasia)
D. Acquired chronic lung disease in term infants
E. Structural pulmonary changes with chromosomal abnormalities
    1. Trisomy 21
F. Others
    1. Associated with congenital heart disease in chromosomally normal children
G. Specific conditions of undefined etiology
    1. Pulmonary interstitial glycogenosis
    2. Neuroendocrine cell hyperplasia of infancy
H. Surfactant dysfunction mutations and related disorders
    1. *SPFTB* genetic mutations—PAP and variant dominant histologic pattern
    2. *SPFTC* genetic mutations—CPI dominant histologic pattern; also DIP and NSIP
    3. *ABCA3* genetic mutations—PAP variant dominant pattern; also CPI, DIP, NSIP
    4. Others with histology consistent with surfactant dysfunction disorder without a yet recognized genetic disorder
	II. Disorders Not Specific to Infancy
	A. Disorders of the normal host
	    1. Infectious and postinfectious processes
	    2. Disorders related to environmental agents: hypersensitivity pneumonia, toxic inhalation.
	    3. Aspiration syndromes
	    4. Eosinophilic pneumonia
	B. Disorders related to systemic disease processes
	    1. Immune-related disorders
	    2. Storage disease
	    3. Sarcoidosis
	    4. Langerhans cell histiocytosis
	    5. Malignant infiltrates
	C. Disorders of the immunocompromised host
	    1. Opportunistic infection
	    2. Disorders related to therapeutic intervention
	    3. Disorders related to transplantation and rejection syndromes
	    4. Diffuse alveolar damage of unknown etiology
	D. Disorders masquerading as interstitial disease
	    1. Arterial hypertensive vasculopathy
	    2. Congestive vasculopathy, including venoocclusive disease
	    3. Lymphatic disorders
	    4. Congestive changes related to cardiac dysfunction
	
	III. Unclassified
	A. Includes end-stage disease, nondiagnostic biopsies, and those with inadequate material

*Many of these entities may present as child interstitial lung disease syndromes.
CPI, chronic pneumonitis of infancy; DIP, desquamative cell interstitial pneumonia; NSIP, nonspecific interstitial pneumonia; PAP, pulmonary alveolar proteinosis.
From Kurland G, Deterding RR, Hagood JS, et al. An official American Thoracic Society clinical practice guideline: classification, evaluation, and management of childhood interstitial lung disease in infancy. *Am J Resp Crit Care Med.* 2013;188:376-394.

purulent or rust-colored sputum. This condition should be considered in patients with chronic or atypical and progressive or frequently relapsing lung diseases, such as asthma or cystic fibrosis, who have undergone clinical deterioration. In developing countries it is often misdiagnosed as pulmonary tuberculosis. ABPA is associated with peripheral eosinophilia and markedly elevated serum IgE levels. Although these laboratory findings are not pathognomonic for this condition, the presence of a normal serum IgE makes the diagnosis of active disease unlikely. Affected individuals have evidence of hypersensitivity to *Aspergillus fumigatus*, and sputum evaluation may demonstrate Aspergillus hyphal elements. Elevated levels of specific IgE and immunoglobulin G antibodies to *Aspergillus fumigatus* can be useful in establishing the diagnosis.

The typical chest radiographic findings include increased bronchopulmonary markings, opacification of the affected area, and localized pulmonary consolidation. Linear radiolucencies and parallel markings radiating from the hilum ("tram lines") caused by dilated, thickened bronchi may also be present. Chest CT may demonstrate bronchiectasis, mucoid impaction, and pleuropulmonary fibrosis. The treatment of choice is systemic corticosteroids, administered for weeks to months. Antifungal agents, such as itraconazole, may be effective in preventing exacerbations, but are not helpful in treating acute exacerbations; therefore these may be a helpful adjunctive therapy.

Other Causes of Respiratory Distress
Aspiration of Oropharyngeal Contents
Central nervous system or neuromuscular disease in infants and children can result in dysfunction of the swallowing mechanism, leading to repeated episodes of pulmonary aspiration. Aspiration is the most common cause of respiratory distress in such children and typically manifests with intractable wheezing, chronic airway inflammation, and recurrent pneumonias.

Video fluoroscopic swallow studies, in which barium-laced foods of a variety of textures and consistencies are fed to a child under direct visualization and fluoroscopy, can be useful in making the diagnosis and establishing that the child has an abnormal swallowing mechanism. These studies can be helpful with regard to therapy and may determine the appropriate feeding techniques, food consistencies, and feeding volumes that are less likely to cause aspiration in a vulnerable child.

Nasogastric tube or gastrostomy tube feedings may be necessary in children who do not respond to conservative management and who continue to have repeated episodes of aspiration. Nevertheless, the affected child can continue to have periodic aspiration of oropharyngeal secretions despite these interventions. A Nissan fundoplication or jejunostomy tube may be needed to reduce the incidence of gastric aspiration.

Gastroesophageal Reflux

Gastroesophageal reflux can be a primary cause of or an exacerbating factor in wheezing in infants and young children (see Chapter 12). Direct inhalation of stomach contents into the lungs can produce bronchospasm and a chemical pneumonitis. Gastroesophageal reflux with aspiration has also been implicated in cases of bacterial pneumonia, bronchiectasis, obliterative bronchiolitis, and lung abscesses. Tachypnea, wheezing, and cough are the usual clinical findings, typically occurring within 1 hour of the aspiration event. The signs and symptoms of the pneumonitis, however, can be delayed.

Although pulmonary aspiration of gastric contents was once assumed to be the basis of reflux-induced wheezing, reflex bronchoconstriction in response to esophageal acidification can also produce bronchospasm in some patients. Other respiratory symptoms associated with gastroesophageal reflux, such as stridor and obstructive apnea, can manifest as the result of reflex laryngospasm. Gastroesophageal reflux can also complicate and worsen underlying lung diseases, such as asthma or subglottic stenosis, by provoking bronchospasm and potentiating airway or laryngeal inflammation and possibly bronchial hyperactivity.

Pneumothorax

A pneumothorax occurs when air leaks from the alveoli or airways into the pleural space. The most common cause of pneumothorax in children is chest wall trauma. Children with asthma or other underlying chest disease may also develop a pneumothorax. However, spontaneous pneumothorax can occur in otherwise healthy children with no antecedent illness or injury, most commonly adolescent boys or young adult men who are tall, thin, and athletic. In patients with an acute pneumothorax with no history of trauma or asthma, the presence of Marfan syndrome should be considered. Clinical presentation usually includes acute onset of dyspnea and chest or shoulder pain. The physical examination reveals hyperresonance to percussion over the ipsilateral chest, with decreased breath sounds auscultated on the affected side. If the air dissects up through the mediastinum, it may escape into the subcutaneous tissues, producing subcutaneous emphysema. Diagnosis can be confirmed by chest radiograph. Progressive air leak without air escape can lead to a tension pneumothorax. With increasing pressure, there is mediastinal shift, airway compression, and a decrease in cardiac output. Tension pneumothorax can be life-threatening if it is not recognized and treated rapidly. Small, spontaneous pneumothoraces will often resolve with supportive care and supplemental oxygen. The treatment of choice for a pneumothorax of greater than 20% volume is drainage with needle aspiration or with an indwelling chest tube.

Cystic Fibrosis

Cystic fibrosis is a multisystem disorder that involves the eccrine and mucous secretory glands. Inherited as an autosomal recessive trait, cystic fibrosis is the most common life-shortening genetic disease in white children and is an important cause of chronic suppurative lung disease (see Chapter 2). Chronic infection and inflammation lead to the weakening and destruction of the airway wall, which results in bronchiectasis, the abnormal dilatation of the subsegmental airways, and in pulmonary abscesses. The pulmonary deterioration characteristic of cystic fibrosis is rather insidious and is characterized by increasing airway obstruction over a period of years. However, some infants and children with cystic fibrosis can present in acute respiratory distress because of pneumonia, empyema, or pneumothorax.

Dyskinetic Cilia Syndrome

Dyskinetic (immotile) cilia syndrome, another progressive lung disease, occurs in approximately 1 in 16,000 children and is the result of ultrastructural abnormalities of the cilia (see Chapter 2). The absence of dynein arms (inner and outer) is the most common form of the syndrome, but other structural abnormalities can result in decreased or absent ciliary movement. Acquired ciliary dyskinesia may be caused by a number of different environmental and infectious agents and is usually a temporary condition. The abnormal mucociliary clearance of endobronchial secretions causes a chronic bronchitis. Wheezing is a common clinical manifestation resulting from the obstruction of the airways by mucus. Repeated or persistent severe upper respiratory tract infections, usually in the form of chronic pansinusitis or recurrent suppurative otitis media, are typical. Male sterility resulting from the impaired movement of spermatozoa is also present. Although Kartagener initially described several patients with *situs inversus totalis*, chronic sinusitis, and bronchiectasis, dextrocardia is present in only 50% of patients with this syndrome.

Arriving at a diagnosis necessitates a high index of suspicion and warrants pursuit in the child with recurrent wheezing, bronchitis, sinusitis, and otitis media. Findings on chest radiographs are generally nonspecific, and frequently demonstrate areas of pulmonary consolidation. Extensive atelectasis with significant respiratory distress has been described in neonates with this condition. Bronchiectasis is a late sequela of dyskinetic cilia syndrome. Functional assays for mucociliary clearance or examination of respiratory epithelial cells for ultrastructural ciliary defects with electron microscopy is necessary to establish a diagnosis.

NONPULMONARY CAUSES OF RESPIRATORY DISTRESS

Cardiac

Cardiac disease is an important and common nonpulmonary cause of respiratory distress. Increased work of breathing and respiratory distress most commonly occur in cardiac diseases caused by large left-to-right shunts, dysfunction of the systemic ventricle, and vascular lesions that obstruct the airway (see Chapter 8). Cardiac failure from any cause is often manifested as respiratory distress. Infants with congenital heart defects that produce a large left-to-right shunt that results in pulmonary vascular engorgement, edema formation, and reduced lung compliance demonstrate tachypnea, dyspnea, and grunting. Wheezing or "cardiac asthma" can occur when there is compression of intrathoracic airways by vascular engorgement and interstial edema. With most congenital heart defects with left-to-right shunts, an abnormal heart murmur and cardiomegaly are prominent clues to the diagnosis. Acute myocarditis, usually of viral etiology, can manifest with tachypnea, dyspnea, grunting, and diaphoresis. The physical examination reveals tachycardia and decreased heart sounds, and chest radiography shows a massively enlarged heart. Cardiomyopathy may be congenital, may have a metabolic or toxic cause, may be familial, or may be idiopathic. Other causes of cardiac failure, such as severe hypertension, renal failure, and severe anemia, should also be sought. Systemic ventricular failure caused by obstructing lesions, such as aortic stenosis, coarctation of the aorta, or mitral stenosis, also causes increased pulmonary vascular engorgement and edema, which results in the same symptoms as those for a large left-to-right shunt. Depending on the severity of the left ventricular outflow obstruction, systemic blood flow may be decreased, resulting in poor perfusion and metabolic acidosis. If blood flow into the systemic ventricle from the

pulmonary veins or left atrium is decreased or obstructed, as in total anomalous pulmonary venous return or mitral stenosis, then severe pulmonary edema, hypoxemia, and respiratory distress ensues. Many of these lesions manifest early in infancy. Tachypnea, wheezing, cyanosis, and metabolic acidosis are typical presenting signs. Accurate diagnosis depends on echocardiography; cardiac catheterization may be needed in complex cases.

Neurologic

Children with certain primary neurologic disorders, such as increased intracranial pressure or neuromyopathic weakness, may present in respiratory distress. Common symptoms include irregular respirations, hypoventilation, or hyperventilation. These symptoms, accompanied by an altered mental status, should prompt an evaluation of the central nervous system for problems such as meningitis, cerebritis or encephalitis, intracranial hemorrhage, mass lesion, or toxic ingestion.

Other

Metabolic derangement that results in acidosis can produce tachypnea and possible dyspnea. Common causes of acidosis include diabetic ketoacidosis, sepsis, and ingestions (such as aspirin). The presence of multisystem involvement in addition to respiratory distress should lead to arterial blood gas determination, urinalysis, and possibly a toxicology screen.

SUMMARY AND RED FLAGS

Respiratory distress may be a result of disorders of the extrathoracic or intrathoracic airways (intrinsic or extrinsic compression-obstruction), alveoli, pulmonary vasculature, pleural spaces, or thorax. The distress may be secondary to respiratory, cardiovascular, hematologic, or central nervous system diseases. The most important aspect of the evaluation of a child with respiratory distress is observation of the child's breathing pattern and a brief, directed history and physical examination. Once the cause is identified, treatment should be started quickly to avoid progression to respiratory failure.

Red flags for impending respiratory failure include sudden onset of distress (epiglottitis, foreign body aspiration), hemoptysis, severe retractions, lethargy, a sitting up–leaning forward posture, dysphagia, drooling, or aphonia. It is imperative to identify the symptoms of impending respiratory failure and not delay treatment with unnecessary clinical or radiologic studies. Epiglottitis should be recognized quickly, and treatment initiated promptly. It is also important not to miss a foreign body, which with time may produce chronic respiratory disease that is often confused with pneumonia or asthma.

Signs of a more chronic process include lack of resolution with normal therapy, chronicity of symptoms, positive family history, digital clubbing, weight loss, and/or failure to thrive. These signs should prompt further work-up and consultation with a pulmonary specialist as needed. Asthma will rarely cause digital clubbing, so its presence should raise concern for another primary lung disease process.

Earache

Brittany Player

INTRODUCTION

Earache (otalgia) is pain that arises from a pathologic process in the external, middle, or inner ear or that is referred to the ear from another structure. Acute otitis media (AOM) is the most common cause of otalgia in children (Tables 4.1 and 4.2). At least 80% of children will experience one or more episodes of AOM in the first three years of life. The second most common cause of ear pain is otitis externa, followed by dermatitis and infections of the pinna (see Table 4.1). Other causes of otalgia are rare (Table 4.3). A careful examination of the pinna, external auditory canal, and tympanic membrane can help the clinician identify most causes of ear pain. When the findings are normal, the clinician should consider referred pain (Table 4.4).

◆ History

Older, verbal children with ear pain are often able to localize and accurately describe their symptoms. Younger children often cannot localize their pain and may present with a variety of nonspecific symptoms, including fever, irritability, rhinorrhea from an associated upper respiratory tract illness (URI), and ear pulling. *Even though ear pulling is associated with ear pain, it is neither specific nor sensitive in the diagnosis of ear disease.* In addition, infants with AOM may occasionally be afebrile and present with various degrees of irritability, such as sleep disturbances and/or eating or drinking inadequately. The clinician should be highly suspicious of ear disease in infants during the first year of life or in any preschool child with fever, irritability, or a URI.

In taking a history from a child who presents with ear pain, the clinician must distinguish between true ear pain and the sensation of fullness and discomfort that children experience when they have an effusion or retracted tympanic membrane secondary to a dysfunctional eustachian tube. The clinician should review the child's history for factors placing the child at risk for infection such as craniofacial (cleft palate) abnormalities, immunodeficiencies, autoimmune disease, diabetes, previous ear infections, placement of tympanostomy tubes, and recent dental procedures, trauma, and air travel. Immunization status should also be reviewed. A careful review of systems should elicit associated fevers, sore throat, reflux symptoms, otorrhea, neurologic symptoms, and symptoms of sinusitis. Children with a middle ear effusion may have decreased hearing acuity.

Acute otitis media presents with abrupt onset of otalgia associated with middle ear fluid, signs and symptoms of inflammation, and local or systemic infection. Risk factors for AOM include a family or personal history of recurrent AOM, trisomy 21, household cigarette smoke exposure, lack of breastfeeding, lower socioeconomic status, male gender, cleft palate, immunodeficiency, and group daycare attendance or siblings in the household.

Children with **otitis externa** ("swimmer's ear") present with either ear pain, purulent otorrhea, or both. Manipulating the tragus and pinna causes extreme pain. On otoscopic exam, the external canal is erythematous and there is typically drainage. Relapsing polychondritis also involves swelling and redness of the pinna; this condition is usually bilateral and recurrent, and other cartilaginous structures are affected. With referred ear pain, such as from tooth decay or teething, there are often additional symptoms associated with the respective head and neck structures (see Table 4.4). Patients with ear pain secondary to maxillary sinusitis may also complain of headaches and purulent rhinorrhea.

◆ Physical Examination

In a child presenting with a chief complaint of ear pain, the general examination includes the temperature, the respiratory rate, and a determination of whether the infant or child has a toxic appearance. Then the clinician proceeds with the complete head, eyes, ears, nose, oral cavity, and throat examination and with an appropriately focused physical examination of other pertinent systems.

The examination of the ear begins with the less symptomatic ear. The clinician should inspect the pinna and adjacent tissues for dermatitis, redness, and edema. The pinna, including the cartilaginous portions, and the mastoid process are palpated for any tenderness. Erythema, swelling, and tenderness over the mastoid process suggest **mastoiditis**; whereas localization of these findings to the external auditory canal and the pinna suggests otitis externa. In both conditions, the swelling may be so severe that the pinna is laterally displaced. The opening of the external ear canal is also examined for the presence of discharge or exudate. Most disorders of the external ear can be detected through this examination (see Tables 4.1 and 4.3).

Otoscopy provides an opportunity to indirectly view the middle ear through the tympanic membrane. The middle ear is normally an air-filled cavity that transmits sound from the eardrum to the ossicle and then into the internal ear (Fig. 4.1). Otoscopy begins by properly positioning and, if necessary, restraining the patient. Both shoulders and hips need to be stabilized so that the patient cannot roll during the examination. Infants are best examined on an examining table in the prone position, with a parent or an attendant firmly holding the patient's shoulders, thus preventing the patient from moving. Toddlers should sit on a parent's lap, with the examiner sitting in a chair opposite them. The child is held against the parent's chest, with one of the parent's hands and arms holding the child's arms and the other around the child's head so that one ear is exposed. To avoid trauma with movement, the otoscope should be held in the examiner's hand making direct contact with the patient's head, allowing the otoscope to move with the head.

Cerumen (ear wax) is a waxy substance consisting of glandular discharge from cells in the outer external canal mixing with exfoliated epithelial cells. Cerumen can both obscure visualization of the eardrum leading to diagnostic errors and be a cause of otalgia if

TABLE 4.1   Differential Diagnoses of Painful External Ear and Auditory Canal Disorders

Disorder	Clinical Features
Acute otitis externa	Diffuse redness, swelling, and pain of the canal with greenish to whitish exudate; often very tender pinna
Malignant otitis externa	Rapidly progressive, severe swelling and redness of pinna; pinna may be laterally displaced
Dermatitis	
Eczema	History of atopy, presence of lesions elsewhere; lesions are scaly, red, pruritic, and weeping
Contact	History of cosmetic use or irritant exposure; lesions are scaly, red, pruritic, and weeping
Seborrhea	Scaly, red, papular dermatitis; scalp may have thick, yellow scales
Psoriasis	History or presence of psoriasis elsewhere; erythematous papules that coalesce into thick, white plaques
Cellulitis	Diffuse redness, tenderness, and swelling of the pinna
Furuncles	Red, tender papules in areas with hair follicles (distal third of the ear canal)
Infected periauricular cyst	Discrete, palpable lesions; history of previous swelling at same site; cellulitis may develop, obscuring cystic structure
Insect bites	History of exposure; lesions are red, tender papules
Herpes zoster	Painful, vesicular lesions in the ear canal and tympanic membrane in the distribution of cranial nerves V and VII
Perichondritis	Inflammation of the cartilage, usually secondary to cellulitis
Tumors	Palpable mass, destruction of surrounding structures
Foreign body	Foreign body may cause secondary trauma to the ear canal or become a nidus for an infection of the ear canal
Trauma	Bruising and swelling of external ear; there may be signs of basilar skull fracture (cerebrospinal fluid otorrhea, hemotympanum)

TABLE 4.2   Differential Diagnosis of Painful Middle Ear Disorders

Disorder	Clinical Features
Acute otitis media	Immobile tympanic membrane that may appear bulging, red, and/or opaque
Bullous myringitis	Hemorrhagic or serous bullae on the tympanic membrane; more severe pain than AOM
Mastoiditis	Tenderness and erythema over mastoid with periostitis process; no destruction of bone trabeculae
Acute mastoid osteitis	Destruction of bone trabeculae; tenderness and erythema over mastoid process coupled with outward displacement of pinna
Granulomatosis	Severe necrotizing vasculitis; ulcerative and destructive granulomatous lesions of upper and lower respiratory tract with polyangiitis
Histiocytosis	Pituitary dysfunction, exophthalmos, seborrheic dermatitis, and bone lesions; if bone lesions involve the ear, patient presents with mastoid tenderness and otorrhea

impaction occurs. To view the eardrum properly, the examiner should remove the wax by irrigating the ear canal gently with lukewarm water, lift the wax out with a blunt curette, or dissolve the wax by placing 1-2 drops of docusate sodium liquid in the canal for 10-15 minutes. Contraindications for irrigation or use of a cerumenolytic solution are the presence of a tympanostomy tube, a perforated tympanic membrane, or an organic foreign body (e.g., legumes swell in contact with fluids).

During the insertion of the speculum, the clinician should note any redness, edema, tenderness, exudate, furuncles, or vesicles that may be present in the external auditory canal. In some illnesses (otitis externa), the ear canal may be so edematous that the speculum cannot be inserted and the eardrum cannot be seen. In addition, in neonates and in some children with craniofacial anomalies such as trisomy 21, the

external canal may be so small that it precludes an accurate assessment of the tympanic membrane.

Pneumatic otoscopy allows evaluation of the tympanic membrane's mobility. Because it is more accurate than otoscopy alone in detecting middle ear effusion, pneumatic otoscopy should be part of every ear examination. In performing pneumatic otoscopy, the examiner should select a speculum that fits snugly in the external auditory canal. The examiner then partially depresses the rubber bulb of the pneumatic otoscope and inserts the otoscope into the ear canal (Fig. 4.2). Once the eardrum is seen, the examiner should observe the color, appearance, position, bony landmarks, and mobility of the tympanic membrane (Table 4.5, Fig. 4.3). If the eardrum is not perforated, the clinician observes its mobility by alternating positive and negative pressure by gently depressing and releasing the bulb of the pneumatic otoscope. Poor mobility of the eardrum may be secondary to middle ear effusion, a perforated tympanic membrane, or lack of an airtight seal (Fig. 4.4).

In neonates and young infants, the eardrum is less perpendicular to the observer, the bony landmarks are less distinct, and the eardrum is less mobile than in older infants and children. Failure to appreciate these normal otoscopic findings may lead to the overdiagnosis of middle ear effusion.

In the first few hours of AOM, the middle ear cavity may not yet be filled with fluid, and the mobility may be normal. By the time the patient is examined, the middle ear is usually filled with fluid, and the eardrum is opaque and bulging with decreased mobility (see Fig. 4.4). A reddened eardrum may indicate inflammation of the tympanic membrane (TM), but this physical finding is not specific because crying alone can induce diffuse redness of the eardrum. In addition, differentiation of color is highly variable among observers, which may in part result from the intensity and type of light source used in otoscopy.

In **otitis media with effusion (OME)**, also known as serous otitis media, the cardinal sign is decreased mobility of the eardrum. The eardrum may be opaque, but not bulging or grossly inflamed (Fig. 4.5; see Table 4.5). A challenge for the clinician is the child with symptoms consistent with AOM (ear pain) but with the physical findings of OME. In such cases, it is difficult to decide whether there is an acute infection

of the middle ear or whether it is OME with an illness at another site causing the symptoms.

When the external ear and tympanic membrane are normal in a child with an earache, the clinician must consider the possibility of referred pain (see Table 4.4). Innervation of the external and middle ear includes pain fibers of the trigeminal, glossopharyngeal, and vagus nerves and, to a lesser extent, the facial nerve and upper cervical nerves. The clinician should examine the neck, parotid gland, thyroid, mouth, tongue, teeth, temporomandibular joint, tonsils, and throat. In children, the cause of referred pain is usually infectious rather than noninfectious (e.g., a tumor).

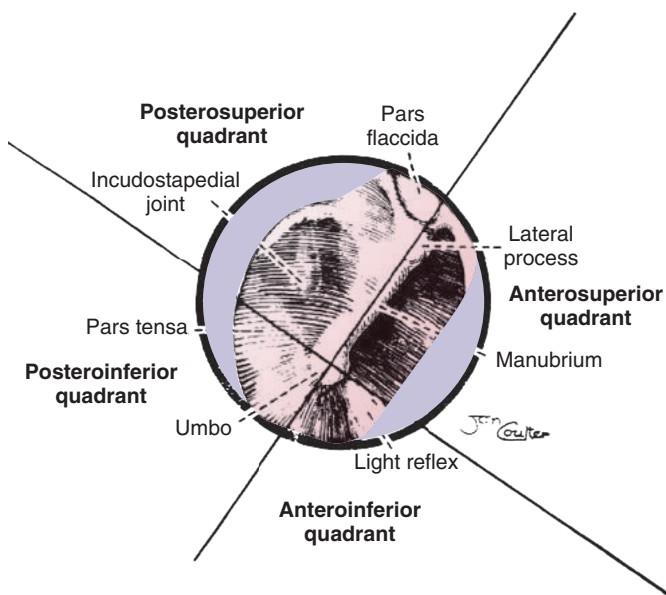
FIGURE 4.2 Technique for pneumatic otoscopy. (From Bluestone CD, Klein JO. *Otitis Media in Infants and Children.* 2nd ed. Philadelphia: WB Saunders; 1995:92.)

TABLE 4.5   The Tympanic Membrane in Acute Otitis Media and Otitis Media With Effusion

Characteristic	Normal Findings	Acute Otitis Media	Otitis Media With Effusion	Comments
Color	Gray to pink	Often red from inflammation; yellow to white from purulent fluid behind tympanic membrane	Usually gray to pink, but may still be yellow or white; not red	Interobserver variation of color is high; redness can occur from crying alone
Appearance	Translucent	Opaque	Translucent or opaque	Opacity is caused by opaque fluid or by scarring of tympanic membrane
Position	Neutral	Fluid under pressure produces bulging of tympanic membrane; bony landmarks may be distorted and the light reflex lost	Not bulging; may be retracted	
Mobility	Tympanic membrane moves freely	Mobility to positive and negative pressure reduced	Mobility to positive and negative pressure reduced	
Other findings		Perforation with otorrhea		

◆ Diagnostic Tests

Bacterial Cultures

Routine cultures of middle or external ear fluid are not required because most infections are self-limited and respond to empirical antimicrobial therapy. In selected instances (e.g., persistent treatment failure, severe pain, an immunocompromised host, a neonate), culture of otorrhea from the external auditory canal or cultures of middle ear fluid by tympanocentesis may guide therapy. In a child with AOM, the offending pathogen is usually present in the nasopharynx. Unfortunately, nasopharyngeal cultures are not helpful in directing therapy because multiple pathogens are present and it is unclear which organism is actually causing the middle ear infection. With the emergence of strains of *Streptococcus pneumoniae* that are resistant to commonly used antibacterials, the incidence of treatment failures may increase. This may necessitate a greater reliance on tympanocentesis for culture of middle ear fluid to determine the appropriate antimicrobial agent.


Tympanometry

Tympanometry is an objective, painless method for detecting the presence of middle ear effusion by providing information about tympanic membrane compliance. A soft plastic probe is inserted into the external auditory canal in order to obtain an airtight seal. The tympanometer measures the flow of sound energy into the middle ear under conditions of changing air pressure. When the air pressure is equal on both sides of an intact eardrum, with the drum in neutral position, the transmission of sound energy through the tympanic membrane is at its maximum. The peak on the tympanogram represents the pressure at which the flow of sound energy is maximal. For example, in a normal air-filled middle ear cavity, the peak occurs at ambient atmospheric pressure (Fig. 4.6A). With eustachian tube dysfunction (a retracted eardrum but no middle ear effusion), the peak occurs in the negative pressure range on the recording (Fig. 4.6C). With middle ear effusion, the sound energy flow into the middle ear is reduced, which produces a flat tympanogram (Fig. 4.6B). A flat tympanogram may also result from cerumen, foreign body, or from occlusion of the opening of the probe by the wall of the external auditory canal. In a perforated eardrum, the sound energy is readily transmitted through the hole in the drum throughout the entire pressure range, resulting in a flat tympanogram.

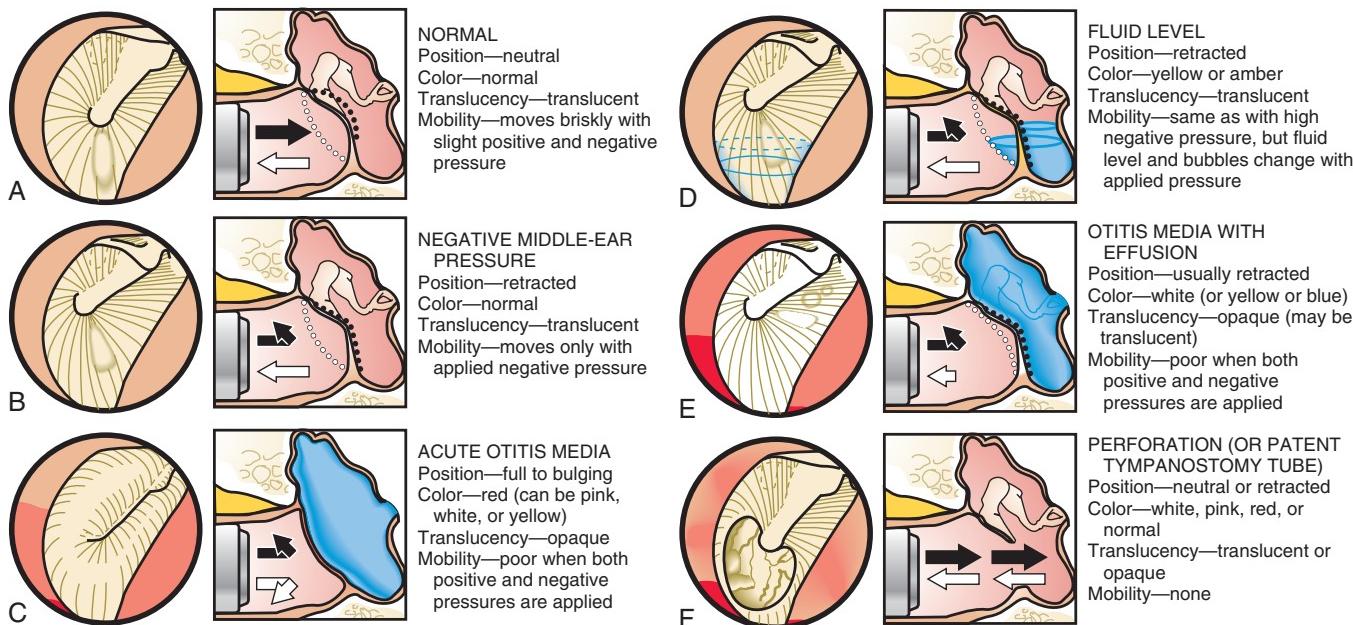
FIGURE 4.3 The four quadrants of a right tympanic membrane. (From Bluestone C, Klein J. Methods of examination: Clinical examination. In: Bluestone CD, Stool, SE, Kenna MA, eds. *Pediatric Otolaryngology*. 3rd ed. Vol 1. Philadelphia, WB Saunders; 1996:157.)


FIGURE 4.4A-F Common conditions of the middle ear, as assessed with the otoscope. (From Bluestone C, Klein J. *Otitis Media in Infants and Children.* 3rd ed. Philadelphia: Saunders; 2001:131.)

(See *Nelson Textbook of Pediatrics*, p. 3090.)

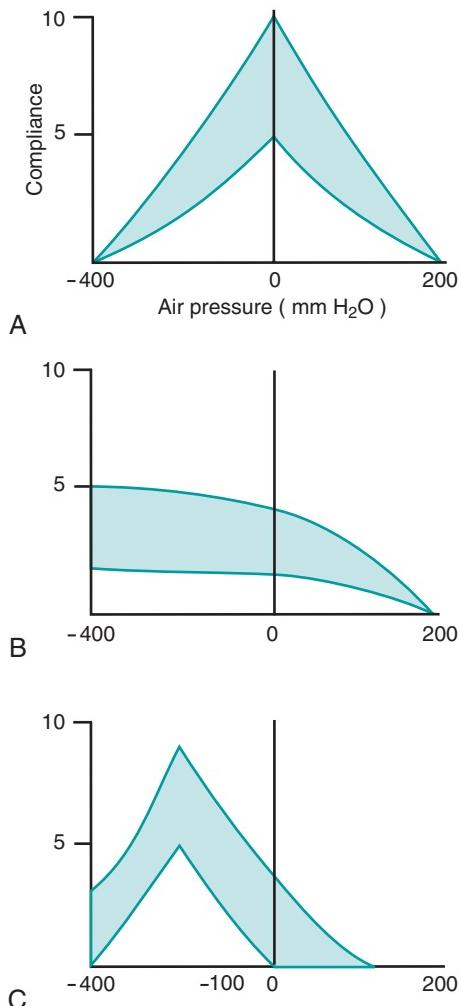
FIGURE 4.5 Tympanic membrane in otitis media with effusion. (From Kerschner J, Preciado D. Otitis media. In: Kliegman R, ed. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2015:3090.)


FIGURE 4.6 *A,* A normal tympanogram with a peak at atmospheric pressure, indicating an air-filled middle ear with normal (atmospheric) pressure. *B,* A "flat" tympanogram, indicating middle ear effusion. *C,* A tympanogram with a negative peak pressure, indicating eustachian tube obstruction.

The use of tympanometry can be limited by patient age and cooperation with testing, cerumen impaction, and the skill of the individual performing the testing. When performed by experts, tympanometry and pneumatic otoscopy have equivalent sensitivity (approximately 90%) and specificity (70%-80%). Tympanometry is neither more accurate nor more convenient than is properly performed pneumatic otoscopy. Some tympanometers do not perform well in infants younger than 6 months of age. Tympanometry is advantageous if the clinician is unsure of the otoscopic findings. *Tympanometry can only indicate middle ear effusion, but cannot distinguish between AOM and OME.*

Acoustic Reflectometry

Acoustic reflectometers are used to detect middle ear effusion. The device directs sonar-like sound waves of varying frequency toward the tympanic membrane and measures the intensity of reflected sound. This hand-held instrument is similar in size to an otoscope. The tip of the reflectometer is inserted into the ear canal. In contrast to tympanometry, an airtight seal is not required. The frequency of maximal reflected sound depends on the distance of the probe from the eardrum. Middle ear effusion is detected not by the frequency but by the magnitude of maximal reflected sound. When middle ear effusion is present, reflectance is increased in comparison with that in the air-filled middle ear.

Improvements in technology have been made such that reflectometry includes spectral gradient analysis. Reflectometry is easily learned, quick, convenient, and useful in a crying child. It has a lower sensitivity and specificity than properly performed pneumatic otoscopy in detecting middle ear effusion. Because the accuracy of current models decreases in infants younger than 1 year, this technique should not be used in infants younger than 6 months of age. Like tympanometry, reflectometry can reveal only whether middle ear effusion is present and cannot reveal whether the effusion is secondary to AOM or OME. Reflectometry is useful if otoscopic findings are indeterminate.

Diagnostic Imaging

Radiologic techniques are rarely required in the evaluation of external or middle ear disease, but they may be useful in the assessment of intratemporal and intracranial complications of otitis media. Opacification of the normally aerated mastoid air cells is usually seen in AOM because the mastoid air cells communicate with the middle ear space. By definition, this is acute mastoiditis; however, this opacification resolves concomitantly with the successful treatment of AOM. In contrast, in acute mastoid osteitis, also called acute coalescent mastoiditis, there is destruction of bone trabeculations in the mastoid air cells. Computerized tomography (CT) scan is the preferred imaging modality to aid in this diagnosis. Imaging studies can be useful in evaluating a patient for other intracranial complications of AOM. CT scans of the head can evaluate for suspected cholesteatomas. Magnetic resonance imaging should be used for diagnosing intracranial mass lesions (brain abscess) and soft tissue sequela of infection, while magnetic resonance venography would identify dural sinus thrombosis.

◆ Differential Diagnosis

Most disorders of the external and middle ear are readily apparent after the examination of the ear (see Tables 4.1 to 4.3). If examination findings are unremarkable, the clinician should consider referred pain (see Table 4.4). Most cases of otitis media are uncomplicated; however, the clinician should be alert to the complications and sequelae of AOM (Table 4.6).

TABLE 4.6 Manifestations of the Sequelae and Complications of Otitis Media

Complication	Clinical Features
Acute	
Perforation with otorrhea	Immobile tympanic membrane secondary to visible perforation, exudate in ear canal
Acute mastoiditis with periostitis	Tenderness and erythema over mastoid process, no destruction of bony trabeculae
Acute mastoid osteitis	Destruction of bony trabeculae; tenderness and erythema over mastoid process coupled with outward displacement of pinna
Petrositis	Infection of perilabyrinthine cells; may present with otitis, paralysis of lateral rectus, and ipsilateral orbital or facial pain (Gradenigo syndrome)
Facial nerve palsy	Peripheral cranial nerve VII paralysis
Labyrinthitis	Vertigo, fever, ear pain, nystagmus, hearing loss, tinnitus, nausea and vomiting
Lateral sinus thrombosis	Headache, fever, seizures, altered states of consciousness, septic emboli
Meningitis	Fever, headache, nuchal rigidity, seizures, altered states of consciousness
Extradural empyema	Fever, headache, seizures, altered states of consciousness
Subdural empyema	Fever, headache, seizures, altered states of consciousness
Brain abscess	Fever, headache, seizures, altered states of consciousness, focal neurologic examination
Nonacute	
Chronic perforation	Immobile tympanic membrane secondary to perforation
Otitis media with effusion (OME)	Immobile, opaque tympanic membrane
Adhesive otitis	Irreversible conductive hearing loss secondary to chronic OME
Tympanosclerosis	Thickened white plaques, may cause conductive hearing loss
Chronic suppurative otitis media	Following acute otitis media with perforation, secondary infection with *Staphylococcus aureus*, *Pseudomonas aeruginosa*, or anaerobes develops, causing chronic otorrhea
Cholesteatoma	White, pearl-like destructive tumor with otorrhea arising near or within tympanic membrane; may be secondary to chronic negative middle ear pressure
Otitic hydrocephalus	Increased intracranial pressure secondary to AOM; signs and symptoms include severe headaches, blurred vision, nausea, vomiting, papilledema, diplopia (abducens paralysis)

OTITIS EXTERNA

Otitis externa is an infection of the external ear canal. The external canal can become vulnerable to infection from excessive moisture from warm humid weather, moisture in the canal, or swimming. The moisture may cause small abrasions in the protective lipid layer of skin in the ear canal. These abrasions become infected on exposure to pathogenic bacteria. Dryness or presence of underlying skin conditions (such as eczema) and trauma (including cotton ear swabs) can also predispose the external canal to infection. Less commonly, otorrhea draining from a perforated tympanic membrane secondary to otitis media may cause otitis externa.

The presenting symptoms are often intense pain (especially with manipulation of the pinna, pressure on the tragus, or jaw movement), erythema, and otorrhea. On physical examination, the ear canal is red, edematous, and tender. Otorrhea may be present in the external canal. While otitis externa can occur at all ages, occurrence peaks between 7 and 12 years of age, with 10% of people having an episode in their lifetime. Otitis externa is rarely bilateral in nature.

Pseudomonas aeruginosa is the predominant organism causing otitis externa, but staphylococcal species (*Staphylococcus aureus* and coagulase-negative staphylococci) and streptococci have been isolated. Gram-negative organisms, such as *Enterobacter*, *Proteus*, and *Klebsiella* species, and fungal organisms, such as *Candida* and *Aspergillus* species, have also been isolated.

Treatment consists of a topical suspension, commonly ofloxacin or ciprofloxacin combined with hydrocortisone or dexamethasone. The addition of the topical steroid has shown improvement in pain relief. Most patients respond within a few days. If there is marked edema of the canal, antibacterials may not reach the site of infection. In this case, the canal should be cleaned with gentle suction, and a cotton wick should be inserted into the auditory canal. Antibacterial suspension is then dripped into the wick, which allows the medication to diffuse further into the ear canal. In some cases, daily cleaning and replacement of the wick are necessary. If the infection progresses, the patient may need parenteral antibacterials and consultation with an otolaryngologist.

Chondritis is a potential complication of severe otitis externa. It occurs when the infection progresses into the cartilaginous structures of the ear canal. This complication is rare without a history of previous trauma or surgery. The most common pathogens are *Pseudomonas* and *S. aureus*. Treatment requires systemic antibacterials and can require surgical debridement of tissue.

MALIGNANT OTITIS EXTERNA

Malignant otitis externa, also known as necrotizing otitis externa, is an extension of infection to the temporal bone and skull base causing extensive tissue destruction. The illness may result in chondritis and osteitis of both the middle and inner ears. This condition occurs

(See *Nelson Textbook of Pediatrics*, p. 3083.)

primarily in immunocompromised pediatric patients. In adults, diabetes mellitus is a common predisposing condition, though it is not a common comorbidity in children. Presenting symptoms include a markedly swollen and laterally displaced pinna associated with fever, malaise, and persistent, deep-seated otalgia out of proportion to findings on examination. Occasionally, facial nerve paralysis may be noted. Aggressive treatment with broad-spectrum parenteral antibiotics is indicated. *Pseudomonas aeruginosa* is the most commonly isolated pathogen, and coverage should include antibacterials directed against it. Surgical intervention may be necessary to obtain cultures for therapy guidance and provide local tissue debridement. This condition is rare in children.

ACUTE OTITIS MEDIA

Acute otitis media is most commonly a bacterial complication of a preceding or concurrent viral upper respiratory tract infection (URI), usually occurring several days after the onset of the URI. The viral infection enables pathogenic bacteria in the nasopharynx to ascend through the eustachian tube into the middle ear either by impairing local host defenses or by eustachian tube dysfunction. The bacterial pathogens then cause a secondary infection.

In 2013, the American Academy of Pediatrics (AAP) revised their guideline on the diagnosis of AOM. According to these guidelines, a diagnosis of AOM should be made in children presenting with:

- Moderate to severe bulging of the TM or new onset of otorrhea not due to acute otitis externa
- Mild bulging of the TM and recent (<48 hours) onset of significant TM erythema or ear pain (Fig. 4.7; see Table 4.5).

Bacteriology/Virology

The leading bacterial pathogens isolated from middle ear fluid in children with AOM are *Streptococcus pneumoniae,* nontypable *Haemophilus influenzae,* and *Moraxella catarrhalis. Staphylococcus aureus* and group A streptococci are uncommon pathogens, though *S. aureus* should be considered in patients with persistent otorrhea after tympanostomy tube placement. In the first month of life (especially the first

2 weeks), gram-negative enteric bacteria (e.g., *Escherichia coli, Klebsiella pneumoniae*) or group B streptococcus may also be isolated. Otitis media with ipsilateral conjunctivitis is often caused by nontypable *H. influenzae.*

The pneumococcal conjugate vaccine (PCV) 7 was introduced in 2000, covering serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F of *S. pneumoniae.* Widespread use of this vaccine resulted in a 29% reduction in AOM caused by all pneumococcal strains in children prior to 24 months of age. There was also a reduction in tympanostomy tube placement. In the first few years following introduction of PCV7, a shift from *S. pneumoniae* to nontypable *H. influenzae* as the leading pathogen causing AOM was noted. Shortly thereafter, a shift to non-PCV7 *S. pneumoniae* isolates as the primary pathogen of AOM, including multiresistant serotype 19A, was noted. Licensing and widespread use of the PCV13 vaccination began in 2010 in the United States, adding coverage for an additional 6 serotypes of *S. pneumoniae* (serotypes included in the PCV7 vaccination plus serotypes 1, 3, 5, 6A, 7F, and 19A). Preliminary studies have demonstrated a significant decline in the number of primary office visits related to AOM with the widespread use of this vaccine.

Viruses also have an important etiologic role. It is not clear whether the virus alone or a combination of virus and bacteria are involved in the pathogenesis. Several studies have documented the presence of viruses (10%-44% with or without bacteria) in the middle ear fluid of children with otitis media. URIs secondary to respiratory syncytial virus, influenza, and adenovirus have been associated with 30%-40% of AOM cases in children attending daycare. To a lesser degree, URIs secondary to parainfluenza, rhinovirus, and enteroviruses have also been associated with AOM. Viruses enhance bacterial adherence and colonization in the nasopharynx, impair local host immune defenses, and cause eustachian tube dysfunction.

Strains of *S. pneumoniae* have emerged with altered penicillin-binding proteins on the bacterial cell wall, which makes them less susceptible to β-lactam drugs (penicillins and cephalosporins). In addition, because resistance genes are frequently linked, organisms with resistance to β-lactam drugs are more likely to be resistant to sulfa antibacterials and to the macrolide class. Nonetheless, high-dose amoxicillin remains the best oral antibiotic available for drug-resistant *S. pneumoniae.* Currently, approximately 40% of *H. influenzae* strains and nearly all strains of *M. catarrhalis* produce β-lactamase enzymes, which hydrolyze penicillins and some cephalosporins, making them resistant to β-lactamase–producing antibacterials. Use of β-lactamase inhibitors such as clavulanate can overcome this resistance.

◆ Treatment

The goals of treatment in AOM are to relieve discomfort and to prevent infectious complications (Fig. 4.8). Evaluating the treatment of otitis media is complicated by the high rate of spontaneous resolution of the infection. Studies have shown that in children with AOM, up to 19% with *S. pneumoniae* and 48% with *H. influenzae* cultured on initial tympanocentesis would be culture negative within 1 week without antibacterial therapy. Despite *M. catarrhalis* resistance to amoxicillin, approximately 75% of children infected with that organism demonstrated cure when treated with amoxicillin. The emergence of drug-resistant *S. pneumoniae* strains and concerns about treating a disease with a high rate of spontaneous resolution has led to change in the recommended treatment for otitis media (see Fig. 4.8).

Some authorities suggest withholding antibacterials in children with low risk for complications. In the Netherlands, antibacterial therapy is commonly delayed until 48-72 hours after the diagnosis, to determine whether there is spontaneous resolution of the infection. Notably, in countries in which conservative use of antibacterials is the

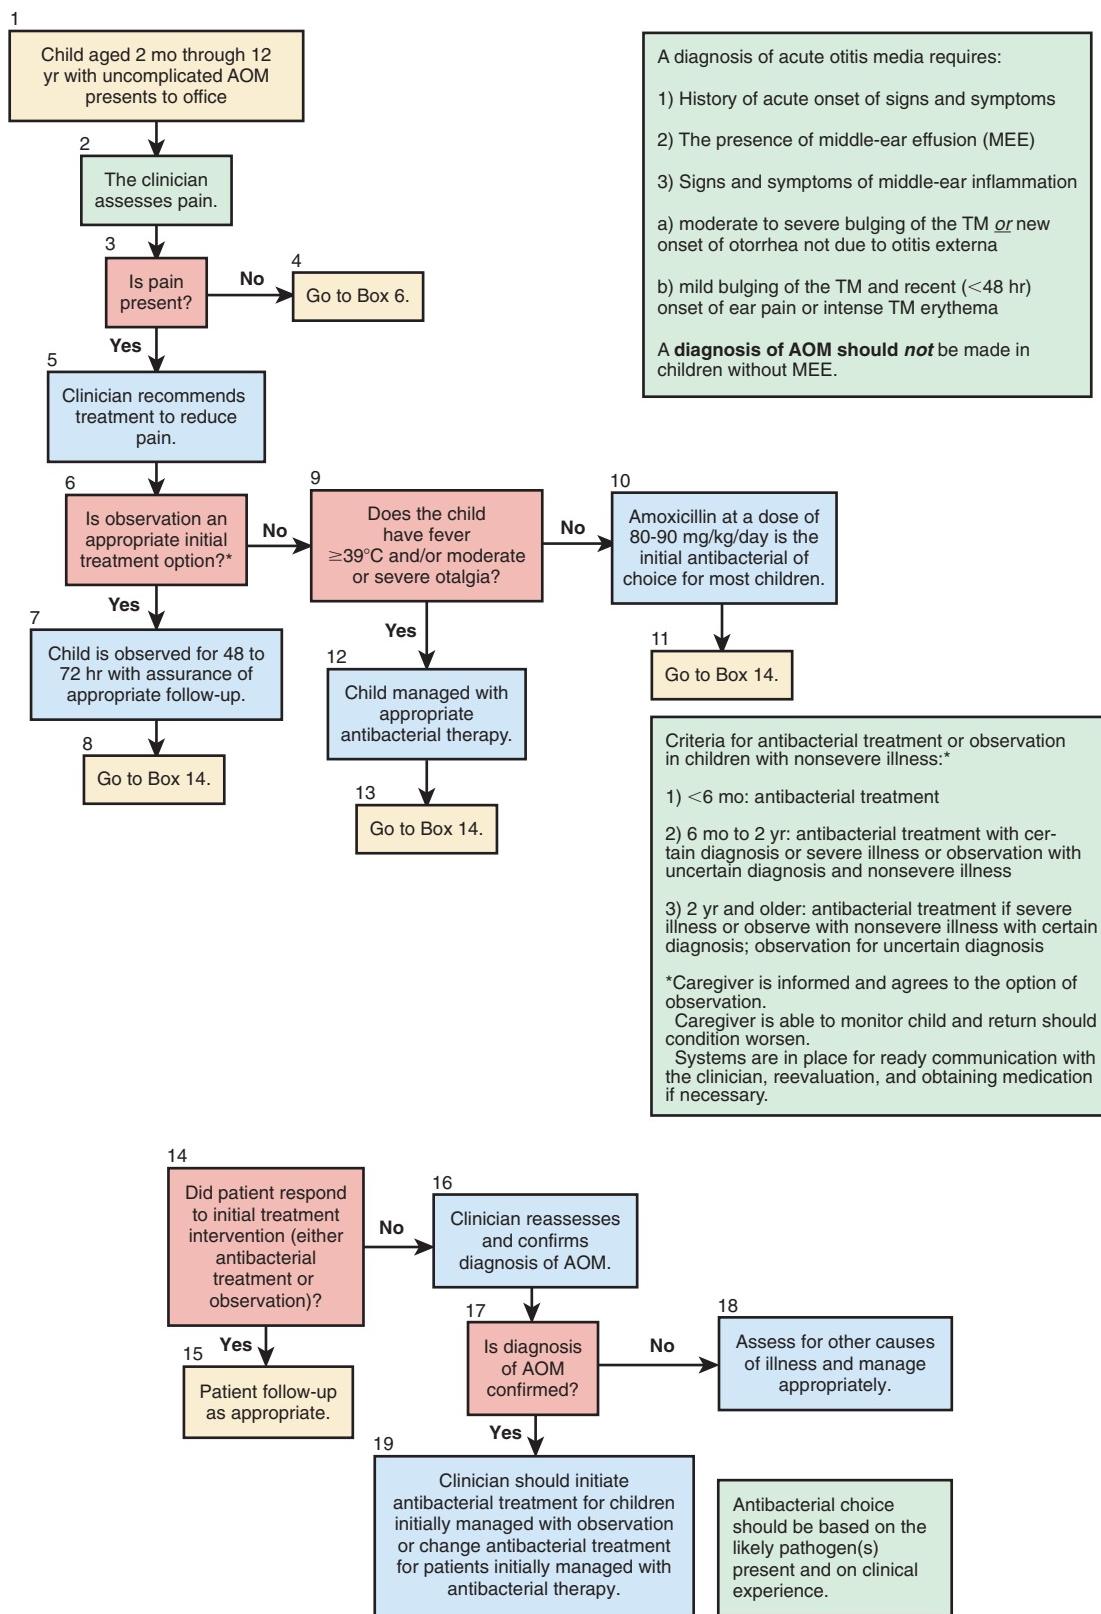
**FIGURE 4.7** Tympanic membrane in acute otitis media. (From Kerschner J, Preciado D. Otitis media. In: Kliegman R, ed. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2015:3089.)


FIGURE 4.8 Management of acute otitis media (AOM). TM, tympanic membrane. (From Kerschner J, Preciado D. Otitis media. In: Kliegman R, ed. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier. 2015: 3093.)

standard, such as the Netherlands and Denmark, rates of acute mastoiditis are slightly higher (1-2 episodes per 100,000 person-years) than in countries with higher rates of antibacterial use. With the 2013 AAP guidelines, the watchful waiting method has been recommended in certain populations of patients (Table 4.7). However, the key to observation prior to antibacterial initiation is close follow-up for assessment of worsening symptoms or spontaneous resolution. Additionally, adequate analgesia, including acetaminophen and/or ibuprofen, should be provided during the observation period. *While watchful waiting is appropriate for certain populations, the benefits of antibacterial treatment are most clearly seen in children younger than 2 years.*

When an antibacterial is used, efficacy against *S. pneumoniae* is the most important consideration. In addition, the clinician must consider the drug's safety, convenience, palatability, and the cost of therapy. High-dose amoxicillin (80-90 mg/kg/day given in two divided doses) is the appropriate initial therapy for most cases (Table 4.8). Because otitis media is usually a self-limited illness, the use of broad-spectrum antibacterials for the initial treatment should be discouraged because

TABLE 4.7　Recommendations for Initial Management for Uncomplicated Acute Otitis Media (AOM)*

Age	Otorrhea With AOM	Unilateral or Bilateral AOM With Severe Symptoms†	Bilateral AOM Without Otorrhea	Unilateral AOM Without Otorrhea
6 mo to 2 yr	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy or additional observation
≥2 yr	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy or additional observation	Antibiotic therapy or additional observation‡

*Applies only to children with well-documented AOM with high certainty of diagnosis (see Fig.4.8).
†A toxic-appearing child, persistent otalgia more than 48 hr, temperature ≥39°C (102.2°F) in the past 48 hr, or if there is uncertain access to follow-up after the visit.
‡This plan of initial management provides an opportunity for shared decision-making with the child's family for those categories appropriate for additional observation. If observation is offered, a mechanism must be in place to ensure follow-up and begin antibiotics if the child worsens or fails to improve within 48-72 hr of AOM onset.

TABLE 4.8　Recommended Antibacterials for (Initial or Delayed) Treatment and for Patients Who Have Failed Initial Antibacterial Treatment

INITIAL IMMEDIATE OR DELAYED ANTIBIOTIC TREATMENT		ANTIBIOTIC TREATMENT AFTER 48-72 hr OF FAILURE OF INITIAL ANTIBIOTIC TREATMENT	
Recommended First-Line Treatment	**Alternative Treatment (if Penicillin Allergy)†**	**Recommended First-Line Treatment**	**Alternative Treatment**
Amoxicillin (80-90 mg/kg per day in 2 divided doses)	Cefdinir (14 mg/kg per day in 1 or 2 doses)	Amoxicillin-clavulanate* (90 mg/kg per day of amoxicillin, with 6.4 mg/kg per day of clavulanate in 2 divided doses)	Ceftriaxone, 3 d, or Clindamycin (30-40 mg/kg per day in 3 divided doses), with or without second- or third-generation cephalosporin
or	Cefuroxime (30 mg/kg per day in 2 divided doses	or	Failure of second antibiotic
Amoxicillin-clavulanate* (90 mg/kg per day of amoxicillin, with 6.4 mg/kg per day of clavulanate [amoxicillin to clavulanate ratio, 14:1] in 2 divided doses)	Cefpodoxime (10 mg/kg per day in 2 divided doses)	Ceftriaxone (50 mg/kg per day IM or IV for 3 d)	Clindamycin (30-40 mg/kg per day in 3 divided doses) plus third-generation cephalosporin
	Ceftriaxone (50 mg/kg per day IM or IV for 1 to 3 d)		Tympanocentesis‡
			Consult specialist‡

Doses of antibiotics in this table are from the AAP Clinical Practice Guideline for the Diagnosis and Management of Acute Otitis Media.
*May be considered in patients who have received amoxicillin in the previous 30 days or who have the otitis-conjunctivitis syndrome.
†Cefdinir, cefuroxime, cefpodoxime, and ceftriaxone are highly unlikely to be associated with cross-reactivity with penicillin allergy on the basis of their distinct chemical structures.
‡Perform tympanocentesis/drainage if skilled in the procedure, or seek a consultation from an otolaryngologist for tympanocentesis/drainage. If the tympanocentesis reveals multidrug-resistant bacteria, seek an infectious disease specialist consultation.
IM, intramuscular; IV, intravenous.
From Lieberthal A, Carroll A, Chonmaitree T, et al. The diagnosis and management of acute otitis media. *Pediatrics*. 2014:133:347.

of their high cost, the increased risk of adverse reactions, and the increased likelihood of the development of resistant strains.

The dose of amoxicillin depends on the risk for the presence of drug-resistant pneumococci. Risk factors for drug resistance include age younger than 2 years, daycare attendance, recent antibacterial exposure, and cigarette smoke exposure. In addition, clinicians should consider resistance patterns within their own community. In penicillin-allergic patients, the cross-reactivity between penicillins and cephalosporins is likely lower than previously reported. Cephalosporins are therefore an alternative therapy option in patients without severe and/or recent allergic reaction to penicillins (see Table 4.8). Clindamycin is not effective against *H. influenzae*, but may be effective against some penicillin-resistant strains of *S. pneumoniae*. Macrolides (i.e., erythromycin, azithromycin) are minimally effective against *S. pneumoniae* or *H. influenzae* and therefore not appropriate alternatives.

Patients With Persistent Symptoms

After 48-72 hours of antibacterial therapy, most patients are either asymptomatic or experiencing improvement. Many patients may have an active viral infection; whereas others may have a persistent inflammatory reaction despite elimination of viable bacteria, both of which may be responsible for continued symptomatology. Studies are conflicting regarding continued presence of bacteria in the middle ear of persistently symptomatic patients. Some studies report continuous bacterial presence while others report sterile bacterial cultures of middle ear fluid in up to 50% of patients with persistent symptoms. Therefore, in children with mild persistent symptoms, a clinician should consider analgesic-antipyretic medications for relief of symptoms while addressing any issues of drug noncompliance, including palatability and dosing interval. In children with more severe, persistent signs of AOM without otologic improvement, a clinician should consider prescribing an alternative antibiotic effective against possible resistant *S. pneumoniae* and β-lactamase–producing *H. influenzae* and *M. catarrhalis*, such as amoxicillin-clavulanate (80-90 mg/kg/day of the amoxicillin component), cefuroxime axetil, or 3 days of intramuscular ceftriaxone (see Table 4.8). With the emergence of *S. pneumoniae* resistance, tympanocentesis with culture of middle ear effusion should be considered for bacteriologic diagnosis and susceptibility testing.

Recurrent Acute Otitis Media

Recurrent otitis media is defined as 3 episodes of AOM in a 6-month period or 4 episodes in a 12-month period with at least 1 episode in the preceding 6 months. Risk factors for recurrent AOM include:
- onset of AOM in the first year of life, especially if the first episode is before the patient is 6 months of age
- male gender
- a sibling's history of recurrent AOM
- cleft palate
- craniofacial anomalies
- trisomy 21
- daycare attendance
- household cigarette smoke exposure
- human immunodeficiency virus infection
- lack of breastfeeding
- history of atopy/allergies

Children with recurrent otitis media present a particular challenge with regard to treatment options. Long-term, low-dose antibacterial agents have been used as a method of prophylaxis in children with recurrent AOM in attempts to prevent additional episodes. While there is some evidence of decreased episodes of AOM, this only occurred while receiving the prophylactic antibacterial, without benefits after discontinuation of the antibacterial. Other studies have not demonstrated a difference in recurrence of AOM among children with or without prophylactic antibacterials. Given the risks of emergence of antibacterial resistance, side effects of antibacterials, and cost of therapy weighed against the questionable benefits of long-term antibacterial use, *prophylaxis is not recommended*.

The use of myringotomy and tympanostomy tube placement for the treatment of recurrent AOM or OME has remained controversial. While these procedures may decrease the number of episodes of acute otitis media and improve quality of life for children with recurrent AOM or OME, more stringent criteria are needed before determining the populations most likely to benefit. Additional considerations regarding cost of the procedure and the risks of surgery and anesthesia should be considered before recommendation for tympanostomy tube placement. Tympanostomy tubes are eventually extruded from the eardrum by the normal process of epithelial growth. Recurrent episodes of otitis media may then resume. Long-term consequences of tympanostomy tubes include focal atrophy, tympanosclerosis, and chronic perforation at the site of tube insertion.

OTITIS MEDIA WITH EFFUSION

Otitis media with effusion, also known as "glue ear," may occur after an acute episode of otitis media or because of eustachian tube obstruction resulting from another cause (most commonly, URI). OME differs from AOM in that there is middle ear effusion present without signs or symptoms of acute infection (Fig. 4.9). The most common presenting complaint with OME is decreased hearing. A middle ear fluid can persist for weeks after AOM. Two weeks after AOM, approximately 75% of children will have persistent effusion. The percentage drops to 50% at 1 month and 10%-25% at 3 months post-AOM. Because most cases of OME resolve without treatment, a period of observation is the most appropriate initial strategy. If effusion persists for 3 months or longer or any time language delay, learning difficulties, or significant hearing loss is suspected, hearing testing should be performed.

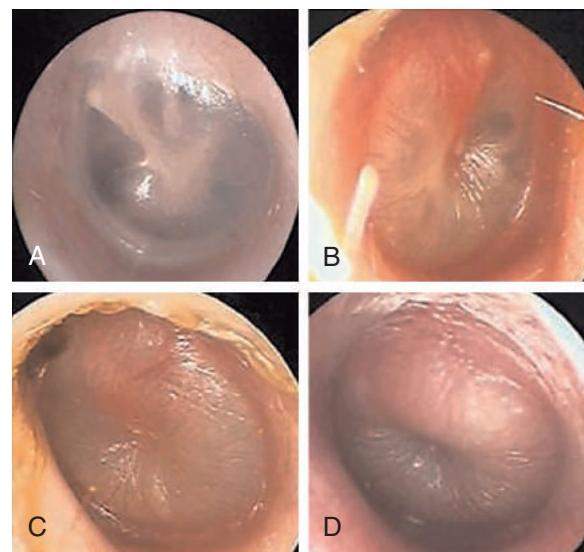

FIGURE 4.9 Examples of normal tympanic membrane *(A)* and of mild bulging *(B)*, moderate bulging *(C)*, and severe bulging *(D)* of the tympanic membrane from middle ear effusion. (From Kerschner J, Preciado D. Otitis media. In: Kliegman R, ed. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2015:3089.)

Medical therapy of OME has not been consistently successful. Antihistamines, decongestants, and nonsteroidal antiinflammatory agents do not promote the resolution of middle ear effusion and should not be used. With systemic corticosteroids (prednisone), the effusion may resolve initially, but it recurs within a few weeks of steroid discontinuation. Additionally, the side effect profile of systemic steroids precludes its use in children with OME. Although bacteria may be present in some cases, antibacterial therapy has only a minimal effect on the resolution of effusion and does not demonstrate long-term benefit. A period of observation for 4-6 months is recommended before surgical intervention is considered.

To assist the clinician in the diagnosis and management of OME, the American Academy of Pediatrics, American Academy of Family Physicians, and the American Academy of Otolaryngology-Head and Neck Surgery have developed a practice guideline for affected children between 2 months and 12 years. The guideline distinguishes between children with OME at risk for speech, language, or learning problems and children not at risk for such problems. The panel recommends documentation of laterality, duration, and severity of effusion with pneumatic otoscopy and confirmation of effusion by tympanometry when pneumatic otoscopy is inconclusive. The panel does not recommend decongestants, steroids, antihistamines, antibacterial agents, tonsillectomy alone, or adenoidectomy alone in the management of persistent OME. Based on the guidelines, the following children are candidates for surgical intervention:

- children with OME persisting for greater than 4 months with associated persistent hearing loss
- at-risk children with persistent OME regardless of hearing status
- children with structural damage to the middle ear or tympanic membrane secondary to OME

Tympanostomy tube placement is the recommended initial surgical intervention, with a mean 62% relative decrease in effusion and improvement in hearing loss by a mean of 6-12 dB. After tube extrusion, up to 50% of children will have a relapse of OME.

MASTOIDITIS

Mastoiditis is a potentially serious acute or chronic suppurative complication of otitis media. Life-threatening complications of mastoiditis are related to intracranial extension of the suppurative process.

Mastoiditis begins with the development of hyperemia and edema of the mastoid process. This progresses to a suppurative process that may produce demineralization and necrosis of bone, abscess formation, and contiguous spread to intracranial or other head and neck areas. Mastoiditis with periosteitis indicates that the infection has spread to the periosteum of the mastoid process and manifests most commonly in children younger than 2 years, although children of any age may be affected. Otalgia, posterior ear pain, fever, and otorrhea are frequent symptoms. Posterior auricular tenderness and erythema, anterior-inferior pinna protrusion, loss of the posterior auricular crease, middle ear effusion, a bulging or perforated tympanic membrane, and sagging of the posterior auditory canal wall are observable signs. Acute mastoid osteitis designates further spread of infection causing bony trabeculae destruction. Mastoiditis may result in transverse sinus thrombosis (Fig. 4.10).

Petrositis occurs when the infection spreads medially to the petrous portion of the temporal bone and often manifests as eye pain secondary to irritation of the ophthalmic branch of cranial nerve V (Fig. 4.11). **Gradenigo syndrome** is the triad of ipsilateral orbital or facial pain, paralysis of the lateral rectus muscle, and suppurative otitis media. Rarely, the infection can spread externally to musculature of the neck resulting in a neck abscess (**Bezold abscess**).

The pathogens responsible for mastoiditis are the same as those of AOM, including *S. pneumoniae* and *H. influenzae,* though *Pseudomonas* and group A streptococci are also causative agents. A CT scan is usually diagnostic and reveals various stages of mastoiditis:

- mastoiditis with periosteitis
- mastoiditis with osteitis with or without subperiosteal abscess

Treatment is based on the stage of the process. High-dose intravenous antibacterials plus tympanostomy and myringotomy with or without tympanostomy tube placement are important therapeutic (for drainage) and diagnostic (for culture) procedures. Mastoidectomy is usually indicated for severe osteitis, mastoid abscess formation, and all intracranial suppurative complications.

CHOLESTEATOMA

Cholesteatomas are cyst-like growths of the middle ear or mastoid formed by keratinizing squamous epithelial cells (Fig. 4.12). They can be either congenital or acquired. Congenital cholesteatomas likely result from epithelial cells implanted during otologic development in utero. Acquired cholesteatomas are potential complications from chronic otitis media or secondary to a deep retraction pocket (or invagination) in the tympanic membrane. The condition can also develop after tympanostomy tube placement with an incidence of 0.8%-1.4%. Cholesteatomas can cause bony resorption by expansion, often to the mastoid, but occasionally intracranially with potentially life-threatening consequences. This condition should be suspected in children with history of chronic OM, persistent otorrhea, and a tympanic membrane with a retraction pocket or perforation with white debris overlying the area. Cholesteatomas commonly present over the superior portion of the tympanic membrane. Urgent otolaryngology consultation should be obtained as delay in treatment can result in intracranial extension, permanent hearing loss, facial nerve injury, and middle and inner ear destruction.

INTRACRANIAL COMPLICATIONS

Meningitis, epidural empyema, brain abscess, and sigmoid sinus thrombosis can develop as complications of acute or chronic ear or mastoid infection. If suspected, imaging of the head should be done prior to lumbar puncture to evaluate for hydrocephalus or mass effect. Meningitis most commonly results from hematogenous spread of the infection and is diagnosed by cerebrospinal fluid (CSF) analysis and culture. Tympanocentesis should be performed for bacterial culture to aid in diagnosis and management choices. Brain abscess can occur from direct extension of an acute or chronic otitis media or can develop adjacent to petrositis (Fig. 4.13). Clinical signs and symptoms should lead one to suspect this complication, and diagnosis can be made with CT or MRI. CSF for culture should be obtained to aid in directing therapy; however, culture may be negative depending on the location and loculation of the abscess. Lateral sinus thrombosis, also known as sigmoid sinus thrombosis, forms when infection from the adjacent mastoid contacts and penetrates the venous wall and forms a thrombus. Embolization of the thrombus can cause distal disease. These intracranial complications require broad-spectrum antibacterials and consultation with otolaryngology and neurosurgery for possible surgical interventions.

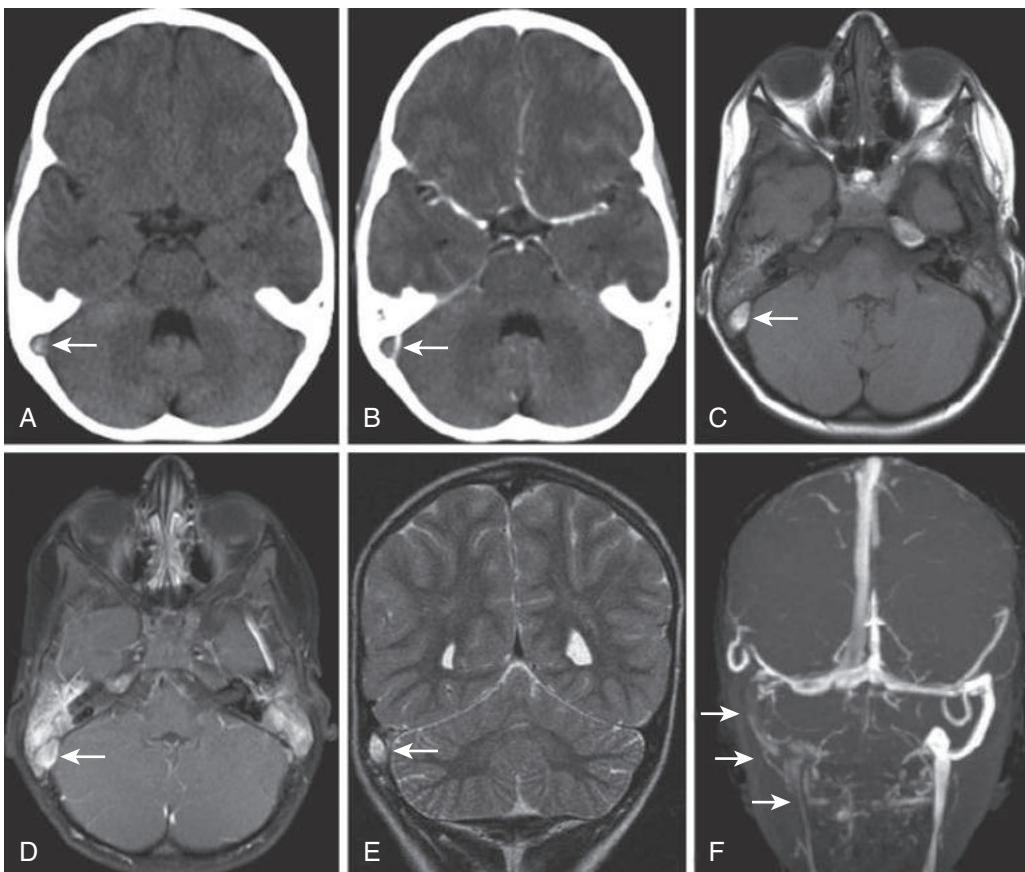
(See *Nelson Textbook of Pediatrics*, p. 3082.)


FIGURE 4.10 Transverse sinus thrombosis associated with otomastoiditis or middle ear disease. A patient with otitis media, headache, and papilledema. Axial noncontrast *(A)* and contrast-enhanced *(B)* computed tomography (CT) of the head through the level of the posterior fossa, axial magnetization transfer T1 precontrast *(C)* and postcontrast *(D)* magnetic resonance imaging scans, coronal T2 *(E)* and coronal multiple intensity projection image from a three-dimensional time-of-flight magnetic resonance venogram (MRV) *(F)* were obtained. Note the dense appearance within the right transverse sinus on the noncontrast CT study *(arrow* in *A)*, with corresponding lack of contrast filling on the postcontrast CT study *(arrow* in *B)*. Corresponding T1 shortening is seen in the precontrast magnetic resonance image *(arrow* in *C)*, with corresponding abnormal signal on the postcontrast images in keeping with clot or slow flow within the region of the right transverse sinus or sigmoid sinus *(arrow* in *D)*. Corresponding T2 prolongation is seen on the coronal T2 image *(arrow* in *E)*. Note the striking asymmetry of flow within the right posterior fossa dural venous system or internal jugular vein on the right on the three-dimensional time-of-flight MRV *(arrows* in *F)*. An effusion is present in the middle ear, and squamous debris emanates from the attic. (From Isaacson G. Diagnosis of pediatric cholesteatoma. *Pediatrics*. 2007;120:603-608.)
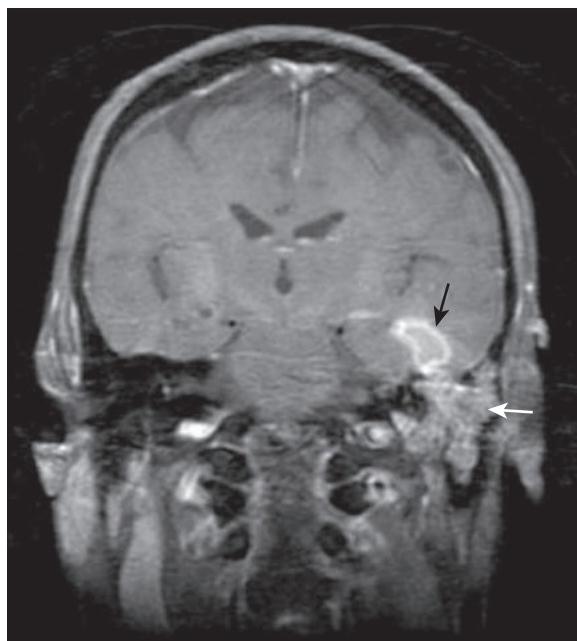

FIGURE 4.13 Coronal enhanced T1-weighted MRI of the patient showing enhancing tissue in left mastoid *(white arrow)* and temporal lobe abscess with enhancing capsule *(black arrow)*. (From Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology Head & Neck Surgery*. 5th ed. Vol 2. Philadelphia: Elsevier; 2010:1995.)

SUMMARY AND RED FLAGS

A careful examination of the pinna, external auditory canal, and tympanic membrane can identify most causes of ear pain. If findings are normal, the clinician should consider pain referred from another source (see Table 4.3). Because young children may have trouble localizing their pain, clinicians should be highly suspicious of ear disease in any infant or preschool child with fever, irritability, or URI.

Even though most conditions causing ear pain respond readily to therapy, the clinician must be aware of the following red flags associated with these conditions:

- laterally displaced pinna (malignant otitis externa, mastoid osteitis)
- mastoid tenderness (mastoid osteitis)
- perforated tympanic membrane
- a pearl-like tumor in the tympanic membrane (cholesteatoma)
- subacute headache, meningismus, and altered mental status (brain abscess, subdural or epidural empyema)

Apparent Life Threatening Event–Brief Resolved Unexplained Event

Amanda Rogers and Sandra Gage

Apparent life-threatening event (ALTE) is a term used to describe an acute, unexpected episode that consists of a change in an infant's breathing, appearance, or behavior. It is a clinical description, rather than a specific diagnosis, and represents a wide variety of presentations with diverse underlying pathology.

DEFINITION

The current definition of ALTE was established at the 1986 National Institutes of Health Consensus Development Conference on Infantile Apnea and Home Monitoring (Table 5.1). ALTE was defined as "an episode that is frightening to the observer, that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid, but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging."

The term ALTE was in part established to replace previously used labels, including "near-miss SIDS" or "aborted crib death," which inappropriately suggested a clear association between ALTEs and sudden infant death syndrome (SIDS). SIDS is defined as the sudden death of any infant or young child, which is unexplained by history and in which a thorough postmortem examination fails to demonstrate an adequate explanation of cause of death. Studies have failed to establish a clear association between ALTEs and SIDS. Although there are some overlapping risk factors between SIDS and ALTEs, they are separate entities. The vast majority of SIDS victims do not have a preceding ALTE. The American Academy of Pediatrics Task Force on SIDS is clear in its stance that there is no evidence that an ALTE is a precursor to SIDS.

The subjectivity and vagueness of the current definition has made it difficult to standardize the care of these patients. In 2016 the American Academy of Pediatrics (AAP) released a clinical practice guideline related to the care of these patients. This guideline includes a change in terminology to **BRUE (brief resolved unexplained event),** which is defined as an event lasting <1 min in an infant under one year of age that is associated with at least one of the following: cyanosis or pallor; absent, decreased, or irregular breathing; marked change in muscle tone (hypertonia or hypotonia); altered level of responsiveness in a patient who at the time of examination is otherwise well-appearing and back to baseline, and, on evaluation, has no condition that could explain the event. The guideline recommends limited interventions for patients designated as being at low risk for recurrence. Low-risk patients include those having their first event who are >60 days old, ≥32 weeks' gestational age, ≥45 weeks postconceptional age, had an event lasting <1 minute and did not require cardiopulmonary resuscitation, and who have no concerning historical or physical exam findings.

EPIDEMIOLOGY

The exact incidence of ALTEs is unknown because the definition of an ALTE is subjective, and not all children with ALTEs present for evaluation. Reported figures may underestimate the true incidence of patients presenting with ALTEs since studies may not include those cases where the underlying cause is ultimately identified. The incidence is estimated to be between 0.46 and 2.46 per 1000 live births, accounting for 0.6-1% of all emergency department visits by patients younger than 1 year and 2% of pediatric hospitalizations. Most occur in infants less than 1 year of age, with a peak incidence between 1 week and 3 months. Occurrence is equal between males and females. The mortality rates reported to be associated with ALTEs vary widely depending on the definition used and the population studied. Due to the diversity of the potential underlying etiology of an ALTE, clinicians should be cautious in the application of these rates to the ALTE population as a whole (Table 5.2).

ETIOLOGY

Because ALTE is a descriptive category based on broad symptomatology, the differential diagnosis is large. Comorbid conditions are frequently identified, but it can be challenging to identify true causation. Thus caution must be used in implicating a specific diagnosis as the true cause of an ALTE. A suspected diagnosis is found in approximately 50% of ALTEs. These diagnoses encompass a wide range of etiologies and systems.

The most commonly cited diagnoses include gastroesophageal reflux (GER), seizures, and lower respiratory tract infections. However, numerous less common but potentially dangerous and/or treatable conditions can also present as an ALTE (see Table 5.2). These need to be carefully considered in order to provide prompt life saving or outcome-altering treatment. A thorough and thoughtful history and physical examination is extremely important in the evaluation of a patient with an ALTE, as it provides essential clues to help narrow the differential. It is often helpful to consider the differential diagnosis by a systems-based approach, considering both common and rare but concerning diagnoses in each category. Key systems-based historical and physical examination findings may help discriminate among possible etiologies (Table 5.3).

CLINICAL EVALUATION

◆ History

The most important diagnostic tool in the evaluation of an ALTE is a thorough history elicited from the caretaker who observed the episode.

(See *Nelson Textbook of Pediatrics*, p. 2004.)

TABLE 5.1   Definitions from the 1986 National Institutes of Health Consensus Panel on Infantile Apnea and Home Monitoring

Apparent life-threatening event (ALTE)	An episode that is frightening to the observer and that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging
Apnea	Cessation of respiratory airflow which can be central (i.e., no respiratory effort), obstructive (usually due to upper airway obstruction), or mixed
Pathologic apnea	Apnea that is prolonged (20 sec) or associated with cyanosis; abrupt, marked pallor or hypotonia; or bradycardia
Periodic breathing	A breathing pattern in which there are three or more respiratory pauses of >3 sec in duration with <20 sec of respiration between pauses
Apnea of prematurity (AOP)	Periodic breathing with pathologic apnea in a premature infant that usually ceases by 37 wk of gestation but occasionally persists to several weeks past term
Apnea of infancy (AOI)	An unexplained episode of cessation of breathing for 20 sec or longer, or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, and/or marked hypotonia in infants who are >37 wk of gestational age at onset of pathologic apnea
Sudden infant death syndrome (SIDS)	The sudden death of any infant or young child, which is unexplained by history and in which a thorough postmortem examination fails to demonstrate an adequate explanation of cause of death

History taking should start with open-ended questions to obtain the story from the caretaker, followed by specific questions geared at characterizing certain key aspects of the episode. The history should focus on the activities and behaviors preceding the event, characteristics of the episode itself, interventions performed and their effect, and post–episode events and behavior. A comprehensive past medical history, social history, and family history should also be obtained for identifying clues that may aid in narrowing the focus of the investigation. Information essential to a complete history is outlined in Table 5.4. Key historical findings by system can be useful in narrowing the differential (see Table 5.3).

The patient's activities and behaviors immediately preceding the episode are important to consider and may provide clues to the diagnosis. Key associations include those with sleep, feeding, crying, cough, and emesis. The location and position of the child prior to the event should also be noted, such as placement in a car seat, on a soft or firm surface, prone or supine, and with or without surrounding blankets or pillows.

Key characteristics of the actual event include respiratory effort, color change, change in tone or movements, level of alertness at onset and during the episode, duration of the event, and associated symptoms such as choking or emesis. ALTEs often include alteration of respiration or perceived apnea. In these cases, the duration of respiratory cessation aids in the determination of true pathologic apnea. Apnea is defined as cessation in breathing that is prolonged (>20 sec) or associated with cyanosis, marked pallor or hypotonia, or bradycardia. The degree of respiratory effort noted assists in differentiating central versus obstructive processes. Central apnea with no respiratory effort may suggest underlying neurologic, cardiac, metabolic, or infectious causes, while obstructive processes include GER, respiratory tract infections, foreign body, suffocation, or airway anatomic anomalies. If there is color change, providers should note not only the color itself (pale, red, cyanotic) but also the location, such as central cyanosis versus flushing or acrocyanosis. The latter two may be consistent with normal changes in perfusion. It is important to determine if tone was increased or decreased. If abnormal movements were identified, it should be noted if the movements were generalized or localized to a certain part of the body. The ability to suppress any abnormal movements should be documented, as this makes conditions such as seizure less likely.

Any interventions performed, by whom, and the effects of the interventions are also important to document. The need for resuscitation, especially when performed by health care providers, has been associated with more severe and significant underlying etiologies. It can be beneficial to obtain a direct history from any emergency personnel who may have been involved with the case.

Postepisode behavior should be carefully documented. Level of alertness following the event and time until return to normal behavior are of particular importance.

Regarding past history, it is essential to note the birth history including gestational age, any prior similar episodes, preceding illnesses, and known medical conditions. Family history should also be obtained with a focus on the presence of ALTEs, SIDS, early deaths, metabolic, or neurologic disorders in first or second degree family members. Social factors to consider include a full list of caregivers, illness exposures, medications in the home, and exposure to smoke.

Three major factors suggestive of risk for future adverse events and/or a serious underlying diagnosis include prematurity, multiple ALTEs, and suspected child maltreatment. Prematurity is a frequently noted risk factor for an ALTE, perhaps due in part to the preterm infants' immature respiratory centers, arousal mechanisms, and airway reflexes. A history of multiple ALTEs raises the concern for serious underlying pathology and progression of future events. With a history of multiple events over days to months, the concern for child maltreatment, seizures, intracranial pathology, and inborn errors of metabolism increases. Multiple events occurring over the course of the day of presentation escalate concern for serious infections and child maltreatment. Clinical suspicion of child maltreatment also increases the likelihood of future adverse events. A history of resuscitation attempt, cyanosis, and more than one ALTE in 24 hours are independent risk factors for the need for subsequent intensive care.

◆ Physical Examination

One of the diagnostic challenges of the evaluation of a child with an ALTE is that in a majority of cases the infant is well-appearing after the event. Infants should undergo a complete head-to-toe examination fully unclothed, including vital signs with pulse oximetry, growth parameters with head circumference, and complete ear, nose, throat, cardiac, respiratory, abdominal, neurologic, musculoskeletal, and skin examinations.

TABLE 5.2 Conditions That Can Cause Apparent Life-Threatening Events or Sudden Unexpected Infant Death

Central Nervous System Arteriovenous malformation Subdural hematoma Seizures Congenital central hypoventilation* Neuromuscular disorders (Spinomuscular atrophy) Chiari crisis Leigh syndrome*	Hyperammonemias (urea cycle enzyme deficiencies)* Glutaric aciduria* Carnitine deficiency (systemic or secondary)* Glycogen storage disease type I* Maple syrup urine disease* Congenital lactic acidosis* Biotinidase deficiency*
Cardiac Subendocardial fibroelastosis* Aortic stenosis Anomalous coronary artery Myocarditis Cardiomyopathy* Arrhythmias (prolonged Q-T syndrome, Wolff-Parkinson-White syndrome, and congenital heart block)*	**Infection** Sepsis Meningitis Encephalitis Brain abscess Pyelonephritis Bronchiolitis (respiratory syncytial virus) Infant botulism Pertussis
Pulmonary Nasal obstruction Pulmonary hypertension Vocal cord paralysis Aspiration Laryngotracheal obstructive diseases	**Trauma** Child abuse* Accidental or intentional suffocation Physical trauma Factitious syndrome (formerly Munchausen syndrome) by proxy*
Gastrointestinal Diarrhea and/or dehydration Gastroesophageal reflux Volvulus	**Poisoning (Intentional or Unintentional)** Boric acid Carbon monoxide Salicylates Barbiturates
Endocrine–Metabolic Congenital adrenal hyperplasia* Malignant hyperpyrexia* Long- or medium-chain acyl coenzyme A deficiency*	Ipecac Cocaine Insulin Others

*May be seen with recurrences in siblings.

Modified from Hunt CE, Hauck FR. Sudden infant death syndrome. In: *Nelson Textbook of Pediatrics*, 20th ed. Philadelphia: Elsevier; 2016:1999.

Any abnormalities on the presenting examination may indicate various possible diagnoses and should prompt additional evaluation for the suggested etiology (see Table 5.3). Particular attention should be paid to the child's general appearance for any dysmorphic features which might suggest an underlying genetic or metabolic syndrome. Abnormal growth parameters may identify failure to thrive, which can be suggestive of pathologic reflux, cardiac disease, or metabolic disorders. Signs of trauma, including retinal hemorrhages, unexplained bruising, or evidence of oral pharyngeal trauma (torn frenulum) suggestive of child maltreatment should also be noted. Abnormality of the neurologic examination should be fully assessed, with concern for intracranial bleed or mass requiring prompt attention.

◆ Diagnostic Evaluation

In approximately 20% of patients with an ALTE, the history and physical examination alone yields the cause; in about 50% of patients, a likely diagnosis is suspected from the history and physical examination and is subsequently confirmed by diagnostic testing. Diagnostic testing alone yields an etiology in only about 15% of patients. When testing is performed, it is most successful when done in a focused and targeted manner geared toward diagnoses suggested by the history and physical examination.

In the patient presenting with an ALTE, it is often difficult to determine the degree to which diagnostic work-up is indicated, especially in well-appearing infants with a nonspecific history and physical examination. The most common laboratory tests performed include a complete blood count (CBC) and serum electrolytes, while the most common radiographic tests/procedures are chest radiograph and electrocardiogram (ECG). Although there are numerous evidence-based algorithms for the diagnostic evaluation of patients with an ALTE, there is no uniformly accepted approach that has been found to be beneficial in the evaluation of all patients.

Well-appearing patients after ALTE, who have reassuring histories and normal examination findings at the time of presentation, require careful follow-up and may not require admission or additional

TABLE 5.3	System-Based Approach to ALTEs/BRUEs			
Diagnostic Categories	Common and/or Concerning Causes to Consider	Suggestive Historical Findings	Suggestive Physical Examination Findings	Testing to Consider
Gastrointestinal	GER Intussusception Volvulus Swallowing abnormalities	Coughing, vomiting, choking, gasping Feeding difficulties Recent preceding feed Irritability following feeds Milk in mouth/nose Bilious emesis Pulling legs to chest Bloody/mucousy stool Lethargy following event	Gastric contents in the nose and mouth Abdominal distention Abdominal tenderness	Upper GI to assess for anatomic anomalies Swallow evaluation Abdominal ultrasound pH probe
Infectious	Upper and lower respiratory tract infection (RSV, pertussis, pneumonia) Bacteremia Meningitis Urinary tract infection	Preceding URI symptoms Multiple events on the day of presentation Sick exposures Foul-smelling urine	Fever/hypothermia Lethargy Ill appearance Coryza Cough Wheeze Tachypnea	NP swab for RSV, pertussis Chest radiograph CBC and Blood culture Cerebrospinal fluid analysis and culture Urinalysis and culture
Neurologic	Seizures Breath holding spells Congenital central hypoventilation syndrome Neuromuscular disorders Congenital malformations of the brain and brainstem Malignancy Intracranial hemorrhage	Multiple events Loss of consciousness Change in tone Abnormal muscular movements Eye deviation Preceding triggers	Papilledema Abnormal muscular movements Hypertonicity or flaccidity Abnormal reflexes Micro- or macrocephaly Dysmorphic features	EEG Neuroimaging
Respiratory/ENT	Apnea of prematurity Apnea of infancy Periodic breathing Airway anomaly Aspiration Foreign body Obstructive sleep apnea	Prematurity Foreign body Aspiration Noisy breathing	Wheezing Stridor Crackles Rhonchi Tachypnea	Chest radiograph Neck radiograph Laryngoscopy Bronchoscopy Esophagoscopy Polysomnography
Child maltreatment	Non-accidental head trauma Smothering Poisoning Factitious syndrome (formerly Munchausen syndrome) by proxy	Multiple events Unexplained vomiting or irritability Recurrent ALTEs Historical discrepancies Family history of unexplained death, SIDS, or ALTEs Single witness of event Delay in seeking care	Bruising (especially in a non-mobile child) Ear trauma, hemotympanum Acute abdomen Painful extremities Oral bleeding/trauma Frenulum tears Unexplained irritability Retinal hemorrhages Depressed mental status	Skeletal survey Computed tomography of the head Dilated funduscopic examination Toxicology screen
Cardiac	Dysrhythmia (prolonged QT syndrome, Wolff-Parkinson-White syndrome) Cardiomyopathy Congenital heart disease Myocarditis	Abrupt onset Feeding difficulties Failure to thrive Diaphoresis Prematurity	Abnormal heart rate/rhythm Murmur Decreased femoral pulses	4 extremity blood pressure Pre- and post-ductal oxygen saturation measurements ECG Echocardiogram Serum electrolytes, calcium, magnesium

evaluation. *However, any concerning historical or physical features require the need for further in-patient evaluation performed in a focused manner based on the clinical presentation and suspected diagnosis* (see Table 5.3).

DIFFERENTIAL DIAGNOSIS BY SYSTEM

Gastrointestinal

A variety of gastrointestinal (GI) etiologies can present as an ALTE, including GER, intussusception, and volvulus.

GER is one of the most commonly cited comorbid conditions in patients presenting with an ALTE. Some infants will present with overt symptoms such as coughing, choking, and laryngospasm following regurgitation. Others can present without visible regurgitation but rather with posturing including arching of the back, torsion of the neck, and lifting up of the chin. This phenomenon, known as **Sandifer syndrome**, can be frightening to the observer and is often confused with seizure activity. Historical findings that should raise the index of suspicion for GER include a history of frequent reflux, the ALTE being immediately preceded by a feeding, poor weight gain, irritability following a feed, or gastric contents noted in the infant's nose or mouth during the episode. However, one must be careful when attributing an ALTE to GER. Approximately 50% of all normal infants less than 3 months of age experience daily regurgitation, and temporal association does not necessarily equate with causation. Although GER may occasionally cause apneic episodes, it also occurs very commonly in most healthy infants without any sequelae. It is therefore important not to let a history of GER in an infant presenting with an ALTE preclude the consideration of other underlying causes.

Although less common, additional GI pathology that can present with an ALTE include conditions such as intussusception or volvulus. Patients who present with these conditions will typically have additional historical and examination findings to suggest their underlying etiology. Patients with intussusception can have sudden and severe abdominal pain, inconsolable crying, and drawing up of the legs to the abdomen. The classic presentation of intussusception is the triad of abdominal pain, a sausage-shaped abdominal mass, and currant-jelly stool. However, this classic triad is frequently not seen at presentation. Some infants present solely with lethargy or altered consciousness, and thus intussusception should be high on the differential for patients with an ALTE presenting in this manner. Similarly, infants with

volvulus can present with sudden onset abdominal pain accompanied by emesis. Volvulus is a medical emergency, which can lead to bowel necrosis and death. As such, it should always be considered in patients with an ALTE and a suggestive clinical presentation.

Most studies do not support routine testing for GER in patients presenting with an ALTE. Because there is a high prevalence of GER in infants, it is expected that a high number of these patients will have positive GER testing. When testing is considered, it is important to understand the utility of various modalities. Upper gastrointestinal fluoroscopy is frequently performed in patients presenting with an ALTE. Although this can be useful in identifying underlying anatomic anomalies that can lead to an ALTE, it should not be used to delineate GER as the cause for the event. This study frequently demonstrates regurgitation in normal infants, and a positive finding on the study does not necessarily indicate that GER was the cause of the inciting event. Although typically not indicated, if further GER testing is desired, esophageal pH analysis via a pH probe could be considered to help demonstrate a causal link by correlating low pH findings with documented apnea on concurrent cardiorespiratory monitoring (see Chapter 12).

Infectious Disease

Various infectious etiologies can present as an ALTE, ranging from common illnesses caused by respiratory viruses to less common, but serious infections such as bacteremia and meningitis. A history of multiple events on the day of presentation is associated with an infectious etiology. Additional historical clues include recent fever, irritability, altered level of arousal, cough, or coryza. Physical examination findings may confirm the suspicion of an infectious etiology, while hypothermia and ill appearance at presentation should lead to concern for more serious infectious etiologies.

Viral respiratory infections are a leading cause of ALTEs. Apnea may be the presenting symptom of viral lower respiratory tract infections, with the telling symptoms of coryza and cough delayed by hours to days. In particular, pertussis and bronchiolitis caused by respiratory syncytial virus (RSV) are commonly reported conditions associated with apnea in young infants. Suspicion of respiratory infection must remain high, especially during peak respiratory illness periods, or if there is a history of recent exposure. Neonates with pertussis may present with or develop few other symptoms, so a careful history of potential exposure is essential for early diagnosis. Although

TABLE 5.4 **Important Historical Features of an ALTE–BRUE**	
Preevent	
Condition of child	Awake vs asleep
Location of child	Prone vs supine, in crib/car seat, with pillows, blankets
Activity	Feeding, crying
Event	
Respiratory effort	None, shallow, gasping, increased Duration of respiratory pauses
Color	Pallor, red, cyanotic Peripheral, whole body, circumoral
Tone/movement	Rigid, tonic-clonic, decreased, floppy Focal vs diffuse Ability to suppress movements
Level of consciousness	Alert, interactive, sleepy, nonresponsive
Duration	Time until normal breathing, normal tone, normal behavior Detailed history of caregiver actions during event to aid in defining time course
Associated symptoms	Vomiting, sputum production , blood in mouth/nose, eye rolling
Post-Event	
Condition	Back to baseline, sleepy, postictal, crying If altered after event, duration of time until back to baseline
Interventions	
What was performed	Gentle stimulation, blowing in face, mouth-to-mouth, cardiopulmonary resuscitation
Who performed intervention	Medical professional vs caregiver
Response to intervention	Resolution of event vs self-resolving
Duration of intervention	How long was intervention performed
Medical History	
History of present illness	Preceding illnesses, fever, rash, irritability, sick contacts
Past medical history	Prenatal exposures, gestational age, birth trauma Any medical problems, prior medical conditions, prior hospitalizations Developmental delay Medications
Feeding history	Gagging, coughing with feeds, poor weight gain
Family history	Neurologic problems Cardiac arrhythmias Sudden death, childhood deaths, ALTEs Neonatal problems Consanguinity
Social history	Home situation Caregivers Smoke exposure Medications in the home

ALTE, apparent life-threatening event; BRUE, brief resolved unexplained event.

uncommon in infants, strong suspicion or the development of a staccato cough with posttussive emesis, or a classic "whoop," should prompt treatment while waiting appropriate testing.

Although the incidence of bacteremia or meningitis is low in patients presenting with an ALTE, the morbidity and mortality of these diagnoses are such that they should always be considered. A history of irritability and/or altered level of arousal may suggest a serious infection. Paradoxical irritability (crying when held) suggests soft tissue or bone infection or a fracture. Examination findings of concern include ill appearance, fever, hypothermia, lethargy, nuchal rigidity, and poor peripheral perfusion. Prompt action is required for the evaluation and treatment of these infants.

Urinary tract infections (UTIs) have also been shown to be a potential cause of ALTEs, with studies reporting a rate of 0-8%. The infection can lead to cardiorespiratory compromise, which can manifest as apnea, color change, altered levels of consciousness, or change in muscle tone. The majority of patients with UTIs significant enough to cause an ALTE will be ill-appearing at presentation. Therefore, most studies indicate that urinalysis and urine culture could be reserved for infants who are febrile, ill-appearing, or who have other clinical symptoms consistent with a UTI.

Neurologic

Neurologic disorders that can lead to an ALTE include seizure, breath holding spells, congenital central hypoventilation syndrome (CCHS), metabolic encephalopathies, and brain or brainstem abnormalities.

The most common neurologic disorder associated with ALTEs is **seizure**, with a rate of up to 25%. Factors that support the diagnosis of seizure include a history of loss of consciousness, poor tone, unresponsiveness, eye deviation, or rhythmic movements that are not able to be suppressed. A history of choking, while commonly reported among patients presenting with an ALTE in general, is typically absent in those presenting with seizure. Thus the lack of this historical fact should raise the suspicion for seizure in the differential.

Breath holding spells have been reported to present to medical attention as an ALTE. These are typically divided into two types: cyanotic and pallid. In cyanotic breath holding spells, there is usually an emotional trigger such as anger or frustration. The infants cry, then become silent and hold their breath in expiration with subsequent cyanosis. This can then be followed by limpness and possible loss of consciousness. Pallid breath holding spells are less common and are typically triggered by pain or fright. The child may gasp, then lose consciousness and become pale, diaphoretic, and limp. This can be followed by a period of increased tone and clonic movements. To determine if an ALTE is consistent with a breath holding spell, it is important to obtain a stepwise history of the event, including any emotional or painful precipitant.

CCHS is a rare but known cause of ALTEs. This is classically characterized by adequate ventilation while awake but hypoventilation while asleep, associated with normal respiratory rates and shallow breathing. In severe cases, patients with CCHS can present similarly to patients with cyanotic heart disease, with cyanosis, edema, and signs of right heart failure. However, in less severe cases, CCHS may present with tachycardia, diaphoresis, or cyanosis during sleep.

Additional rare, but potentially life-threatening, neurologic disorders to consider include brain tumors, neuromuscular disorders, metabolic encephalopathies, and malformations of the brain and brainstem. Examiners should therefore pay particular attention to any focal weakness, cranial nerve abnormalities, or signs of increased intracranial pressure including papilledema and Cushing triad (bradycardia, respiratory irregularities, and hypertension).

Given the relatively high incidence of seizures in infants presenting with an ALTE, some diagnostic algorithms recommend electroencephalograms (EEGs) in the initial investigation. However, at only 15%, the sensitivity of EEGs in diagnosing future epilepsy is poor. Since infants presenting with an ALTE who go on to develop chronic epilepsy will likely have recurrent events, most experts recommend that EEGs be reserved for those patients with recurrent events or historical or physical examination findings specifically concerning for seizures. In patients with suspected seizures, evaluation of serum electrolytes may also be beneficial to identify possible derangements including hypo- or hypernatremia, hypocalcemia, or hypoglycemia. If specific electrolyte abnormalities are identified, further work-up should be undertaken to determine underlying pathology.

Neuroimaging is frequently obtained in patients presenting with an ALTE. Current evidence does not support routine neuroimaging for asymptomatic infants presenting with an ALTE given the low diagnostic yield, high cost, and radiation concerns. However, neuroimaging should always be considered in the infant with an abnormal neurologic examination or a clinical concern for seizure, child maltreatment, metabolic encephalopathies, or tumor to assess for intracranial malformation, bleeding, or mass.

Airway/Pulmonary

Infections of the upper and lower respiratory tract are common causes of ALTEs, but other respiratory etiologies have been cited as well. These include apnea of prematurity and infancy, periodic breathing, and airway abnormalities.

The most common cause of apnea in preterm infants is **apnea of prematurity**. It occurs in virtually all infants born at less than 28 weeks' gestation, and the frequency is indirectly proportional to the gestational age. Apnea of prematurity is thought to be due to immature respiratory control in premature infants and typically presents with either central or mixed (central and obstructive) apnea. It is a diagnosis of exclusion and should be considered only after other etiologies have been ruled out. The apneic events typically begin within the first week of life, and as such, symptom onset after that time should stimulate consideration of other causes. Apnea of prematurity typically resolves by 37 to 40 weeks' postconceptual age in infants delivered at ≥28 weeks but can persist later in infants delivered prior to 28 weeks.

Apnea of infancy (AOI) refers to apnea that develops in neonates older than 37 weeks' postconception. The etiology is unknown. It is reserved for cases when a cause for an ALTE is not identified and is typically seen as a diagnosis of exclusion.

Periodic breathing is a common entity that is often confused by parents for an ALTE. Periodic breathing is defined as three or more respiratory pauses of greater than 3 seconds' duration within a 20 second portion of the breathing cycle. Sometimes several pauses occur, one after the other, followed by a set of short rapid respirations before the respiratory rhythm is restored. Importantly, no associated change in color, tone, or heart rate and no prolonged respiratory pauses (>20 seconds) are reported in association with periodic breathing. A clear history of the ALTE event is essential in differentiating true apnea from periodic breathing. Video of concerning events can prove very helpful. If determined to be periodic breathing, it is a benign entity and does not require any additional work-up or intervention.

Less common respiratory etiologies to consider include **anatomic airway abnormalities** such as anomalies of the pharynx (adenotonsillar hypertrophy), the larynx (laryngomalacia, edema, subglottic ductal cyst, subglottic stenosis), or the trachea (tracheomalcia, aberrant innominate artery). A history of associated respiratory distress, obstructive apnea, positional symptoms, or noisy breathing, or

physical examination findings such as stridor should raise the index of suspicion for these otolaryngologic etiologies. Aspiration can also present as an ALTE and can be the result of a foreign body, neurologic abnormalities leading to swallowing dysfunction, or anatomic disorders such as cleft palate or tracheoesophageal fistula.

Chest and neck radiographs can be beneficial in assessing for signs of airway abnormalities or radiopaque foreign bodies. If there is high concern for anatomic abnormalities, evaluation by direct laryngoscopy, bronchoscopy, and/or esophagoscopy could be considered. However, in patients who are well-appearing without clinical concern for airway anomalies, the yield for these tests is low. Polysomnography can be useful in differentiating between central versus obstructive processes.

Child Maltreatment

Child maltreatment should always be considered in infants presenting with an ALTE, especially given the detrimental consequences of missing the diagnosis. Possible etiologies include head trauma (direct injury or repetitive shaking), smothering, ingestions, and factitious syndrome (formerly Munchausen syndrome) by proxy.

Concerning historical facts include unexplained vomiting or irritability, recurrent ALTEs, historical discrepancies (history is confusing, varies among caregivers, changes over the course of the evaluation), or a family history of ALTEs, SIDS, or unexplained death. There is a higher rate of child maltreatment in infants presenting with more severe initial episodes and in those requiring resuscitation.

Any bruising should be noted, especially in a nonambulatory infant. A careful ear, nose, and throat examination should be performed, noting any ear bruising, bleeding from the nose or mouth, or frenulum tears. A thorough neurologic examination is also essential, assessing for altered sensorium, fontanelle fullness, pupillary abnormalities, or other focal neurologic findings. These findings should all raise suspicion for child maltreatment. However, it is also important to note that infants with child maltreatment may appear well on presentation with no external signs of trauma; the absence of these findings does not rule out maltreatment as the cause for the ALTE.

If there is clinical suspicion for child maltreatment, a skeletal survey, cranial/brain imaging, select laboratory studies, and a dilated funduscopic examination should be considered to assess for supportive findings. Video surveillance while the infant is hospitalized can also be considered in these cases. In addition, if there is concern for possible intentional or unintentional poisoning, a toxicology screen could be considered to identify the presence of medications that could cause the presenting symptoms. However, in patients without historical or physical examination findings concerning for child maltreatment, the evidence does not support the routine use of any of these assessments.

Cardiac

Though relatively rare, with a reported rate of 0-2%, cardiac pathology can lead to an ALTE in a myriad of ways. Children with structurally normal hearts may experience an ALTE due to arrhythmias, cardiomyopathy, and myocarditis. Those with structurally abnormal hearts, such as vascular anomalies, cyanotic heart disease, and left-sided obstruction may also present with an ALTE. A history of multiple and/or escalating events over days to weeks, feeding difficulties, diaphoresis, failure to thrive, or a positive family history of cardiac disease should raise the index of suspicion for cardiac pathology. A complete cardiac examination should be performed, noting abnormalities that might suggest underlying cardiac pathology, such as irregular rhythms, decreased femoral pulses, or murmurs.

Given the low rate of cardiac disease in patients presenting with an ALTE, routine echocardiograms are generally not useful in the initial work-up of these patients. ECGs may be a more useful screening tool,

as they are relatively easy to perform and are highly sensitive in identifying cardiac abnormalities. Therefore ECG could be considered to help exclude cardiac etiologies in patients where this is a clinical concern. However, the examiner should note that there is a high false-positive rate for ECGs in these patients, which could lead to additional unnecessary testing. If arrhythmia is strongly suspected or identified, assessment for electrolyte disturbances, such as hypo- or hyperkalemia should be undertaken.

Metabolic/Genetic

ALTEs can be the initial presentation of various metabolic disorders including organic acidemias, urea cycle disorders, fatty acid oxidation disorders, and mitochondrial disorders. Similarly, an ALTE can be the presenting symptom of hypoglycemia and hypocalcemia. Although metabolic entities are rare, they can be progressive and life threatening and therefore should be considered in the differential for these patients.

Clinical findings that may suggest an inborn error of metabolism include: recurrent or severe events, associated developmental delay, failure to thrive, or positive family history of seizure disorders, SIDS, or early infant deaths. Physical findings such as dysmorphic features should also be noted as these could suggest an underlying syndromic etiology. Disorders of the face and upper airway, such as cri du chat and Pierre Robin syndromes, can lead to obstructed respiratory patterns.

Serum chemistries, while not necessarily diagnostic of an inborn error of metabolism, can be helpful in screening patients with potential metabolic abnormalities and should be considered in patients when this is a clinical concern. Serum glucose, bicarbonate, ammonia, lactate,

ALTE, apparent life-threatening event; BRUE, brief resolved unexplained event; SIDS, sudden infant death syndrome.

and pyruvic acid levels are useful screening tests in these patients because abnormalities signal the possibility of metabolic disorders requiring additional evaluation. The **newborn screen** should also be reviewed to ensure no abnormalities were identified. If there is a high index of suspicion, it is prudent to repeat the newborn screen to ensure that the findings remain normal following the introduction of enteral feeds.

SUMMARY AND RED FLAGS

A thorough history and physical examination is paramount in the evaluation of patients with an ALTE–BRUE. Concerning historical factors and physical examination findings, such as multiple ALTEs, suspicion for child maltreatment, and requirement for resuscitation should prompt further evaluation (Table 5.5).

Syncope and Dizziness

Gary Cohen

Dizziness is a common but very nonspecific chief complaint about which some elaboration by the patient is generally required for the physician to understand exactly what the patient is experiencing. The description of the sensation is critical in distinguishing whether it is caused by vertigo, disequilibrium, lightheadedness, presyncope, or even ataxia (Table 6.1). Although the differential diagnoses of these entities may overlap, there are conditions that are most specific to the individual symptom. All of the entities are conditions that may affect children at any age, but older children are more capable of articulating the abnormal sensation they feel. Children younger than 6 years of age may present with nausea, vomiting, ataxia, or frank syncope.

Syncope is the transient loss of consciousness and postural tone that results from inadequate cerebral perfusion. Syncope is a common phenomenon in children and adolescents that is usually benign. Between 20% and 35% of all young adults have had one episode of syncope.

Presyncope is the feeling that the person is "about to pass out." The patient feels as if he or she is going to lose consciousness but does not. Presyncope may or may not reflect the same pathophysiologic process as true syncope. The diagnostic approach to presyncope is the same as for syncope.

Dizziness must be considered a change in mental status. It may potentially herald serious underlying central nervous system dysfunction. Dizziness must be better defined to distinguish vertigo from lightheadedness. The principal distinction with *vertigo* is the description of perceived motion: swaying, whirling, or spinning. **Lightheadedness** is frequently associated with psychological stress, including anxiety, hyperventilation, depression, and panic attacks. The history surrounding episodes of lightheadedness is vital for formulating the differential diagnosis.

Disequilibrium refers to "balance problems" without vertigo. The characteristic historical feature is difficulty ambulating. A rare complaint among children, disequilibrium in the young is most often caused by vestibular or cerebellar dysfunction and manifests as ataxia. **Ataxia** is an impairment of coordination, movement, and balance; this impairment is generally associated with dysfunction of the cerebellum or of the sensory and/or motor pathways connecting to the cerebellum. There are transient forms and progressive degenerative conditions that produce ataxia.

SYNCOPE

Syncope is a common phenomenon among children and adolescents. As many as 25% of children experience a syncopal event between the ages of 8 and 18 years. Before age 6 years, syncope is very unusual except in the setting of seizure disorders, breath-holding spells, and primary cardiac dysrhythmias. Syncopal episodes cause a large number of health care visits and a surprising number of admissions to hospitals. The differential diagnosis of syncope is noted in Tables 6.2 and 6.3; distinguishing features are noted in Tables 6.4 and 6.5.

The pathophysiologic mechanism of syncope follows a common pathway with many inciting stimuli. Cerebral perfusion is compromised by a transient decrease in cardiac output as a result of vasomotor changes, decreasing venous return, primary dysrhythmia, or impairment of cerebral vascular tone. Adolescents with syncope subjected to a head-up tilt-table test report blurred vision and constriction of visual fields before losing consciousness, as well as nausea, pallor, sweating, and dizziness, which are accompanied by hypotension (systolic blood pressure <60 mm Hg) and by bradycardia (heart rate <40 beats/min) with an occasional junctional rhythm and even asystole. Symptoms are relieved by returning to the supine position. Several situational factors can exacerbate this response, including warm temperature, a confined space such as being in a crowded room, anxiety or fear, sudden surprise, the sight of blood, pain, such as needle sticks or shots. Other situational factors include urination, swallowing, coughing, defecation, and hair combing.

This response is caused by an imbalance of parasympathetic and sympathetic tone, which results in peripheral vasodilatation, including venodilation, but in no augmentation of venous return, because there is no accompanying increase in large skeletal muscle activity to augment systemic venous return and maintain cardiac filling. Subsequent vagal output results in inappropriate bradycardia and further compromises cardiac output. The child faints and becomes supine, which restores systemic venous return. Awakening is accompanied by increased sympathetic output, which restores the heart rate. The episode tends to be brief but may recur if the patient is "helped up" too quickly.

In obtaining the history of a syncopal episode, attention should be paid to the time of day, time of last meal, activities leading up to the

(See *Nelson Textbook of Pediatrics*, p. 514.)

	Vertigo	**Presyncope**	**Disequilibrium**	**Lightheadedness**
Patient complaint	"My head is spinning" "The room is whirling"	"I feel I might pass out" "I feel faint" "I feel like blacking out"	"I feel unsteady" "My balance is off"	"I feel dizzy" "I feel disconnected, drugged"
Associated features	Motion, swaying, spinning, nystagmus	Syncope: loss of postural tone, brief loss of consciousness Situational	Poor balance No vertigo or ataxia	Anxiety, hyperventilation, paresthesias, respiratory alkalosis, panic attacks
Usual cause	Vestibular disorders	Impaired cerebral perfusion	Sensory and/or central neurologic dysfunction	Anxiety and/or depressive disorders
Key differential diagnoses	Peripheral (labyrinthine-cochlear) vs Central neurologic disorder	Neurocardiogenic (vagal) vs Cardiac syncope vs Neuropsychiatric syncope	Sensory deficit vs Central neurologic disease	Anxiety/depression vs Hyperventilation vs Medication effects

event, and associated symptoms (e.g., palpitations, racing heartbeat, chest pain, headache, shortness of breath, nausea, diaphoresis, visual changes, and hearing changes). **Cataplexy** may be confused with syncope and is characterized by partial or complete paralysis of skeletal muscles resulting in a rapid progression of weakness of the face and neck followed by the muscles of the trunk and extremities. The patient loses tone and may fall to the floor but remains awake and immobile for 1-2 minutes. Triggers include intense positive or negative emotions, such as laughing, frustration, fright, or anger. Details of the syncopal event, such as the patient's position (syncope while supine suggests a cardiac arrhythmia) when symptoms appeared, duration of the episode, and characterization of the patient's appearance during and immediately after the episode are also important. Almost without exception, by the time the patient presents to the office or emergency room, the physical examination findings are normal. Therefore, the history becomes the most important piece of information for developing the differential diagnosis, diagnostic evaluation, and management plan.

NEUROCARDIOGENIC SYNCOPE

There are several causes of **neurocardiogenic syncope**. Excessive vagal tone may be primary or secondary to breath-holding, cough, (deglutition syncope), micturition or defecation, carotid sinus pressure sensitivity, and orthostasis. Neurocardiogenic syncope has been described in association with hair brushing, swallowing, stretching, orthodontic maneuvers, anomalies of the cervical spine, and dental trauma. Many of these episodes may actually be forms of carotid sinus sensitivity. Cough syncope probably is related to prolongation of high intrathoracic pressure that results in decreased venous return and subsequent decreased cardiac output.

The prodromal history is very important in evaluating neurocardiogenic syncope. *In contrast, syncope without warning, while the patient is supine or during exercise implies a primary cardiac and usually more serious etiology; it is associated with greater morbidity and potential mortality* (see Table 6.3).

Neurocardiogenic syncope is a type of autonomic dysfunction that is also referred to as **vasodepressor syncope, vasovagal syncope**, and **reflex syncope**. Potential mechanisms include:
1. The first response is primary bradycardia, sometimes to the extreme of sinus arrest or even brief asystole, with subsequent hypotension. This is known as the cardioinhibitory response.

2. The second is a primary vasodepressor response that is characterized by hypotension with the heart rate being relatively preserved.
3. The third is mixed and is the most common response that features *simultaneous* hypotension and bradycardia.

The common pathway producing the heart rate and blood pressure responses and cerebral hypoperfusion is the Bezold-Jarisch reflex (Fig. 6.1). For most children and adolescents, **prodromal warning signs** herald the impending syncopal episode and can, after the first episode, allow the child enough time to prevent fainting by sitting with the head between the knees or by lying supine.

The physiologic mechanisms of neurocardiogenic syncope have been demonstrated with head-up tilt-table testing. **Tilt-table testing** can be performed with or without invasive blood pressure monitoring. The goal is to reproduce the patient's symptoms under close monitoring. Various tilt angles and durations have been described, as has the use of isoproterenol as a provocative stimulus.

If the history suggests the diagnosis of neurocardiogenic syncope with normal physical examination findings and a normal electrocardiogram (ECG), treatment may be empirically started (Tables 6.6 and 6.7). The first line of treatment is education and counseling. Most patients will eventually outgrow neurocardiogenic syncope. Patients should maintain hydration and increase dietary salt if there are not any contraindications. Patients should be counseled to avoid situations that precipitate an event and taught to abort an event by lying down.

If the patient fails conservative therapies, pharmacologic treatments may be tried. Physicians have used fludrocortisone with increased salt intake, β-adrenergic blockers, and midodrine which has had promising results. None of these medications has demonstrated consistent benefit to treat neurocardiogenic syncope.

ORTHOSTATIC SYNCOPE

Conditions that produce **hypotension** (orthostatic or supine) frequently produce syncope or presyncope. Cardiac function and structure are usually normal before the episode; during the predisposing illness, cardiac filling pressures are often reduced because of reduced venous return from hypovolemia or decreased peripheral vascular resistance (peripheral pooling of blood). Dehydration from diarrhea and vomiting, hyperthermia, hyperpyrexia, heat exhaustion, polyuria (diabetes mellitus) or poor intake from anorexia, together with the systemic effects of the primary illness, may produce orthostatic or true hypotension and syncope. In these conditions, dizziness, hypotension,

or syncope occurs rapidly when the patient assumes an upright position (seconds). Prolonged bed rest, combined with poor fluid intake during an illness, may also result in syncope or presyncope when the child arises to leave the bed. In most of these situations, fluid administration is sufficient to restore intravascular volume and venous return to alleviate postural or supine hypotension.

POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME (POTS)

Postural orthostatic tachycardia syndrome is characterized by recurrent and chronic symptoms of orthostatic intolerance, exercise intolerance, light headedness, fatigue, sweating, tremor, anxiety, and presyncope when upright. The syndrome may be secondary to autonomic dysfunction. Symptoms are improved with lying down. Criteria to diagnose POTS include symptoms that have lasted greater than 6

(See *Nelson Textbook of Pediatrics*, p. 516.)

TABLE 6.4   Clinical Features Suggesting Specific Causes of Syncope

Diagnostic Consideration

Neurocardiogenic

Symptoms after prolonged motionless standing, sudden unexpected pain, fear, or unpleasant sight, sound, or smell

Syncope in a well-trained athlete after exertion (without heart disease)

Situational syncope during or immediately after micturition, cough, swallowing, or defecation

Syncope with throat or facial pain (glossopharyngeal or trigeminal neuralgia)

Organic Heart Disease (e.g., Coronary Artery Disease, Aortic Stenosis, Primary Arrhythmia, Obstructive Hypertrophic Cardiomyopathy, Pulmonary Hypertension)

Brief loss of consciousness, no prodrome, history of heart disease

Syncope with exertion

Family history of sudden death

Neurologic

Seizures: confusion for >5 min after regaining consciousness

Transient ischemic attack, subclavian steal, basilar migraine: syncope associated with vertigo, dysarthria, diplopia, arm exercise

Migraine: syncope associated with antecedent headaches

Other Vascular

Carotid sinus: syncope with head rotation or pressure on the carotid sinus (as in tumors, shaving, tight collars)

Orthostatic hypotension: syncope immediately on standing

Subclavian steal or aortic dissection: differences in blood pressure or pulse between the two arms

Drug Induced

Patient is taking a medication that may lead to long QT syndrome, orthostasis, or bradycardia

Psychiatric Illness

Frequent syncope, somatic complaints, no heart disease

Modified from Kapoor WN. Syncope. *N Engl J Med.* 2000;343:1856-1862.

TABLE 6.5   Comparison of Clinical Features of Syncope and Seizures

Features	Syncope	Seizures
Relation to posture	Common	No
Time of day	Diurnal	Diurnal or nocturnal
Precipitating factors	Emotion, injury, pain, crowds, heat, exercise, fear, dehydration, coughing, micturition	Sleep loss, drug/ alcohol withdrawal
Skin color	Pallor	Cyanosis or normal
Diaphoresis	Common	Rare
Aura or premonitory symptoms	Long	Brief
Convulsion	Rare, brief	Common
Other abnormal movements	Minor twitching	Rhythmic jerks
Injury	Rare	Common (with convulsive seizures)
Urinary incontinence	Rare	Common
Tongue biting	No	Can occur with convulsive seizures
Postictal confusion	Rare	Common
Postictal headache	No	Common
Focal neurologic signs	No	Occasional
Cardiovascular signs	Common (cardiac syncope)	No
Abnormal findings on EEG	Rare (generalized slowing may occur during the event)	Common

From Bruni J. Episodic impairment of consciousness. In: Daroff RB, Jankovic JM, Mazziotta JC, Pomeroy SL, eds. *Bradley's Neurology in Clinical Practice.* 7th ed. Philadelphia: Elsevier; 2016:9.

months, heart rate that increases by at least 40 beats/min, if <18 years or 30 beats/min if >18 years, after assuming a standing from supine position for at least 10 minutes, symptoms worsen with standing and improve with recumbence, and the absence of other overt causes of orthostatic intolerance.

A detailed history of orthostatic intolerance may identify symptoms of headache, fatigue, sleep disorder, weakness, hyperventilation, shaking, sweating, anxiety, dizziness, and presyncope. An evaluation for POTS may include a complete blood count, glucose, electrolytes, and thyroid function. Cardiac evaluation should include an ECG. A tilt-table test may be helpful to demonstrate the effects of orthostatic stress (increased heart rate).

There is no specific treatment for POTS. Medications that may aggravate symptoms of POTS should be avoided including antihypertensive agents, sedatives, and many other psychiatric medications. Patients should avoid aggravating factors, such as dehydration, extreme heat, and alcohol. Nonpharmacologic treatment includes aerobic exercise, compressive stockings, and increased fluid and salt intake. Pharmacologic treatment should be tailored to the variant the patient exhibits.

CARDIAC SYNCOPE/SUDDEN CARDIAC DEATH

A variety of cardiac conditions can result in hypotension and syncope (Tables 6.8 and 6.9; see Table 6.3). Dysrhythmias are common and are usually silent between episodes (see Table 6.8). Supraventricular tachycardia, ventricular tachycardia, and heart block are the most common types of dysrhythmia and may be primary or may result from medications or illicit drugs. Any form of acquired heart block carries a high mortality rate (Fig. 6.2). A common cause of acquired heart block is Lyme disease. Heart block may necessitate temporary or permanent electronic pacing to maintain cardiac output.

Lead II

FIGURE 6.2 Congenital complete atrioventricular (AV) block. The ventricular rate is regular at 53 beats/min. The atrial rate is somewhat variable, from 65-95 beats/min, and completely dissociated from the ventricle. The QRS morphology is normal, which is common in congenital complete AV block. (From Van Hare GF. AV block. In: Kliegman RM, Stanton BF, St. Geme III JW, Schor NF, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:2260.)

Primary cardiac conduction abnormalities that may result in syncope include Wolff-Parkinson-White syndrome, long QT syndromes, and catecholamine-sensitive ventricular tachycardia. **Wolfe-Parkinson-White syndrome** is characterized by a *short PR interva*l, preexcitation seen as a widened QRS duration and a delta wave on the proximal portion of the QRS. The delta wave represents the presence of accessory electrical tissue from atria to ventricle, with rapid antegrade conduction causing excitation of ventricular tissue before atrioventricular node–His bundle stimulation. If that pathway can conduct in the retrograde manner, a reentrant circuit is created, causing a narrow QRS complex tachycardia. This greatly shortens the diastolic ventricular filling time and results in diminished left ventricular end-diastolic volume, with subsequently decreased stroke volume and decreased cardiac output. Although the tachycardia is rarely sufficiently fast to result in syncope, some children have profound hypotension and a rapid loss of consciousness. In adults, a similar mechanism results from atrial flutter or fibrillation if the ventricular response rate is fast.

Long QT syndromes are inherited (usually autosomal dominant) abnormalities in the electrical recovery (repolarization) of the heart (Fig. 6.3). Prolongation of the repolarization phase results in the risk of simultaneous depolarization, the "R-on-T" phenomenon, which causes disorganized ventricular electrical stimulation characterized by **torsades de pointes** (coarse ventricular tachycardia), a potentially lethal dysrhythmia (Fig. 6.4). There may be a family history of sudden cardiac death. Family studies with the same mutation have demonstrated that affected patients may not always have a long QT interval on ECG as defined for the syndrome, but an increased QT interval may become evident with exercise or during catecholamine infusion. Long QT syndromes may be responsible for some of the incidents of sudden infant death syndrome and drowning. Although additional genetic forms have been described, most mutations for prolonged QT involve either a sodium channel or potassium channel (Table 6.10). Genotype may predict the patient's presentation with LQT1 events associated with stress, while LQT3 may be associated with sleep. Long QT syndromes may present as a syncopal episode, seizures, palpitations, or presyncope. Diagnosing long QT is based on clinical history and ECG findings of a prolonged rate-corrected QT interval. Genetic testing may identify approximately 75% of patients. Acquired prolongation of the QT interval may also be seen in electrolyte abnormalities (hyperkalemia) and with a variety of medications (Table 6.11). A drug history and toxicology screen may be warranted if there is any question of QT prolongation.

Patients who have undergone **corrective or palliative surgery** for congenital cardiac disease are at risk for both early and late onset dysrhythmias that might result in syncope. Sinus node disease

(See *Nelson Textbook of Pediatrics*, p. 2261.)

FIGURE 6.4 Episode of torsades de pointes in a patient with long QT syndrome. (From Van Hare GF. Sudden Death. In: Kliegman RM, Stanton BF, St. Geme JW III, Schor NF eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia, Elsevier; 2016:2262.)

(in patients undergoing atrial surgery) may result in tachycardia-bradycardia episodes that can be associated with hypotension. Ventricular dysrhythmias are particularly common after repair of tetralogy of Fallot, double-outlet right ventricle, truncus arteriosus, and pulmonary atresia involving right ventriculotomy with subsequent ventricular scar formation.

Uncorrected structural heart disease is a relatively rare cause of a sudden decrease in cardiac output. However, **hypertrophic cardiomyopathies** can result in obstruction of left ventricular outflow with resultant high transmural pressure and secondary cardiac ischemia,

which can be fatal. This type of obstruction is exacerbated by high sympathetic tone, which causes increased contractility and is a frequent mechanism of syncope associated with exercise in competitive athletes. The presence of an outflow tract murmur in the setting of syncope, especially if there is a positive family history, warrants evaluation with *both* electrocardiography and echocardiography. Any condition that impedes left ventricular outflow (valvular aortic stenosis or subaortic stenosis), left ventricular inflow or filling (mitral stenosis or pericardial tamponade), or blood flow through the pulmonary vasculature (primary or secondary pulmonary hypertension) may also result in syncope. In almost all cases, characteristic physical findings lead the clinician to the diagnosis. Pulmonary hypertension may be associated with cyanosis, in which case there is cerebral hypoxia resulting from right-to-left shunting, as well as decreased left ventricular output resulting from poor transpulmonary flow and decreased left ventricular filling.

Other rare causes of cardiac syncope are thoracic masses and intracardiac tumors or masses, coronary artery abnormalities, and inflammatory cardiac diseases (myocarditis). Masses or tumors, such as myxomas, fibromas, and rhabdomyomas, tend to produce paroxysmal symptoms, which are often associated with position changes, especially from the recumbent position. **Coronary artery anomalies** are usually not accompanied by signs of ischemia. Rather, the most

common manifestation is syncope or sudden cardiac death from compression of the anomalous left main coronary artery as it courses between the pulmonary outflow and the aortic root (Fig. 6.5). This usually occurs in a competitive athlete whose hypertrophied heart responds to catecholamine stimulation during activity and inadvertently compresses the anomalous coronary artery. Inflammatory conditions, such as heart block associated with Lyme disease and ventricular tachycardia associated with myocarditis or pericarditis, predispose to dysrhythmias.

Cardiac syncopal episodes can be accompanied by brief tonic-clonic seizure activity known as **Stokes-Adams syndrome**. The seizure activity appears 10-20 seconds after the onset of asystole and is usually of short duration with no subsequent postictal phase. This may explain why many children with cardiac syncope frequently see a neurologist.

Sudden cardiac death is discussed with cardiac causes of syncope because cardiac causes of syncope may also produce sudden death (see Table 6.3). Sudden cardiac arrest or death is defined as the abrupt and unexpected loss of heart function. Structural causes include valvular aortic stenosis, coronary artery anomalies, cardiomyopathies, and myocarditis. Cardiac arrhythmias associated with sudden death include Wolff-Parkinson-White syndrome and prolonged QT syndrome. A less common cause is **commotio cordis** resulting from non-penetrating blunt trauma to the chest. Warning events or symptoms may not always be evident prior to sudden cardiac death; if it presents, patients may complain of episodes of dizziness, lightheadedness, presyncope, syncope, dyspnea, or palpitations. Other relevant history may include fatigue, unexplained seizure, or chest pain. It is important for the physician to perform a detailed history and physical examination to look for warning signs of cardiovascular disease in the patient *and* family (Table 6.12). Key elements of the physical examination should include measurement of blood pressure, a complete cardiovascular exam with attention to heart rate, rhythm, murmurs, pulses, and signs of Marfan syndrome.

NEUROLOGIC CAUSES OF SYNCOPE-LIKE EPISODES

Primary neurologic causes of syncope are more unusual in otherwise healthy children and adolescents than in adults. Seizures must be considered if there is a history of an aural prodrome, focal or generalized tonic-clonic activity, and a prolonged postictal phase of lethargy or confusion (see Tables 6.4 and 6.5). Prolonged post-event lethargy is unusual with more common causes of syncope if the vital signs have returned to normal. Seizures are a common cause of loss of consciousness in the recumbent patient. Seizures are often accompanied by tachycardia and normal or elevated blood pressure. A premonitory

TABLE 6.12 **Pediatric Sudden Cardiac Death Risk Assessment***
Patient History Questions:
Tell Me About Any of These in Your Child... Yes or No
Has your child fainted or passed out during or after exercise, emotion, or startle?
Has your child ever had extreme shortness of breath and/or discomfort, pain, or pressure in his or her chest during exercise?
Has your child had extreme fatigue associated with exercise (different from other children)?
Has a doctor ever ordered a test for your child's heart?
Has your child ever been diagnosed with an unexplained seizure disorder? Or exercise-induced asthma not well controlled with medication?
Family History Questions:
Tell Me About Any of These in Your Family...
Are there any family members who had a sudden, unexpected, unexplained death before the age of 50 (including SIDS, car crash, drowning, others) or near-drowning?
Are there any family members who died suddenly of "heart problems" before the age of 50?
Are there any family members who have had unexplained fainting or seizures?
Are there any relatives with certain conditions, such as:
Enlarged heart: hypertrophic cardiomyopathy
Dilated cardiomyopathy
Heart rhythm problems: Long QT syndrome
Short QT syndrome
Brugada syndrome
Catecholaminergic ventricular tachycardia
Arrhythmogenic right ventricular cardiomyopathy
Marfan syndrome (aortic rupture)
Heart attack, age 50 or younger
Pacemaker or implanted defibrillator
Deaf at birth (congenital deafness)
Please Explain More About Any "Yes" Answers.

*Ask these questions (or have parents complete for your review) at periodic times during well-child visits (neonatal, preschool, before or during middle school, and before or during high school).

aura may herald vertebrobasilar vascular spasm, which appears to occur when syncope is with **basilar type migraines**. There may be a history of unilateral visual changes; the loss of consciousness usually has a somewhat longer onset and duration. The patient frequently complains of headache after regaining consciousness. Basilar type migraine or migraine affecting the vertebrobasilar circulation can cause dizziness, vertigo, ataxia, confusion, and headache. There is often a positive family history of migraines.

METABOLIC CAUSES OF SYNCOPE

Hypoglycemia should always be included as a cause of syncope, but it is rare in children and adolescents except in patients with insulin-dependent diabetes or inborn errors of glucose or glycogen metabolism (see Chapter 44). With hypoglycemia, the patient feels weak, hungry, sweaty, agitated, confused, and eventually experiences altered mental status. Onset is gradual, and the patient remains hemodynamically stable, although tachycardia may be evident. Ingestion of oral hypoglycemic agents may exceed the body's normal glucose homeostasis, resulting in hypoglycemia.

PSYCHIATRIC CAUSES OF SYNCOPE

Patients with a history of panic attacks may become syncopal secondary to hyperventilation. The mechanism is not completely understood, but may involve the reaction of cerebral blood flow in response to hypocapnia and respiratory alkalosis. Tetany or paresthesias may be present in some patients. The history of the episode is critical and witnesses are especially helpful. The patient frequently relates a feeling of suffocation, smothering, shortness of breath, or chest tightness. In retrospect, the patient may also admit to numbness and tingling of the extremities and visual changes. Hyperventilation and hypocapnia may be detected during a tilt-table test by measuring end-tidal CO_2.

A psychiatric cause of syncope (or pseudosyncope) is a diagnosis of exclusion. The patient is usually an adolescent and frequently has episodes in the presence of an audience. The patient is unusually calm in describing the episodes and relates details that may indicate no loss of consciousness. During the episode, there are no associated hemodynamic changes and no pallor, sweating, or respiratory changes. Typically, the patient falls gracefully and gently without injury. The key is to define what secondary gain the patient attains through the factitious disorder.

EVALUATION OF THE SYNCOPAL CHILD

◆ History

The history of the event is the critical information for most patients (see Table 6.4). A detailed account of what the patient felt immediately before losing consciousness, what the patient was doing, what the posture or position was, how the patient looked, how long the episode lasted and associated signs or symptoms direct the diagnostic work-up. A thorough and detailed family history is necessary to discover risk for sudden death, dysrhythmia, heart disease, seizures, and metabolic disorders. The medication history, including over the counter, prescribed, and illicit drugs, as well as any accessible medication of other family members should be gathered.

◆ Physical Examination

Any person who has a syncopal episode should undergo a thorough physical examination, with special attention to the cardiovascular and neurologic systems. The examination should include obtaining vital signs with the patient supine and after standing for 5-10 minutes.

Upon careful auscultation, the presence of an outflow tract murmur radiating to the neck, an abnormally loud second heart sound, or the presence of a long decrescendo diastolic murmur at the apex leads to more involved diagnostic testing. In most cases, patients with a history of syncope have normal physical findings at the time of the examination.

◆ Diagnostic Tests

Because the child or adolescent who has had a syncopal episode is often evaluated hours or days after the episode, testing serum glucose, and electrolytes or urine toxicology screening is usually of no value. *All patients presenting with syncope need an ECG* (Fig. 6.6). The ECG should be inspected for the rhythm, with special attention to non-sinus rhythms and bradycardia. Measurements of the intervals should be performed manually regardless of any preprogrammed measurements printed on the ECG. Abnormalities of the PR, QRS, or QT/corrected QT (QTc) interval imply an underlying conduction abnormality. The P wave, QRS, and T wave amplitudes may indicate chamber enlargement or hypertrophy, each of which carries an increased risk for dysrhythmia. In the patient who also has a history of **palpitations** associated with syncope, long-term cardiac monitoring, with or without a subsequent patient-activated cardiac event recorder monitor, may help capture the cardiac rhythm when the patient is symptomatic. If a heart murmur is appreciated, if there is a family history of sudden death or cardiomyopathy, or if the ECG is at all questionable, a cardiology consultation should be obtained, and two-dimensional, Doppler, and color-flow echocardiography should be performed. If the syncopal event is associated with exercise, echocardiography is critical; if the results are normal, a graded treadmill exercise stress test should be performed with full ECG and blood pressure monitoring. Patients with primary dysrhythmias may require cardiac catheterization and electrophysiologic testing.

Patients exhibiting prolonged loss of consciousness, seizure activity, and a postictal phase of lethargy or confusion should be referred for neurologic consultation and electroencephalography. Without this history, the reported positive yield of electroencephalography is less than 1 in 300 studies. Likewise, neuroimaging studies generally have an exceptionally low yield in the absence of abnormality upon physical examination (see Fig. 6.6).

SUMMARY AND RED FLAGS

Hypotension, both supine and orthostatic, is a major red flag, as are associated palpitations, exertional symptoms, or chest pain (Tables 6.13 and 6.14); participation in gym class or sports must be restricted until a complete diagnostic work-up is completed. Additional red flags include syncope while supine, a positive family history, prolonged loss of consciousness, prolonged seizures, prolonged postevent neurologic signs, and abrupt onset with no prodrome. Laboratory tests, except for the ECG which is mandatory, are generally of limited value unless guided by pertinent findings in the history and physical examination. The ECG allows screening for Wolfe-Parkinson-White syndrome, heart block, and long QT syndrome as well as hypertrophic cardiomyopathies and myocarditis. The most common identifiable etiology in an otherwise healthy child or adolescent is neurocardiogenic syncope, usually a benign and transient condition.

VERTIGO

The characteristic description of vertigo is the illusion of **motion** usually described as spinning or whirling. The perception of motion may be internal ("My head is [or eyes are] spinning") or external ("The

room is spinning or moving"). The sensation is usually rotatory, but it can be linear ("It feels like the swaying of a boat").

Obtaining an accurate description from younger children is difficult. Using terms that the child may understand such as "sliding" or "swinging" may be helpful. The patient's description is critical although potentially vague; further questioning may lead to the rather discrete differential diagnosis of vertigo.

The presence of associated symptoms may help locate the pathology to a central or peripheral cause of vertigo (Tables 6.15, 6.16, and 6.17). Fortunately, peripheral causes of vertigo are more common. Spontaneous **nystagmus** and abnormal head positions are symptoms

associated more with peripheral causes of vertigo along with nausea, vomiting, sweating, faintness, and fright. Peripheral vertigo results in stimulation of the autonomic nervous system with resultant intense nausea, vomiting, pallor, and diaphoresis. If the dizziness occurs with abrupt changes in the position of the head, peripheral causes of vertigo should be suspected. Peripheral vertigo can be caused by the following: middle ear infections, paroxysmal positional vertigo, labyrinthitis, vestibular neuronitis, Ménière disease, or trauma (see Table 6.16).

Patients suffering from acute ongoing peripheral vertigo appear very ill and very uncomfortable. Because middle ear infection can cause peripheral vertigo, some children seen with otitis media and

TABLE 6.14	Summary of Clinical Recommendations for Transient Loss of Consciousness
Topic	**Recommendations**
Initial assessment	Detailed history, especially from witnesses Full clinical examination 12-lead ECG

Uncomplicated faints	Suggestive features include:
	    Posture: occurrence during prolonged standing or previous similar episodes avoided by lying down
	    Provoking factors, such as pain or a medical procedure
	    Prodromal symptoms, such as sweating or feeling warm or hot before TLoC
	    Further investigation and specialist referral are not needed.

Epilepsy	Suggestive features are a bitten tongue; head turning to one side during TLoC; no memory of abnormal behavior that occurred
	    before, during, or after TLoC; unusual posturing; prolonged limb jerking; confusion after the event; or prodromal déjà vu or
	    jamais vu.
	If features of epilepsy are present, arrange for early review by an epilepsy specialist.
	Do not arrange for EEG before neurologic assessment.
	Note that brief seizure-like activity often occurs during syncope, including uncomplicated faints.
	Do not suspect epilepsy unless suggestive features are present. Arrange for cardiovascular assessment if the cause of TLoC is
	    unclear.

Urgent specialist referral	Give immediate treatment for clinically urgent problems (such as complete AV block or severe bleeding). Arrange for urgent specialist cardiovascular assessment for patients at risk for a severe adverse event (such as those with long QT interval, cardiac arrhythmia, or structural heart disease).

Further cardiovascular
    assessment
	Focus on specific disorders that may cause TLoC, such as orthostatic hypotension, the carotid sinus syndrome, structural heart
	    disease, or cardiac arrhythmia.
	Assessment should include repeated history, clinical examination, and 12-lead ECG.
	For suspected cardiac arrhythmia or unexplained TLoC, use ambulatory ECG for further assessment:
	Very frequent episodes: use 24- to 48-hr Holter monitoring.
	Moderately frequent episodes: use external event monitoring.
	Infrequent episodes: use an implantable event recorder.

AV, atrioventricular; ECG, electrocardiography; EEG, electroencephalogram; TLoC, transient loss of consciousness.

vomiting may in fact have peripheral vertigo and secondary vomiting.

A more indolent course, change in consciousness or behavior or seizures may indicate a central origin of vertigo (see Table 6.17). Underlying causes of central vestibular dysfunction include acute vascular ischemic or thromboembolic events, acute demyelinating diseases, pharmacologic vertigo (alcohol, barbiturates, benzodiazepines), more indolent causes, including tumors of the brainstem or cerebellum and chronic demyelinating diseases or trauma (see Table 6.17).

EVALUATION OF THE PATIENT WITH VERTIGO

◆ History

A careful, detailed description of the prodrome and the actual symptoms, including timing, duration, associated symptoms, preceding infections (especially of the upper respiratory tract, such as otitis media or sinusitis), medications, and a history of trauma must be documented. A past, personal, or family history of vertigo or any other neurologic condition is important.

TABLE 6.15 **Differences Between Peripheral and Central Vestibular Dysfunctions**		
Symptom/Sign	**Peripheral**	**Central**
Severity of vertigo	Marked Nausea and vomiting common	Often mild
Nystagmus	Bilateral Unidirectional Rotatory/horizontal Never vertical Fast phase usually opposite to side of lesion Improves with visual fixation Begins within 2-10 seconds Fatigues with time Habituates	Bilateral or unilateral Bidirectional or unidirectional May be vertical Usually no change with visual fixation Begins immediately Persistent Reproducibly repetitive
Direction of environmental spin	Toward fast phase of nystagmus	Variable
Direction of past pointing	Toward slow phase of nystagmus	Variable
Tinnitus/deafness	Often present	Usually absent
Examples	Labyrinthitis Ménière disease Positional vertigo (see Table 6.16)	Multiple sclerosis Vertebrobasilar ischemia (see Table 6.17)

Modified from Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:191.

◆ Physical Examination

Special attention must be paid to the head, ears, eyes, nose, and throat examination. Good visualization of the tympanic membranes and of their mobility is necessary, along with testing both air and bony conduction with a tuning fork (Figs. 6.7 and 6.8). Visualization of the fundi is important. Testing of all the cranial nerves should be performed.

The neurologic examination must include an evaluation of the gait, a Romberg test, and an assessment of the visual fields and visual acuity (Fig. 6.9). In most children and adolescents, the physical examination results are normal with only subtle findings when the symptoms are provoked.

◆ Diagnostic Tests

The history and physical examination results direct the diagnostic work-up and indicate which tests need to be performed. Imaging studies important in the work-up of the vertiginous patient include computed tomography and magnetic resonance imaging. Both techniques allow visualization of the inner ear and the labyrinthine apparatus, as well as the brainstem and cerebellum. If an infectious cause is suspected, it may be useful to perform a lumbar puncture as long as increased intracranial pressure is not suspected. In the setting of trauma, the simple use of the pneumatic otoscope may allow the examiner to perform a "fistula test," reproducing or worsening the patient's symptoms because of an abnormal communication to the labyrinthine system. If hearing loss is a feature, audiometry and evoked response testing should be considered.

SUMMARY AND RED FLAGS

Vertigo is characterized by the perception of movement, particularly rotational movement, and can be a most distressing and incapacitating phenomenon. The history and examination should allow the examiner to distinguish between peripheral and central vestibular dysfunction.

In children and adolescents, peripheral vertigo is far more common than central vertigo. However, in certain at-risk populations, such as children with sickle cell disease, hemophilia, or congenital heart disease (especially children with right-to-left shunts or mixing lesions), and children receiving anticoagulation therapy, the central causes resulting from hemorrhagic and thromboembolic phenomena must be considered. Chronicity, persistence, vertical nystagmus, and signs of increased intracranial pressure are red flags. Because the diagnosis of vertigo requires that the patient be able to articulate the perception of movement, it is difficult to make this diagnosis in young children; the condition must be carefully distinguished from other movement impairments, especially disequilibrium.

DISEQUILIBRIUM

When a "dizzy" patient describes feeling unsteady on his or her feet, off balance, or uncoordinated, the patient is describing a disturbance in the body's equilibrium system. The fundamental complaint is difficulty in walking, not from weakness but from a feeling of lack of control.

Walking is a complex activity. The constant integration of visual, vestibular, and proprioceptive afferent information regarding the changing spatial orientation is performed by using all levels of the central nervous system: the cerebral cortex, cerebellum, brainstem, spinal cord, and peripheral neuromuscular system. These spatial data are then utilized by the efferent system, producing both voluntary and involuntary movements and spatial adjustments (Fig. 6.10). Disturbances in any of these pathways can result in difficulty with locomotion.

Disequilibrium, therefore, may result from any perceptual distortion of spatial orientation. The most common is visual impairment, to which any child who has played "Pin the Tail on the Donkey" or "Blind Man's Bluff" can attest. Humans depend heavily on visual perception to orient themselves in space. Vestibulocochlear dysfunction can also severely impair a person's ability to ambulate. Peripheral neuropathies affecting proprioceptive function impair the ability of the central nervous system to accurately perceive the position of the limbs with regard to one another and to either the ground or the body. Disorders causing diffuse damage to the integrative mechanism or cortical or cerebellar diseases can impair proprioception as well. Likewise, efferent motor disability produces impairment of locomotion by producing weakness or apraxias (Table 6.18).

TABLE 6.16 Peripheral Vestibulopathy

Syndrome	Usual Presentation	Typical Course	Hearing Loss?	Diagnosis
Benign paroxysmal positional vertigo	Paroxysmal, brief, purely positional vertigo	Often polyphasic illness with gradual improvement but intermittent brief recurrences for weeks/months Does not cause ongoing severe vertigo	No	History Nylen-Bárány maneuvers
Vestibular neuronitis	Acute-onset, severe vertigo, sometimes after viral respiratory infection	Severe ongoing vertigo for many hours or a few days Monophasic illness Resolves spontaneously No hearing loss	No	Clinical history Normal hearing Peripheral nystagmus Rapid (hours–days) resolution without recurrence
Infectious labyrinthitis	Usually, mild vertigo accompanying obvious sinusitis, otitis media, or serous otitis	Resolves over several days with resolution of otitis/sinusitis Very rarely: severe purulent labyrinthitis, mastoiditis, meningitis	No, unless conductive loss due to otitis associated	ENT examination: otitis media? serous otitis? sinusitis?
Toxic vestibulopathy	Vertigo and/or hearing loss associated with use of toxic drugs	Usually dose related and reversible after withdrawal or dose reduction of offending drug	Depends on drug, but sensorineural deafness is common with aminoglycosides, aspirin, loop diuretics, platinum; hearing is usually normal with alcohol and quinidine	Peripheral vertigo with or without hearing loss while/after patient takes vestibulotoxic drugs; most are reversible with discontinuation of drug

Cervicogenic vestibulopathy	Brief positional vertigo, associated with head and neck movements	Usually recurrent, brief, nondebilitating vertigo in patients with cervical spondylosis or other craniovertebral disease (rheumatoid arthritis, Klippel-Feil deformity)	No (but unrelated presbycusis common in this age group)	Typical history
				Nylen-Bárány maneuvers not consistent with benign positional vertigo
				Exclude:
				    Vertebrobasilar ischemia
				    Carotid sinus hypersensitivity

Cholesteatoma	Recurrent, often positional vertigo in patients with a history of chronic otitis, TM perforation, mastoiditis	Indolent progression of symptoms	Conductive	Usually visible (at superior border of tympanic membrane) on otoscope examination of ear
Otosclerosis	Progressive hearing loss, sometimes with intermittent vertigo	Indolent progressive hearing loss	Conductive	Family history Audiometry
Post-Traumatic				
Basilar (temporal bone) fracture	Severe vertigo, often with profound hearing loss immediately after head trauma	Gradual (days–weeks) resolution of vertigo; hearing loss, facial nerve injury often permanent	Often: sensorineural	Radiograph: fracture Hemotympanum? CSF otorrhea? Facial paresis?
Postconcussive	Ongoing, often mild/chronic vertigo after concussion, without fracture	Gradual resolution but often delayed for months–years	No	Persistent/chronic symptoms without evidence of other post-traumatic syndromes
Cupulolithiasis	Classic benign positional vertigo, but after head trauma	Same as for benign positional vertigo	No	Clinical history Nylen-Bárány maneuvers Exclude fistulas
Perilymphatic fistula	Trauma may be remote or indirect (swimming, diving injuries) Usually, positional vertigo, recurrent; or mild persistent vertigo	Post-traumatic vertigo that does not improve over time	Often: mixed or sensorineural	Clinical history Positive fistula test Valsalva maneuver: symptoms worsen?
Whiplash	Positional vertigo, worse with neck extension or turning, after deceleration neck injury	Gradual but slow improvement with resolution of neck symptoms	Usually none	Clinical history Exclude fractures and fistulas
Ossicular disruption	Hearing loss, acute vertigo, following head/facial trauma	Gradual (days) resolution of vertigo; hearing loss persists	Conductive	Clinical history Audiometry Exclude fistulas

CSF, cerebrospinal fluid; ENT, ear–nose–throat; TM, tympanic membrane.
Modified from Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:196-197.

TABLE 6.17	Central Vertigo	
Cause	**Clinical Clues**	**Diagnosis**
Vertebrobasilar ischemia	Known (suspected) vascular disease: hypertensive, diabetic Almost always accompanied by brainstem symptoms and signs: diplopia, dysarthria, dysesthesias, motor weakness	TIA: clinical history Stroke: neurologic examination CT scan may be unreliable MRI more sensitive Angiography?
Cerebellar hemorrhage	Hypertensive, anticoagulated, posttraumatic Sudden headache: diplopia, ataxia usually more prominent than vertigo	CT scan
Cerebellopontine angle tumors (acoustic neuroma)	Hearing loss, tinnitus much more prominent than vertigo Mild disequilibrium Early: normal neurologic examination, except sensorineural hearing loss Later: cranial nerves V and VII abnormal; papilledema?	Audiometry: retrocochlear, sensorineural hearing loss CT scan, MRI Internal audiometry canal tomography ENG, ABER
Multiple sclerosis	Optic neuritis Internuclear ophthalmoplegia Spastic paraparesis/incontinence Vertigo first isolated symptom in only 10% of cases	Multiplicity of symptoms and signs dissociated in time and space MRI scanning CSF: oligoclonal bands
Drug toxicity	Alcohol, sedatives, tranquilizers, opiates, anticonvulsants	Discontinue drug
Basilar migraine	Vertigo part of headache syndrome Usually positive family history	Clinical history
Vertiginous (temporal lobe) epilepsy	Vertigo as aura prior to loss of consciousness Very rare	Clinical history Exclude other diagnoses EEG

Cranial neuropathy	Many types, all uncommon:
	  Herpes zoster: external ear/palate skin lesions and cranial nerve VIII symptoms
	  Postinfectious: after viral syndromes: polyneuritis and/or cerebellitis and/or encephalitis
	  Chronic meningitis: syphilis, tuberculosis, sarcoid, carcinomatous
	  Vasculitis: Cogan syndrome, polyangiitis with granulomatosis, temporal arteritis, syphilis
	  Head and neck carcinoma
	  Vascular compression syndromes	

Others: Heredofamilial disorders (Friedreich ataxia, spinocerebellar degeneration, olivopontocerebellar degeneration) Cerebellar degeneration (alcohol, cancer) Tumor of brainstem, cerebellum Syrinx cervical cord Post-traumatic concussion		

ABER, auditory brainstem-evoked response; CT, computed tomography; CSF, cerebrospinal fluid; EEG, electroencephalography; ENG, electronystagmography; MRI, magnetic resonance imaging; TIA, transient ischemic attack.
Modified from Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:200.

The history is critical for patients complaining of dizziness or difficulty ambulating. For children, this includes a detailed developmental history, because the differential diagnosis varies significantly for children who were walking and then stop and for those who do not achieve that milestone. For younger children, it may be very difficult to determine whether refusal or reluctance to walk is related to imbalance, pain, or weakness. Nausea and vomiting are usually associated with vertigo but tend to be rare with disequilibrium. Nausea and vomiting may accompany a viral illness that results in an **acute cerebellar ataxia** and thus, may precede the onset of disequilibrium. If nausea is simultaneous with the disequilibrium, drug or alcohol intoxication must be considered. Morning nausea or vomiting can be seen with increased **intracranial pressure**, as in hydrocephalus and posterior fossa tumors. Any history of head trauma, especially in toddlers, and any history of congenital heart disease with the potential for paradoxical embolization, including septic emboli resulting in brain abscess, must be considered.

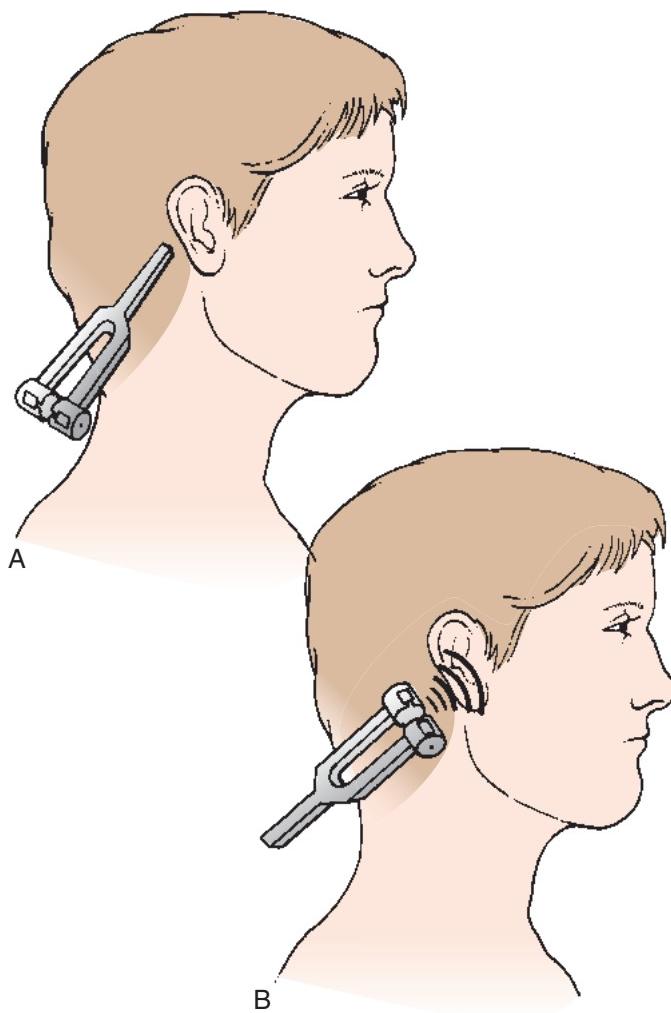
It is important to distinguish acute intermittent ataxia from more chronic or progressive forms (Tables 6.19 and 6.20). Drugs and **postviral cerebellitis** are common causes of acute sudden-onset ataxia. Varicella-associated postinfectious acute cerebellar ataxia usually comes after the infection, but in rare instances, it may occur before or during chickenpox. Its nature is benign. **Metabolic hereditary disorders** may cause intermittent symptoms provoked by fever, as in maple syrup urine disease, ataxia-telangiectasia, Hartnup disease, Refsum disease, pyruvate decarboxylase deficiency, abetalipoproteinemia, biotinidase deficiency, and some enzyme deficiencies. These must be distinguished from hypothyroidism, demyelinating disorders, muscular dystrophies, and neoplasms of the posterior fossa, brainstem, and spinal cord. **Paraneoplastic effects** of neuroblastoma produce ataxia,


FIGURE 6.7 The Rinne test. The tuning fork is first placed on the mastoid process *(A)*. When the sound can no longer be heard, the tuning fork is placed in front of the external auditory meatus *(B)*. Normally, air conduction is better than bone conduction. (From Swartz MH. *Textbook of Physical Diagnosis: History and Examination.* Philadelphia: WB Saunders; 1989:175.)

FIGURE 6.8 The Weber test. When a vibrating tuning fork is placed on the center of the forehead, the sound is normally heard in the center without lateralization to either side *(top)*. *A,* In the presence of a conductive hearing loss, the sound is heard on the side of the conductive loss. *B,* In the presence of a sensorineural loss, the sound is better heard on the opposite (unaffected) side. (From Swartz MH. *Textbook of Physical Diagnosis: History and Examination.* Philadelphia: WB Saunders; 1989:175.)

opsoclonus, and myoclonus. The Miller Fisher variant of **Guillain-Barre syndrome** produces ataxia, ophthalmoplegia, and areflexia.

Progressive ataxias have a poorer prognosis. Age at onset can be used to distinguish some causes: posterior fossa tumors and neuroblastoma generally occur within the first decade, Friedreich ataxia and Duchenne muscular dystrophy during the late first to second decades, and multiple sclerosis and diabetic peripheral neuropathy in the second decade.

Observation of the child's gait is an important component of the physical examination. Sufficient room should be found to allow the child to initiate walking, to proceed in a straight line for 10-20 paces and to turn and return. The normal child, older than 2-3 years, initiates walking without hesitation and steps smoothly with a consistent stride length and height and a narrow base. The arms should swing freely and rhythmically, alternating with the feet and there should be little sway in the trunk. When the child stops, there should be no hesitation again and no wavering or compensation. The observer should practice watching children walk normally to develop a sense for each part of the complex motion.

One of the most common gait abnormalities in children is the **wide-based gait**. Careful observation of toddlers at various stages of development familiarizes the observer with the transition from the wide-based, lurching steps of a 12-month-old to the smooth, sure, rhythmic stride of children older than 2-3 years. Excessive trunk sway is typical of cerebellar ataxia. Waddling tends to be caused by proximal muscle weakness with a forward leaning, stiff appearance. It is important to distinguish an unsteady gait with irregular steps from a limp or a sensory deficit resulting in a high step with a slapping foot plant.

In a toddler, passive and active range of motion exercises should be performed to ensure the observer that there is no joint or muscle pain. Reflexes, including the Babinski sign, should be carefully tested. Testing the sensory system in a toddler, especially proprioception, vibration, and two-point discrimination, can be a challenge. The Romberg test may also be difficult for younger children.

EVALUATION OF THE PATIENT WITH DISEQUILIBRIUM

◆ History

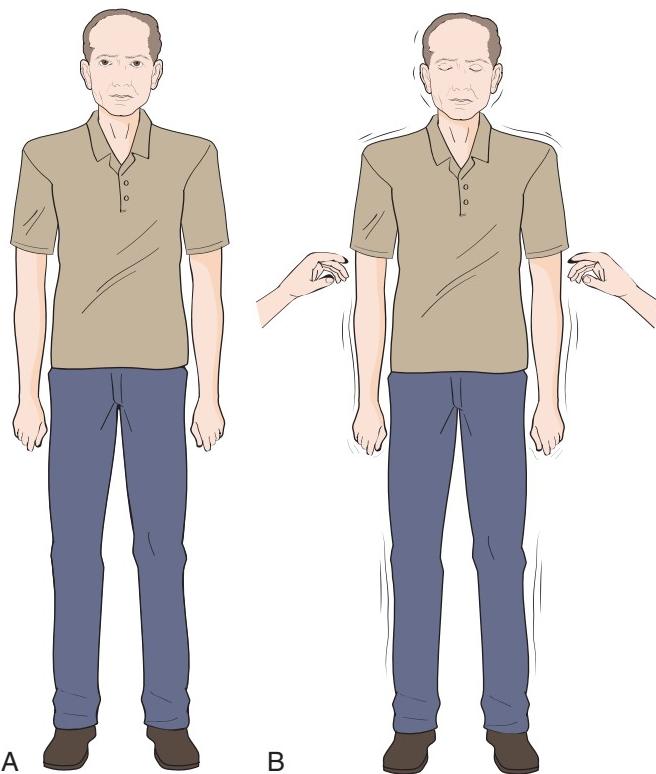
A detailed developmental history, especially for a younger child, is obtained. The family history should also be complete. The examiner should check for prodromal illnesses, especially viral (varicella) in nature:


FIGURE 6.9 The Romberg test. The patient stands upright, feet together, arms at sides. The examiner should stand next to the patient. The test is performed in two stages: with the patient's eyes open and then with the eyes closed. Even a normal person may experience mild subjective disequilibrium and may "waver" with the eyes closed. Thus, the Romberg test can sometimes stimulate the feeling of disequilibrium. *A*, With the eyes open, the patient can stand unsupported without difficulty. *B*, With the eyes closed, the patient loses his or her balance. This test result suggests peripheral neuropathy or vestibular dysfunction or both. Cerebellar disease more often results in an inability to maintain posture with the eyes either open or closed. (From Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:168.)

FIGURE 6.10 The afferent, integrative, and efferent components of the equilibrium system. (From Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:166.)

Is there any history of trauma?

What is the character of the disability?

Does the child feel unsteady standing, starting to walk, stopping or turning?

How do the parents characterize the child's gait?

Are there associated symptoms, such as nausea, vomiting, pain, or vertigo?

Does the child take or have access to any medications or drugs?

Is the disequilibrium intermittent or constant?

Are there any other medical conditions?

◆ Physical Examination

A thorough general physical examination should precede a very detailed neuromuscular examination. The presence of a goiter, cutaneous lesions of neurofibromatosis or tuberous sclerosis may point to a diagnosis immediately. The neuromuscular examination should proceed from head to toe in an organized and systematic manner. Muscle tone, bulk, and symmetry of the face, trunk and extremities are important. Cranial nerves should be examined, as should the sensory system. During the motor examination, the physician should isolate muscle groups and joints by observing the gait more than once before assessing overall function. The Romberg test should be performed in all patients old enough to cooperate, as should the lateralizing cerebellar tests, such as the finger-to-nose and rapid, alternating movements. Attention to detail in the history and physical examination findings usually yields a diagnosis.

◆ Diagnostic Tests

Other than for drug ingestion, obvious peripheral neuropathies or myopathies, focal extremity infections, or varicella-associated cerebellar ataxia, magnetic resonance imaging is the principal diagnostic test for children and adolescents with disequilibrium. Metabolic tests and thyroid function tests are indicated by either history or physical findings. Especially in younger children, imaging is necessary to rule out the posterior fossa tumors and demyelinating diseases. The lumbar puncture and analysis of the cerebrospinal fluid may also be indicated in cases preceded by a viral or infectious prodrome. When weakness is associated with the disequilibrium, there may be a place for electromyography and nerve conduction studies.

SUMMARY AND RED FLAGS

Ataxia can be seen in children at any age; it may portend serious pathologic processes, including posterior fossa tumors, leukodystrophies, metabolic disorders, and familial-hereditary disorders. The history must be obtained carefully, with attention to developmental milestones, family history, and specifics of prodromal illnesses (chickenpox), associated symptoms, and a description of the gait. The physical examination must also be detailed and methodical, with special emphasis on the neuromuscular examination. Imaging studies of the central nervous system are usually required, especially for younger children, in whom the possibility of neoplasms is the greatest.

TABLE 6.18 Disequilibrium

Cause	Clues	Gait/Romberg Test Result
Most Common		
Multiple sensory deficits	Visual impairment? Hearing/vestibular dysfunction? Neuropathy? Spondylosis/degenerative joint disease? Neuropathy? Weakness?	Timid: slow, short-stepped, apprehensive Remarkably improved with sensory assist (cane, companion) Romberg: normal or sensory
Hyperventilation/anxiety disorders	Young, healthy, anxious patient with *episodic "spells"* of disequilibrium *or* Constant, chronic, elusive disequilibrium with or without obvious medical/psychosocial stress	Usually normal gait Romberg: normal *or* "Nonphysiologic"
Vestibular disorders	*Chronic* unilateral vestibulopathy may cause ongoing disequilibrium: Ménière disease, cholesteatoma, fistula, acoustic neuroma, drug-induced vestibulopathy	Usually normal gait May veer to side of vestibular lesion Romberg: sensory
Drug induced	Central nervous system agents: tranquilizers, barbiturates, sedatives, alcohol, H_2 blockers, β blockers, calcium agents, indomethacin Vestibulotoxic agents: aspirin, loop diuretics, aminoglycosides, quinidine	Timid and/or ataxic gait Romberg: normal or cerebellar Romberg: sensory or normal
Alcoholic	Heavy alcohol abuse may cause cerebellar and/or sensory degeneration Nystagmus uncommon	Ataxic gait Romberg: cerebellar or sensory
Painful ambulation	Arthritis? Claudication? Pain is limiting factor!	Limping? Waddling? Normal gait? Romberg: usually normal
Fear of falling	Normal examination No apraxia or ataxia Rarely, phobic	Timid gait Romberg: often cerebellar but fluctuates, inorganic
Less Common		
Hypothyroidism	Weight gain or poor growth, cold intolerance, hoarseness, fatigue	Usually normal gait Severe: ataxic gait
Hypoglycemia	Episodic	Romberg: usually normal
Apraxia	Usually diffuse cortical dysfunction or frontal lobe disease Usually apraxic in execution of other skilled movements (e.g., combing hair, brushing teeth)	Apraxic gait Romberg: normal
Peripheral disease	Diabetes, alcoholism, pernicious anemia Only very severe (proprioceptive) neuropathy causes gait disorder	Sensory gait: footdrop and/or circus clown Romberg: sensory
Cerebellar disease (nonalcoholic)	See text	Ataxic gait Romberg: cerebellar
Spasticity	Multiple sclerosis, spinal cord tumor/trauma Legs: weak, hyperreflexic, clonus Often bowel/bladder dysfunction	Spastic, scissors gait Romberg: often normal
Normal-pressure hydrocephalus	Urinary incontinence Cognitive impairment Gait disturbance	Ataxic/apraxic
Hemiplegia	Prior cerebrovascular accident Hemiparesis on neurologic examination	Hemiplegic gait Romberg: often normal (if able to perform at all)
Proximal myopathy	Severe bilateral proximal leg weakness: hip disease, muscular dystrophy, myositis, etc.	Waddling gait Romberg: normal
Hysterical	Unpredictable, intermittent or bizarre "Secondary gain"	Gait varies: sometimes normal, timid, limping, apraxic Romberg: often cerebellar, but fluctuates, inorganic

LIGHTHEADEDNESS

Lightheadedness is the most difficult to characterize without using the term "dizzy." The lightheaded patient's description is vague and non-specific. Terms such as "woozy," "spaced-out," "dreamy," "giddy," or "drugged" are frequently used. The key for the clinician is to elicit an adequate description from the patient to rule out vertigo, disequilibrium, and presyncope. The differential diagnosis for lightheadedness is then rather short in comparison with the other "dizziness" conditions (Fig. 6.11). It is often difficult to distinguish lightheadedness from presyncope.

In the patient who complains of lightheadedness, voluntary hyperventilation may reproduce his or her symptoms. Voluntary hyperventilation in normal subjects produces a variety of symptoms (Table 6.21). This test is predictive only if the patient's symptoms are precisely reproduced, and all other investigation results are negative.

Lightheadedness that is episodic frequently follows a pattern related to the underlying psychogenic disorder: phobic disorders, post-traumatic stress syndrome, panic attacks, and anxiety disorders. Such situational anxieties, phobias, or panic attacks may occur with or without hyperventilation. Careful history taking is the key to recognizing the pattern. If the history is that of constant lightheadedness ("always there"), the origin is almost always psychogenic. This is a **somatization** generally of anxiety disorder or depression. The clinician must nonetheless remain cautious with predictable episodes because postural episodes, drug-related episodes, and perimenstrual episodes

can follow a pattern and represent physiologic abnormalities that predispose to lightheadedness.

Especially if the episodes of lightheadedness are unpredictable, the clinician is advised to consider a broader differential diagnosis. Severe anemia, low cardiac output, thyroid disease, and some medications may produce occasional lightheadedness. Of greater concern are episodes of lightheadedness associated with other symptoms, especially chest pain, seizures, confusion, and visual or auditory changes. Likewise, exertional lightheadedness must be pursued to definitively rule out a cardiac dysrhythmia.

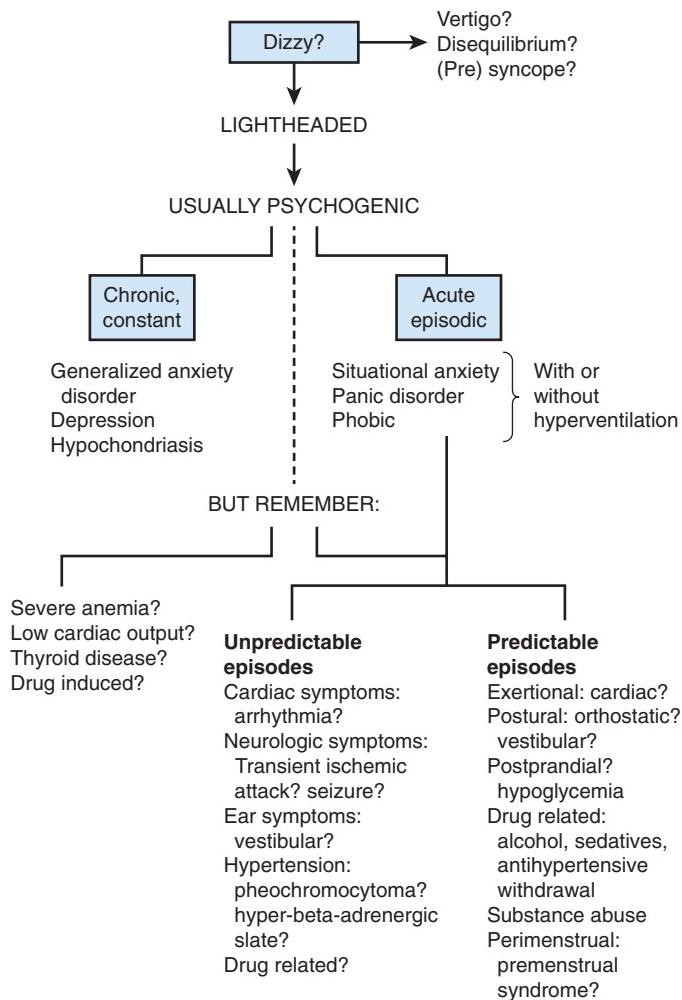
If hyperventilation reproduces the patient's symptoms, it is not the diagnosis in and of itself. Hyperventilation is a feature of many psychogenic syndromes and may be acute or chronic. Part of the performance of the hyperventilation should be educating the patient to the feelings and the scenario leading to the hyperventilation reaction. Even young children can then be trained to regulate their breathing to avoid the symptoms. However, this does not address the underlying cause of


FIGURE 6.11 Evaluation for lightheadedness (From Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:206.)

the hyperventilation reaction; that requires patient, nonjudgmental, longer term counseling, and careful categorization of the underlying disorder. The clinician should not hesitate to consult a psychiatrist to facilitate this process as well as treat the definitive psychogenic disorder.

EVALUATION OF THE PATIENT WITH LIGHTHEADEDNESS

◆ History

The examiner should listen for descriptions suggesting vertigo, disequilibrium, or presyncope and should establish whether there is any pattern to the occurrence of the feeling of lightheadedness. The child, parents, or siblings are asked about associated symptoms, such as diaphoresis, hyperpnea, pallor or flushing, headache, and chest pain. After the more serious physiologic disorders are ruled out by history, physical examination, or diagnostic testing, psychogenic disorders should be pursued.

◆ Physical Examination

After a thorough general physical examination, including examination of the fundi, a full, detailed neurologic examination should be performed. In addition to allowing primary cardiac, endocrine, or

neurologic disorders to be ruled out, the examination allows the clinician to gain the confidence of the patient and demonstrates the physician's concern about the patient's complaints. The patient should be given feedback, reassurance, and information about the purpose of various maneuvers in the physical examination.

◆ Diagnostic Tests

Diagnostic testing is directed by the history and physical examination findings. In the setting of lightheadedness, tests are generally done to rule out potentially serious cardiovascular and neurologic conditions.

SUMMARY AND RED FLAGS

Lightheadedness must be distinguished from vertigo, disequilibrium, and presyncope. Frequently, the patient's description of the sensation is vague and uncertain. A pattern of the appearance of the symptoms may suggest an underlying cause. The coexistence of any other symptoms must be carefully sought. Physical findings are generally normal, including the neurologic examination; specific attention is given to cerebellar, vestibular, and sensory function. Voluntary hyperventilation in the supine position frequently reproduces the patient's lightheadedness. Hyperventilation may be acute or chronic and is a symptom itself, rarely a diagnosis.

Treatment must address the underlying psychogenic cause in order to be successful.

Chest Pain

Julie M. Kolinski

Chest pain can be the presenting complaint for a child feeling chest tightness, burning, pressure, stabbing sensations, palpitations, or heartburn. This can make quickly discerning an etiology difficult, particularly in young children who are not able to verbalize precise symptoms. Chest pain as a symptom affects equal numbers of girls and boys and children under and over 12 years of age. Diagnostically, children younger than 12 years with chest pain are more likely to have cardiorespiratory etiologies for their pain; whereas, adolescents are more likely to have musculoskeletal or psychogenic etiologies.

The general public has been adequately educated on the significant morbidity and mortality that chest pain can imply in adults in the form of cardiac ischemia. Therefore, when children complain of chest pain, it can provide significant anxiety for patients, families, and providers. Due to this anxiety, cardiology consultation is often sought. Unlike adults, underlying cardiac pathology is rare in children with chest pain. Only 4-6% of children without known congenital heart disease are found to have a cardiac etiology. The challenge for the medical care provider is to distinguish chest pain as a commonly benign pediatric complaint from significant cardiac disease, limit unnecessary evaluation, and provide adequate reassurance for an anxious patient and family.

Due to the rarity of cardiac pathology as the cause for chest pain, it is difficult to develop evidence-based guidelines for evaluation, and the implication of a misdiagnosis of a serious disorder is high. Chest pain caused by noncardiac causes may be the combination of multiple diagnoses, leaving medical providers seeking to "rule out" life-threatening cardiac causes of chest pain. The evaluation, if nonconclusive, can leave patients and families without precise answers. Most final diagnoses of noncardiac chest pain represent clinical impressions rather than confirmed diagnoses; between 20 and 45% of pediatric cases of chest pain are labeled idiopathic. The lack of a defined etiology or the presence of multiple causes for a particular patient can heighten worry, anxiety and subsequent morbidity, which is reflected in missed days of school, reduced exercise, and psychologic distress. Furthermore, chest pain can become a chronic condition in the pediatric population; up to 45-69% of patients have been noted to have persistent symptoms with 19% of patients reporting symptoms lasting for more than 3 years.

Overall, if medical providers methodically approach a child or adolescent's complaint of chest pain, they can provide thoughtful diagnostic evaluations that not only discover serious cardiac pathology if present but also reassure families when a noncardiac etiology is suspected.

CAUSES OF CHEST PAIN

The most common causes of chest pain in descending frequency include idiopathic, musculoskeletal, pulmonary, psychogenic, gastrointestinal, and cardiac diagnoses (Table 7.1). A differential diagnosis of pediatric chest pain is listed in Table 7.2. The etiology of chest pain in the absence of cardiac pathology can be multifactorial and includes multiple items on this list.

APPROACH TO THE PATIENT WITH CHEST PAIN

A practical approach to chest pain first requires a detailed history and physical examination. An awareness of indicators (red flags) and prioritization that may suggest serious disease and necessitate immediate treatment are essential (Table 7.3 and Table 7.4). *In particular, children and adolescents who have chest pain or syncope that is exertional should be taken seriously, particularly if there is a family history of sudden death.* Children rarely come in complaining of "shortness of breath on exertion" or "palpitations." Instead, children should be asked if they keep up with their same-age peers when participating in activities, if they finish last in races, or whether they have to pause in the middle of a flight of stairs. If concerned for palpitations, a provider can ask if a child's heart ever skips a beat or seems to do flip flops or somersaults in their chest. If red flags are not present but a potentially serious noncardiac etiology of chest pain is suspected, a continued investigation of the pain itself is necessary to make a diagnosis; it can also serve as a therapeutic intervention. A deliberate, orderly, and complete approach to the clinical evaluation often calms an anxious child and family.

A complete history and physical examination usually with an electrocardiogram (ECG) used to diagnose chest pain allows medical providers to avoid missing life-threatening cardiac pathology. Further testing has been debated when this evaluation indicates a noncardiac diagnosis as the vast majority of patients with a cardiac cause of chest pain have had suggestive symptoms (exertional chest pain, concerning family history findings, abnormal examination findings, and/or abnormal ECG findings), which appropriately lead to further investigation. The considerable anxiety generated among patients, families, and even providers in regard to this symptom can promote evaluations that are extensive, costly, and often low yield.

◆ History

The goal of a thorough history of a patient with chest pain is to determine if the etiology is life threatening, a manifestation of a chronic condition with possible serious complications, a specific acute cause or multiple acute and/or chronic causes. Although chest pain affects children and adolescents of all ages equally, the age of a child can assist in diagnosis. Adolescents are more likely to have musculoskeletal or psychogenic causes of chest pain, while younger children have more respiratory disorders and vague complaints.

One possible approach includes a stepwise, directed history that includes:

(See *Nelson Textbook of Pediatrics,* p. 2155.)

TABLE 7.1 **Causes of Chest Pain in Children and Adolescents by Frequency of Causes**	
Idiopathic	12-85%
Musculoskeletal	15-31%
Pulmonary	12-21%
Psychiatric	5-17%
Gastrointestinal	5-7%
Cardiac	4-6%
Other	4-21%

- Description of pain (Table 7.5)
- Assessment for red-flag symptoms, including targeted family history
- Medication review
- Review of known illnesses
- Review of systems including psychosocial evaluation

Eliciting the basics of the chest pain's duration, quality, propensity to radiate, severity, and timing is essential. Details that have been noted to be particularly helpful include duration, aggravating and relieving factors, and associated symptoms. Severe pain that lasts only a few seconds up to 1 or 2 minutes is often from the chest wall, but chest pain that persists longer is more likely to be organic in nature. Aggravating and alleviating factors can include position changes that accompany the pain from pericarditis or onset after eating spicy foods in gastroesophageal reflux. The character and location of the pain in pediatric patients are less helpful in the diagnostic evaluation due to often vague descriptions; nonetheless, medical providers should continue to obtain this information to understand the whole picture. Providers should remember that children often complain of chest pain when the pain is in a different place, such as the epigastrium or flank. Finally, it is important to determine whether or not the chest pain has had an impact on the child's activity.

Red-flag symptoms (see Table 7.3) are high-yield, must-know characteristics of a child or adolescent's chest pain. Oftentimes, after a patient's complete description of the pain, a medical provider will already know the answers to multiple red-flag symptoms, such as when the pain occurs, if it wakes the patient from sleep, and if it is associated with syncope. A targeted family history includes asking about inherited conditions such as familial hypercholesterolemia, hypertrophic cardiomyopathy, asthma, and Marfan syndrome. It also can provide information regarding relatives with adult-onset cardiac illnesses associated with chest pain, such as heart failure or ischemia, which may be providing added anxiety for the family.

Medications that the child may already be taking are important to consider. Some medications have specific links to etiologies of chest pain, such as tetracyclines with erosive esophagitis or oral contraceptives with pulmonary embolism. Other illicit medications such as cocaine and other sympathomimetic agents (such as amphetamines, synthetic marijuana) have been associated with chest pain. A child's known underlying illnesses and surrounding medical complaints discovered in a review of systems can complete the clinical picture for medical providers. The presence of joint pain or rash could suggest collagen vascular disease or the presence of increased drooling could represent an esophageal foreign body.

A full psychosocial review should be performed on each patient to ensure that details of personal stressors and behaviors emerge. It is useful to learn about these aspects of the child's chest pain from

TABLE 7.2 **Differential Diagnosis of Pediatric Chest Pain**

Musculoskeletal
Trauma (accidental, abuse)
Exercise, overuse injury (strain)
Costochondritis
Tietze syndrome
Precordial catch syndrome
Slipping rib syndrome

Esophageal rupture
Cholecystitis
Subdiaphragmatic abscess
Perihepatitis (Fitz-Hugh–Curtis syndrome)
Peptic ulcer disease
Pancreatitis

Cardiac
Hypertrophic cardiomyopathy
Aortic stenosis
Mitral valve prolapse
Dilated cardiomyopathy
Pericarditis
Myocarditis
Endocarditis
Idiopathic ventricular tachycardia
Exercise-induced ventricular tachycardia
Wolff-Parkinson-White syndrome
Aortic dissection
Pulmonary hypertension
Ischemia (anomalous coronary artery, systemic lupus erythematosus, post heart transplant, Kawasaki disease, sympathomimetic drugs, hypercholesterolemia)

Other
Herpes zoster (cutaneous)
Sickle cell anemia vasoocclusive crisis (rib infarction)
Primary or metastatic cancer
Splenic rupture
Drug-related: cigarette smoking, cocaine use, sympathomimetic use, tetracycline ingestion
Anorexia nervosa
Breast-related disease

TABLE 7.3 Red Flags That Increase the Likelihood of a Cardiac Cause for Chest Pain

Sudden onset of severe pain
Pain occurs with exercise
Exertional syncope
Pain that awakes the patient from sleep
Palpitations and/or dysrhythmias
Family history of sudden death, young onset ischemic heart disease,
    inherited arrhythmias such as long QT syndrome or Brugada syndrome,
    deep vein thrombosis or pulmonary embolism
Cyanosis
Personal past or current history of congenital heart disease
Personal history of connective tissue disease, hypercoagulable or
    hypercholesterolemic state, systemic lupus erythematosus, Kawasaki
    disease, sickle cell anemia, Marfan syndrome, cystic fibrosis, Ehlers-
    Danlos syndrome
Personal history of cocaine, huffing, and/or amphetamine use

TABLE 7.4 Categorization and Prioritization of Chest Discomfort

Category 1: Does the Complaint Indicate Life-Threatening Emergency, Such As…
Acute ischemic heart disease
Aortic dissection
Pulmonary embolism
Spontaneous pneumothorax/pneumomediastinum
Acute arrhythmia

Indicators:
Acute onset
Severe pain
High or low blood pressure
Significant tachycardia
Cyanosis
Loss of consciousness
Pleuritic-type pain

Category 2: Does the Complaint Indicate a Chronic Condition That Might Result in Serious Complications, Such As…
Aortic stenosis
Pulmonary hypertension
Coronary disease
Hypertrophic cardiomyopathy
Marfan syndrome
Nonbenign cardiac arrhythmias, such as Wolf-Parkinson-White syndrome,
    long QT syndrome, ventricular arrhythmias

Indicators:
Recurrent intermittent discomfort, especially with exercise
History of syncope
Family history of heart disease
Heart murmur

Category 3: Does the Complaint Indicate Specific Acute Causes, Such As…
Asthma
Pericarditis
Pneumonia
Pleural effusion
Herpes zoster
Chest wall injury
Hyperventilation

Indicators:
Acute onset
Fever
Associated signs and symptoms of lung disease, such as cough or dyspnea

Category 4: Does the Complaint Indicate Specific Chronic Causes, Such As…
Gastroesophageal reflux disease
Fibromyalgia
Panic disorder

Indicators:
Chronic intermittent symptoms
Other gastrointestinal symptoms
Psychosocial indicators such as school absences, mood symptoms, family
    problems

the child and the parent/family separately. Make sure to interview the patient alone if the child is older or an adolescent. It is difficult for children to discuss areas of difficulty, such as family relationships, school difficulties or concerns about physical development, with family present. It is useful to ask "What are you concerned that this pain is caused by?" of both the patient and the family. This question frequently gives information about overriding fears and concerns that can help medical providers know how to appropriately reassure the family in the likely event that the chest pain has a benign, noncardiac etiology.

Musculoskeletal

Musculoskeletal chest wall pain is perhaps the most identifiable cause of chest pain due to its association with localized tenderness elicited by specific manipulation of the thorax (Fig. 7.1). Pain can involve the ribs, costochondral junctions, costal cartilages, intercostal muscles, sternum, clavicle, or spine. The pain is often worse with movement, coughing, and inspiration. In considering musculoskeletal etiologies, thoroughly consider any trauma to the chest wall. Both contusion and rib fracture can be particularly painful with exquisite tenderness on palpation and pain on inspiration. Table 7.6 highlights common causes of musculoskeletal chest pain.

In general, chest wall pain can result from the strain of any muscle group present in the chest; however, multiple syndromes have been described in relation to specific patterns of muscular pain (Fig. 7.2). Some of these syndromes include pectoral syndrome (pain in a band across the anterior parasternal chest wall on the right or the left), coracoid syndrome (pain at the site of the pectoralis minor muscle with tenderness at its insertion onto the coracoid process), and xiphoid process syndrome (pain over the xiphoid process).

Respiratory

Respiratory causes of chest pain are often diagnosed through use of history and general appearance of the patient (Table 7.7). Some of these causes can require urgent evaluation and treatment. In a patient with sudden, significant chest pain, medical providers should consider acute pneumothorax or acute pulmonary embolism (along with acute pericarditis, myocarditis, or aortic dissection—discussed in cardiac etiologies of chest pain). Asthma or reactive airway disease is more likely in a patient with audible wheezing and cough. Notably, patients with chest pain from undiagnosed causes after complete evaluation

have a greater likelihood than normal control subjects to have abnormal results on methacholine challenges and exercise testing, indicating reactive airway disease is a more common etiology of chest pain than providers realize. Finally, pneumonia and respiratory infections are the most common causes of chest pain when it presents with fever.

Psychogenic/Idiopathic

Psychogenic causes of chest pain are more common in adolescents than in children under the age of 12. Patients with psychogenic etiologies of chest pain may also have additional physiologic causes of pain;

> ### TABLE 7.5   Historical Features of Chest Pain That Are Essential to Its Assessment
>
> Duration of pain (how long present but also duration of each episode)
> Acuteness of onset
> Severity of pain (use scale of 1-10)

> Recent activity, injury, and stresses
> Full psychosocial review, including behaviors
> Medical history
> Family medical history

psychologic risk factors can amplify the clinical presentation of chest pain. Psychologic forms of chest pain are typically recurrent with particular stressors. Children and adolescents may have a history of anxiety and/or stressful life events that are not easily apparent but can have a large impact on their perception of pain. Many psychologic factors, such as anxiety, depression, and psychosomatic features often coexist. Patients with psychogenic causes of chest pain are the most likely to have other somatic symptoms, including breathlessness, fatigue, nervousness, near-syncope, and palpitations. These patients also often demonstrate more bodily worries, more limitation of general activity, and more school absences. The most common etiologies of psychogenic chest pain are hyperventilation and underlying psychiatric illness, such as anxiety, depression, or somatoform disorders (conversion or somatization).

Hyperventilation, most often in the setting of a **panic attack**, is characterized by rapid breathing accompanied with dyspnea and anxiety to the degree that systemic symptoms result, such as paresthesias, dizziness/lightheadedness, palpitations, and confusion (Table 7.8). This can occur as an acute one-time episode or can represent an underlying panic disorder if recurrent. These symptoms are manifestations of physiologic phenomena caused by hypocapnic respiratory alkalosis, chest muscle strain from use of accessory muscles, tachycardia and arrhythmias, spasm of the diaphragm, and gastric distention caused by aerophagia (Fig. 7.3). Typically, the patient's chest pain complaint will include sharp, nonradiating pain over the left precordium. It is the easiest to diagnose when these symptoms arise without exertion. However, it is often difficult to differentiate hyperventilation from asthma as both diagnoses can include dyspnea, chest tightness, cough during exercise, and symptoms characteristic of bronchospasm.

**FIGURE 7.1** Palpable and/or visible abnormalities of the chest wall that may be found in different chest wall syndromes. In addition, various proximal abdominal causes of chest pain, such as disease of the gallbladder, liver, stomach, pancreas, or subdiaphragmatic space must be considered. (From Reilly BM. Chest pain. In: *Practical Strategies in Outpatient Medicine*. 2nd ed. Philadelphia: WB Saunders; 1991.)

TABLE 7.6   Causes of Musculoskeletal Chest Pain

Signs and Symptoms	Diagnosis
Aching pain after new or intense exercise or repetitive coughing Can appear up to 2 days later Pain reproduced by range of motion testing or palpation	Muscular strain
Sharp, anterior pain over costochondral junctions Exacerbated by deep breathing 1st through 5th ribs are most common	Costochondritis
Sharp, localized pain at one costochondral junction Area is swollen, ± warm, erythematous bulbous or fusiform 1-4 cm mass 2nd or 3rd costochondral junction is most common Age predominance in adolescents and early twenties	Tietze syndrome
Pain and increased mobility of 8th, 9th, or 10th ribs (which are not attached to the sternum), resulting in impingement of superior intercostal nerve Intermittent sharp pain in chest or upper abdomen Brought on by exertion, especially sudden upward and anterior movement ("hooking maneuver"; see Fig. 7.2) Can have popping sensation at onset of pain Caused by trauma or dislocation of these ribs	Slipping rib syndrome (lower rib pain syndrome)
Brief (30 sec–3 min), nonradiating, sharp pain in the left parasternal area or cardiac apex ("Texidor twinge") Occurs at rest or with mild activity Exacerbated with inspiration and alleviated by shallow breathing or straightened position Related to poor posture	Precordial catch syndrome
Pain over both anterior chest and back Spasm in muscles innervated by nerve root causes pain No midline spine bony tenderness History of vertigo, headache, pain after prolonged recumbence or straining	Spinal cord or nerve root compression, typically lower cervical or upper thoracic spine
Chronic aching and stiffness Multiple points of tenderness on palpation of muscle with minimal pressure Associated with fatigue and sleep disturbance	Fibromyalgia

Hyperventilation can also occur concurrently with costochondritis or asthma, further complicating diagnosis.

Anxiety, depression, and somatiform disorders can cause episodic chest pain with or without hyperventilation. Within anxiety disorders, chest pain and other symptoms are typically temporally related to stressful situations. Anxiety-related psychogenic chest pain is 4 times as likely to occur in a patient with a family history of chest pain (often an adult with a history of cardiac ischemia), and the pain is often fleeting and vague in its description.

Gastrointestinal

Esophagitis (reflux, infectious, eosinophilic) and esophageal motility disorders (diffuse esophageal spasm, achalasia) can cause chest pain in both adults and children. Esophagitis is characterized by symptoms typical of "heartburn," a substernal burning sensation that is exacerbated by eating or position changes, specifically lying supine. However, heartburn is less common in children with esophagitis than adults. More commonly, children will have the presence of epigastric tenderness on exam. In fact, epigastric tenderness is one of the best indicators of a gastrointestinal etiology of pain in a child. Often, a trial of H_2-blocking agents or proton pump inhibitors helps diagnostically and therapeutically in the evaluation of esophagitis. Motility disorders of the esophagus cause chest pain that lasts from only a few seconds to several hours. The pain is nonexertional but can be exacerbated by bending forward. Achalasia classically causes dysphagia, nocturnal regurgitation, and chest pain. It can occur at any age and the chest pain is variably associated with the diagnosis (19-95% of the time). Eosinophilic esophagitis can cause chest pain secondary to esophageal inflammation, dysmotility, and reflux. Other notable gastrointestinal disorders can also cause chest pain including esophageal foreign body, gastric and duodenal ulcers, cholecystitis, pancreatitis, hepatitis, and infections of the subdiaphragmatic space. Esophageal rupture is a rare cause of chest pain; it has been described in patients with bulimia nervosa or after surgical repair of a tracheoesophageal fistula.

Other

Other causes of chest pain are diverse and variable. Patients with herpes zoster often experience chest pain *prior* to the typical vesicular rash over a unilateral dermatome. These patients can continue to have burning chest pain for weeks to months. Breast-related causes of chest pain can occur in both males and females. Females may complain of throbbing or burning chest pain caused by fibrocystic disease, fibroadenoma, swelling with menstruation, mastitis, or pregnancy. Gynecomastia in males can lead to unilateral or bilateral chest pain. Substance abuse of tobacco and/or cocaine in addition to other sympathomimetic substances can also cause chest pain. Other medications, such as tetracyclines, iron, or nonsteroidal antiinflammatory agents, can cause pill-induced esophagitis. Foreign bodies in the airways and/or esophagus can be unusual causes of chest discomfort; these diagnoses are typically evident due to other symptoms such as dysphagia, drooling, choking, stridor, or dyspnea. Neoplastic diseases such as mediastinal tumors or lymphomas can also manifest primarily as chest pain.

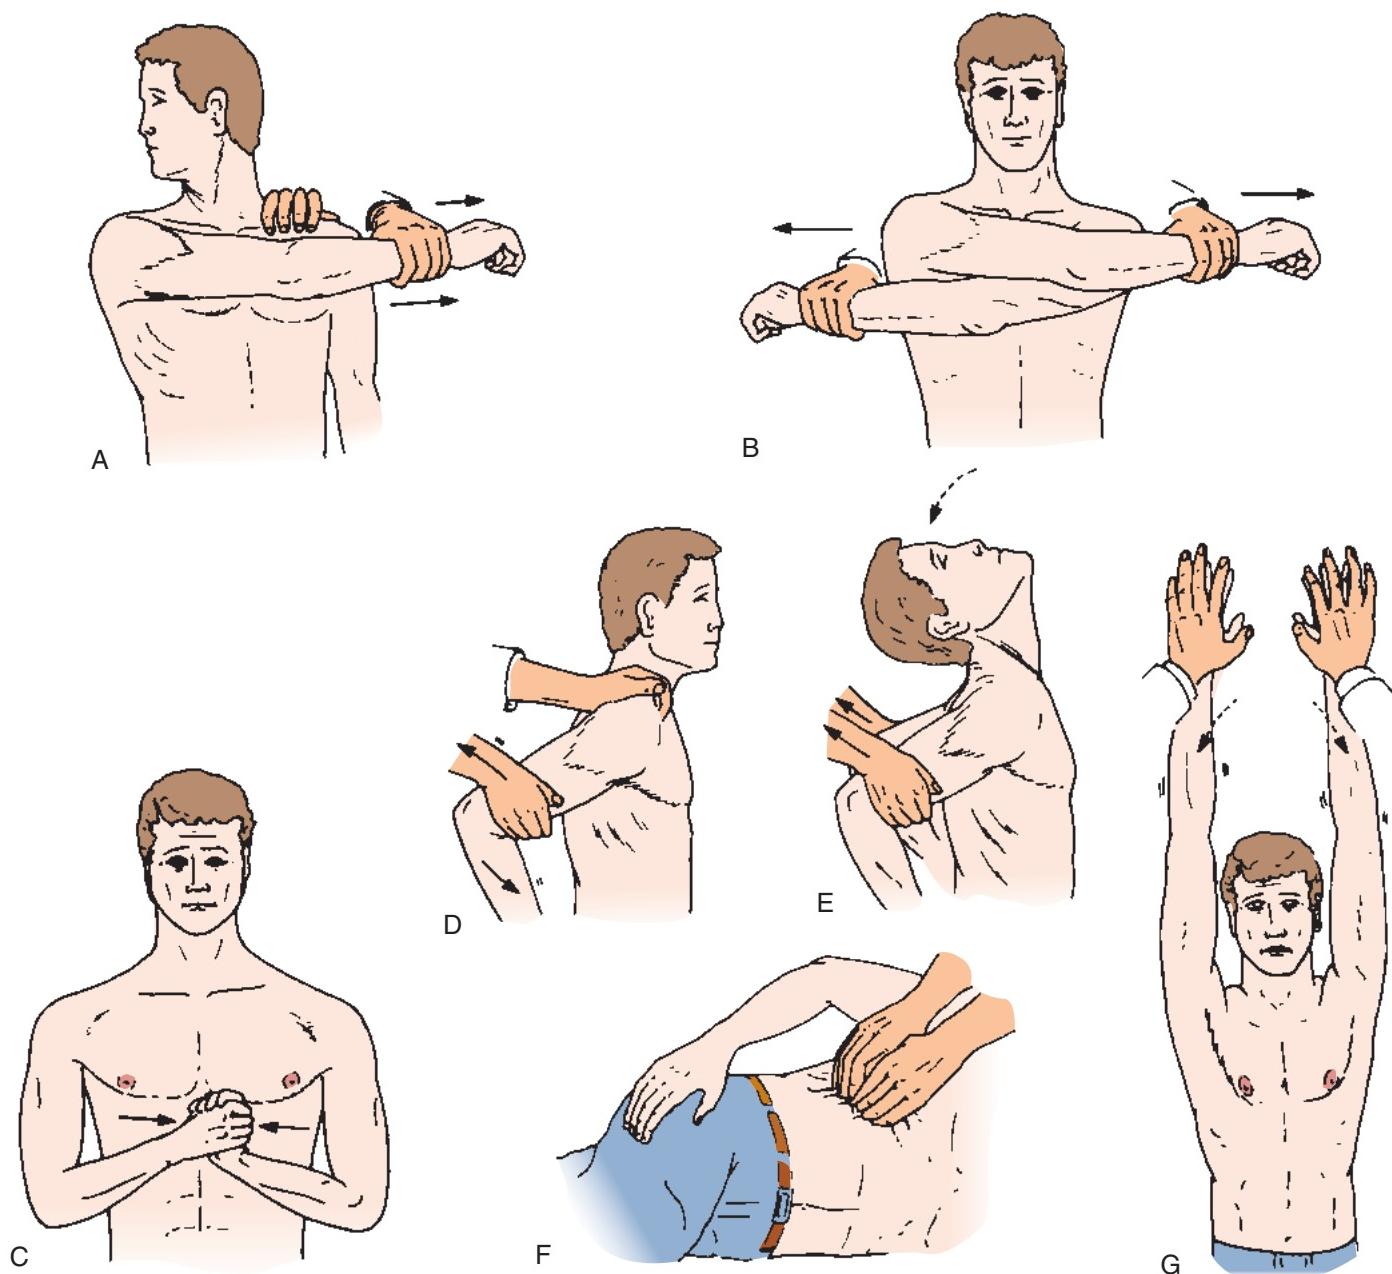
In addition, certain underlying disease processes have clinical courses that can manifest as chest pain. In patients with sickle cell anemia, chest pain can be secondary to acute chest syndrome and rib or pulmonary infarction. Long-term complications of Kawasaki disease include coronary artery stenosis and coronary artery aneurysm, both of which can present as chest pain. Patients with these cardiac complications of Kawasaki disease often have associated symptoms of fatigue, shortness of breath, and diaphoresis. Patients with Marfan syndrome are at high risk for dissecting aortic aneurysm, as are patients with Turner syndrome, type IV Ehlers-Danlos syndrome, and homocystinuria. A dissecting aortic aneurysm will often have the history of a sharp, sudden onset of chest pain with radiation to the back. Rheumatic fever is an acquired condition that can present with the major manifestations of carditis, which may include tachycardia out of proportion to degree of fever, mitral regurgitation or aortic regurgitation, and signs of pericarditis or heart failure. Chest pain also can be present before the onset of lower spinal symptoms in ankylosing spondylitis, a disease of the sacroiliac joints with variable involvement in the thoracic and cervical spine. A phenomenon that can occur with any cardiac procedure is postpericardiotomy syndrome, which includes fever, chest pain, and an audible friction rub approximately 1-2 weeks post-surgery.


FIGURE 7.2 Chest wall maneuvers. *A, B,* The "scissors" maneuver. The patient's arm is adducted across the anterior chest, and the examiner pulls the patient's hand beyond the contralateral shoulder *(A).* When both arms are tested together, traction is applied to both *(B)*; the patient turns the head to either side, and the arms form a "scissors." Pain originating in the scapula, thoracic spine, pectoral muscles, or ribs and intercostal structures is often precipitated by the scissors maneuver. *C,* The "hedge clipper" maneuver. The pectoralis major muscles are stressed by the patient's pressing the palms forcefully together with the elbows flexed anterior to the chest. The pectoral muscles are thus more clearly defined, and pain is often appreciated within the muscles or at their insertion in the upper parasternal area (see Fig. 7.1). *D,* The "racing dive" maneuver. The pectoralis minor muscles are stressed by forcefully resisting the patient's attempt to throw forward the shoulder and upper arm from an initial position behind (dorsal to) the chest wall. The attempted arm motion is that of flinging the arm and hand forward, as a swim racer would when beginning a racing dive. The examiner resists this forward arm and shoulder motion. *E,* The "crowing rooster" maneuver. The patient hyperextends the neck while the examiner lifts both of the patient's arms backward and superiorly. Pain originating in the cervical spine or anterior chest wall or both is often thus reproduced. *F,* The "hooking" maneuver. With the patient supine, the examiner stands at the patient's side, facing the patient's feet. The examiner then "hooks" his or her fingers around the lower costal margin of the patient's rib cage and pulls anteriorly (ventrally) and superiorly (cephalad). This maneuver may elicit pain when costochondritis or traumatic rib injuries involve the lower rib cage, when the upper rectus abdominis muscle is torn, or when a "slipping rib" is the problem. *G,* The "high ten" maneuver. The patient raises both hands overhead, elbows extended, and then presses forward with the hands against resistance offered by the examiner. Pain originating in the anterior rib cage, thoracic spine, or pectoral muscles may be elicited here. *(A, B,* and *G* from Reilly BM. Chest pain. In: *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991.)

TABLE 7.7 Respiratory Causes of Chest Pain

Signs and Symptoms	Diagnosis
Unilateral pain associated with severe dyspnea Can have radiation to ipsilateral shoulder Degree of pain does not correlate to extent of pneumothorax Risk factors include tall and thin body habitus, asthma, cystic fibrosis, inhalation of cocaine/marijuana	Pneumothorax, primary or secondary
Sudden pain, dyspnea, tachycardia ± hypoxia Pain is pressure-like or pleuritic Can have hemoptysis (rare) Risk factors include central venous catheter, trauma, malignancy, immobilization, oral contraceptive use, recent abortion or surgery, hypercoagulable state ECG with sinus tachycardia, right heart strain	Pulmonary embolism
Wheeze, ± shortness of breath, ± cough If exercise-induced, can cause chest pain in absence of wheeze	Asthma, reactive airway disease
Fever, cough ± sputum production Midsternal or parasternal pain that can be diffuse Pain exacerbated by deep breathing, coughing, straining	Pneumonia with pleurisy

Cardiac

Although cardiac disease is a rare cause of chest pain, there is potential for dangerous morbidity and mortality if left undiagnosed. One of the foremost concerns of families with children who have chest pain is whether or not their child is having a heart attack, although this is extremely uncommon. Etiologies of chest pain due to cardiac disease include arrhythmias, ischemia, structural abnormalities, and pericardial or myocardial disorders (Tables 7.9, 7.10, and 7.11). Arrhythmias are the most common, whereas patients with myocarditis or myocardial infarction are often the most acutely ill. Heart disease is more commonly found in adolescents than in younger children who complain of chest pain, and adolescents represent the largest group of patients between 1 and 21 years of age who die suddenly of cardiac causes.

Supraventricular and ventricular tachyarrhythmias can put adolescents at risk for sudden death. Supraventricular tachycardia (SVT), a

narrow complex tachycardia, is the most common arrhythmia in children. Patients with pre-excitation, accessory pathways that cause an arrhythmia such as Wolff-Parkinson-White syndrome are at the highest risk for SVT. Ventricular tachycardia is a wide complex tachycardia that is often associated with mitral valve prolapse, viral myocarditis, or long QT syndrome. Chest pain caused by an arrhythmia is typically associated with palpitations and/or dyspnea but not necessarily with exercise. The pain is caused by an imbalance of myocardial oxygen supply and demand, subendocardial wall stress, and diminished diastolic coronary perfusion. The pain itself is typically intermittent as most arrhythmias are inherently sporadic in their onset and resolution.

Chest pain that increases during physical exertion or other stress and is relieved by rest, is often poorly localized to the substernal area, and can radiate to the left arm and/or jaw is secondary to a cardiac etiology. This pain is often referred to as anginal and can be secondary to ischemia, although ischemia is not common in children or adolescents. Other conditions that can cause anginal chest pain in children are listed in Table 7.9. Any sign of anginal chest pain should prompt investigation of obstructive, structural cardiac abnormalities and anomalies of the coronary arteries. Associated presyncope, syncope, and/or palpitations with these symptoms should significantly raise a provider's suspicion for underlying cardiac disease, and a complete physical examination with an electrocardiogram is essential for further diagnostic evaluation.

Structural abnormalities lead to chest pain through altered cardiac output, which can lead to syncope or death. Tables 7.10 and 7.12 review the signs, symptoms, and electrocardiogram findings of the structural cardiac abnormalities that can cause chest pain.

TABLE 7.10 Structural Cardiac Abnormalities that Can Cause Chest Pain

Signs and Symptoms	ECG	Diagnosis
Chest pain with associated dyspnea is brought on by exercise Patient history of syncope, presyncope Seen in adolescence due to rapid growth of left ventricle in puberty Crescendo-decrescendo systolic ejection murmur from outflow tract gradient	Prominent septal Q wave, left ventricular hypertrophy, left axis deviation	Hypertrophic cardiomyopathy
Chest pain is brought on intermittently Patient history of tiring easily, exertional dyspnea +/− syncope, cool extremities Signs of right heart failure is a late finding High-pitched, early diastolic decrescendo murmur (pulmonary regurgitation)	Right ventricular hypertrophy	Pulmonary Hypertension (often secondary to pulmonary stenosis or Eisenmenger complex)
Chest pain is brought on with exercise Patient history of syncope at late stages Harsh crescendo-decrescendo systolic murmur radiating to carotid arteries +/− thrill	Left ventricular strain	Aortic stenosis
Chest pain that is vague, non-exertional, but most children are asymptomatic Patient history of postural hypotension, palpitations, or syncope Late to mid-systolic click preceding a systolic murmur	Normal, T-wave abnormalities or prominent U waves	Mitral valve prolapse
Chest pain that is acute, present on anterior or posterior chest that can migrate to arms, abdomen and legs Patient history may include Marfan syndrome, Ehrlos-Danlos syndrome, previously healthy weight-lifting athletes High-pitched early diastolic decrescendo murmur (aortic regurgitation)	Normal, can have low QRS voltages	Aortic dissection
Chest pain may be present but unclear due to patient age (for example, symptoms occur at 2-3 mo of age) Patient history of poor feeding, diaphoresis, tachycardia, irritability Signs of heart failure can be present	Anterolateral myocardial infarction pattern with Q waves and ST changes	Anomalous left coronary artery from pulmonary artery

TABLE 7.11   Etiology of Pericarditis and Pericardial Effusion

Idiopathic (Presumed Viral) **Infectious Agents** Bacterial: Group A streptococci, *Staphylococcus aureus*, pneumococci, meningococci,* *Haemophilus influenzae*,* *Salmonella* species, *Mycoplasma pneumoniae, Borrelia burgdorferi, Mycobacterium tuberculosis*, rickettsiae, tularemia Viral[†]: Coxsackievirus (group A, B), echovirus, mumps, influenza, Epstein-Barr virus, cytomegalovirus, herpes simplex, herpes zoster, hepatitis B virus Fungal: *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis, Cryptococcus neoformans, Candida* species, *Aspergillus* species Parasitic: *Toxoplasma gondii, Entamoeba histolytica*, schistosomes **Collagen Vascular–Inflammatory and Granulomatous Diseases** Rheumatic fever Systemic lupus erythematosus (idiopathic and drug induced) Juvenile idiopathic arthritis (JIA) Kawasaki disease Scleroderma Mixed connective tissue disease Reactive arthritis Inflammatory bowel disease Granulomatosis with polyangiitis Dermatomyositis Behçet syndrome Sarcoidosis Vasculitis Familial Mediterranean fever Serum sickness Stevens-Johnson syndrome	**Traumatic** Cardiac contusion (blunt trauma) Penetrating trauma Postpericardiotomy syndrome Radiation **Contiguous Spread** Pleural disease Pneumonia Aortic aneurysm (dissecting) **Metabolic** Hypothyroidism Uremia Gaucher disease Fabry disease Chylopericardium **Neoplastic** Primary Contiguous (lymphoma) Metastatic Infiltrative (leukemia) **Others** Drug reaction Pancreatitis Post–myocardial infarction Thalassemia Central venous catheter perforation Heart failure Hemorrhage (coagulopathy) Chylous Biliary-pericardial fistula

*Infectious or immune complex.
[†]Common (viral pericarditis or myopericarditis is probably the most common cause of acute pericarditis in a previously normal host).

Acute pericarditis causes substernal chest pain that is sharp, stabbing and aggravated by deep inspiration, coughing, or straining. Typical pericarditis pain is improved by being in the sitting position, and patients will avoid lying supine. There are many causes of pericarditis and/or pericardial effusion (see Table 7.11). Idiopathic or viral pericarditis has a preceding or accompanying flulike illness with myalgias, arthralgias, and fever. Evaluation for acute pericarditis includes physical examination during which a 3 component pericardial rub (atrial systole, ventricular systole, diastolic filling) may be present on auscultation. Of note, this rub may disappear with the development of pericardial effusion. Electrocardiogram findings of acute pericarditis go through a 4-stage evolution. Stage 1, the most classic stage for diagnosis (Fig. 7.4), may reveal diffuse PR depressions with upright P waves followed by J-point ST elevations. The ST elevations noted in pericarditis are referred to as J-point elevations due to their upsloping "J" shape. Subsequently, stage 2 shows descent of the J-point elevations followed by stage 3 with T wave inversions. Stage 4 then shows restitution back to the child's baseline ECG. These J-point ST elevations are markedly different from ST elevations caused by cardiac ischemia, which are more dome-shaped (see Fig. 7.4). In pericarditis, in order to clarify the amount of pericardial fluid present and whether or not there is ventricular dysfunction, an echocardiogram is performed.

Acute myocarditis often is caused by or follows viral infections. Symptoms of acute myocarditis include lethargy, pallor, low-grade fever, anorexia, chest or abdominal pain, and signs of congestive heart failure. ECG abnormalities tend to be diffuse and nonspecific, and complications of myocarditis include arrhythmias and conduction blocks. Patients with myocarditis have the propensity to become severely ill and often require inpatient or even intensive care hospitalization.

◆ Physical Examination

A physical examination can often confirm a medical provider's suspicion of a particular diagnosis or diagnoses, especially when it comes to the complaint of chest pain. The cardiovascular assessment of children requires patience, thoroughness, and flexibility to adapt to children who may not desire you to examine them. All physical examinations for the complaint of chest pain should start with observing the child for general states of distress, pain with breathing, and interaction with parents. Vital signs can indicate the presence of pain by revealing signs of tachycardia and tachypnea, and can provide information regarding potential serious medical illness, including fever, hypoxia, or hypotension. Blood pressures should be obtained in upper and lower extremities, monitoring closely for a gradient between extremities. All

TABLE 7.12	**Systolic Murmurs Important in the Diagnosis of Chest Pain**	
Innocent ejection murmur	Loudest left sternal border at base, 1-3 intensity, peaks early in systole; no click, gallop, heave, or diastolic murmur	Diminishes with standing and Valsalva maneuver
Valvular aortic stenosis	*Mild:* Similar to innocent murmur but ejection click is possible *Severe:* Loudest over right second intercostal space, peaks late in systole; delayed carotid upstroke, thrill present; left ventricular heave; audible S_4 gallop; aortic insufficiency murmur may also be present	
Hypertrophic cardiomyopathy	Loudest over left second intercostal space, peaks in midsystole; carotid upstroke brisk or bisferiens; no diastolic murmur	Increases with standing or Valsalva maneuver; decreases on squatting
Pulmonic stenosis	*Mild:* Similar to innocent murmur but ejection click is possible *Severe:* Loudest over left second intercostal space; loud, widely split S_2; thrill present; right ventricular heave; ejection click at left second intercostal space	
Mitral valve prolapse	Loudest at left sternal border and apex; mid- to late-systolic murmur; click precedes murmur	Increases with standing after squatting and during expiration

Pericarditis

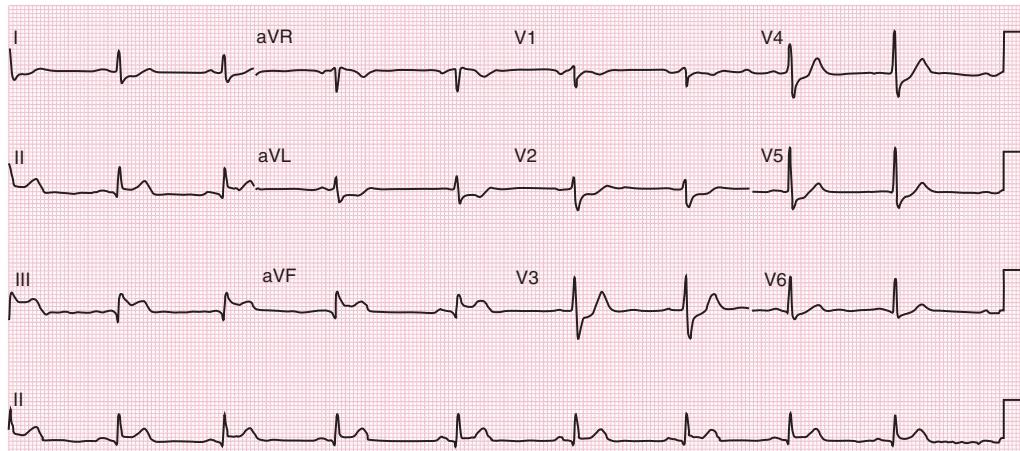
Infarction


B

FIGURE 7.4 A, Acute pericarditis. Note diffuse J-point ST elevations and near ubiquitous PR segment depressions. B, Acute ST elevation myocardial infarction: Note dome-shaped, sometimes referred to as "tombstone shaped," ST elevations in leads II, III, and aVF with reciprocal ST depressions in leads I, aVL, and V_1-V_5 consistent with an acute inferior wall myocardial infarction. (A from Spodick DH. Acute pericarditis: current concepts and practice. *JAMA.* 2003;289:1150-153; B from Hwang C, Levis JT. ECG diagnosis: ST-elevation myocardial infarction. *Perm J.* 2014;18:e133.)

vital signs should be evaluated in the context of reference ranges for a child's age and height.

A helpful physical exam finding is elicitation of chest wall tenderness upon palpation of the thorax, which is pathognomonic for chest wall pain (see Fig. 7.1). Therefore, medical providers are encouraged to palpate over the chest including the ribs, intercostal areas, sternum, xiphoid, manubrium, axilla, clavicles, epigastric area, spinous processes, and paraspinal areas. Chest wall maneuvers can also be performed in order to better understand what muscle group is causing the pain (see Fig. 7.2).

Palpation of the chest wall should be performed to identify the point of maximal intensity and to determine if there is a cardiac heave or thrill. Palpation of the abdomen should be done for tenderness and organomegaly. Both distal and proximal pulses should be felt for equality and caliber. After palpation, percussion should be done. Dullness to percussion can suggest consolidation, effusion, or atelectasis, whereas hyperresonance to percussion can suggest pneumothorax or asthma.

Every medical provider should allow ample time for auscultation of the lungs and heart. Medical providers should follow a constant, systemic procedure for listening to heart sounds. Heart sounds include S_1-S_4. S_1 is caused by mitral and tricuspid valve closure, and S_2 is caused by aortic and pulmonary valve closure. The sounds caused by these valves opening are not heard in healthy individuals. Because the left-sided valves close before the right-sided valves, the S_2 heart sound can be physiologically split into the aortic valve and then the pulmonic valve closing during inspiration. S_3 and S_4 are harder to understand and hear. S_3 is a result of the deceleration of blood at the end of early rapid filling of the ventricles. An S_3 is normal in children with hyperdynamic circulations (such as athletes) and thin chest walls (of note, in adults an S_3 is always abnormal). An S_4 is a result of deceleration of blood at the end of late rapid filling of the ventricles. Audible S_4 sounds are always abnormal, no matter what age the patient is. Therefore, a gallop rhythm (3 heart sounds) can be normal or abnormal.

Subsequently, medical providers must listen to what occurs between S_1 and S_2. A mid-systolic click is often an indicator of the mitral valve prolapsing into the left atrium. It can be a single click or series of clicks. Then, the medical provider should listen for heart murmurs. Heart murmurs can provide additional clinical evidence for potential cardiac causes of chest pain. Listening for heart murmurs should be performed with the patient supine, sitting, standing, squatting, and standing after squatting. Many murmurs increase in intensity with decreased ventricular filling or decreased afterload (standing, release of Valsalva, squatting); however, hypertrophic cardiomyopathy's murmur does the opposite. It increases in intensity with the Valsalva maneuver and decreases with squatting. Of note, all diastolic murmurs or murmurs grade 3/6 or higher should be further evaluated with an echocardiogram. The presence of a gallop rhythm or a friction rub can make an immediate cardiac diagnosis. A pericardial friction rub is a scratchy, high-pitched, to-and-fro sound caused by the inflamed pericardial surfaces rubbing together during cardiac motion and that is loudest when the patient is upright and leaning forward.

Electrocardiogram

An electrocardiogram may be helpful if there is a suggestive history and/or physical examination for potential cardiac disease. In the absence of a suggestive history and physical, the yield of an electrocardiogram is considered low as it may be normal in patients with structural heart disease or arrhythmias. Regardless, because of its relatively low cost and noninvasive nature, electrocardiograms should be performed in the evaluation of chest pain if there are any concerns discovered in the history assessment or physical examination. After a medical provider obtains an ECG, there are a few important principles to keep in mind. ECG findings are age-specific (for example, infants have a right ventricular-dominant ECGs and T waves are usually inverted), arrhythmias are often not found on routine ECGs, and provider should be careful in using the "machine" read in regard to myocardial infarction, pericarditis, or long QT syndrome (the computer is prone to overdiagnosis).

◆ Further Diagnostic Testing

One of the biggest challenges for primary care providers is when to refer to a cardiology subspecialist. Cardiac consultation is reasonable for any child with red-flag symptoms, specifically chest pain associated with exertion, syncope with exertion, chest pain with concurrent palpitations, abnormal findings on cardiac examination or ECG, a history of cardiac surgery/intervention, or a high-risk family history. If a patient has chest pain with concurrent fever or signs of hemodynamic instability, the child should be referred to the emergency department for further evaluation for myocarditis.

When the previous evaluation results in a positive screening result, echocardiogram is the diagnostic test of choice for further assessment. However, of note, referral to a cardiologist is generally more cost-effective than obtaining an echocardiogram without a cardiologist. An echocardiogram should be obtained urgently if there are signs of cardiac tamponade (hypotension, tachycardia, pulsus paradoxus) or poor cardiac output. It is also useful if mitral valve prolapse, valvular heart disease, hypertrophic cardiomyopathy, septal defects, endocarditis, or pericarditis is suspected.

Other diagnostic modalities can include chest radiographs, exercise stress tests, and Holter monitors. A chest radiograph is helpful if there is a clinical finding that needs further investigation, such as a history of trauma or fever. Other than pulmonary disease, a chest radiograph can note cardiomegaly or pneumothoraces. Regardless, a chest radiograph in the absence of febrile illness or trauma has not been shown to be largely beneficial as the likelihood of finding bone or intrathoracic abnormalities in the absence of these features is low. Exercise stress tests should be reserved for anginal cardiac pain in the setting of other normal testing. Due to the difficulty of determining anginal chest pain in the pediatric population, there has been an increased frequency of exercise stress tests ordered. However, medical providers should remember that in the setting of chest pain with a normal echocardiogram evaluation, an exercise stress test has low yield. A 24-hour Holter monitor or a 30-day loop recorder only should be utilized if an arrhythmia is suspected but the resting electrocardiogram is normal. Testing for other underlying abnormalities as the cause of noncardiac chest pain can include pulmonary function testing and/or methacholine challenge testing as well as esophageal manometry testing.

Laboratory testing for biochemical markers of cardiac damage is used extensively in the adult population, primarily to diagnose and assist in management of acute myocardial infarction. In pediatrics, they are not often utilized. Biochemical markers include the MB isoenzyme of creatine kinase (CK-MB) and troponin T. In adults, the MB isoenzyme of creatine kinase often is only measured if the troponin T is found to be elevated. Troponin T is a protein present in high concentrations in the myocardium but not in other tissues and is released rapidly after myocardial injury in direct proportion to the extent of injury. Troponin T has a high specificity and a low sensitivity for myocardial injury; therefore false positives often occur, especially in pediatrics where the prevalence of myocardial ischemia and injury is extremely low. In general, nonischemic causes for elevated troponin have not been well studied in children. Multiple studies have noted that troponin T shows elevation in postoperative cardiac surgery patients and in diagnoses of myocarditis. Cut off values have not been well

defined; however, low-level troponin T elevations can signify serious disease in children, as opposed to adults where these small elevations would be considered insignificant. Selective use of the troponin assay may be useful in conjunction with the presence of ECG abnormalities. Additional studies in pediatrics are continually ongoing regarding the potential usefulness of cardiac biochemical markers in diseases with muscle breakdown such as Duchenne muscular dystrophy or in determining subtle cardiac dysfunction after convulsive seizures.

◆ Treatment

Medical providers should refer patients to cardiology specialists if cardiac etiologies are still a concern after thorough history, physical, and necessary ancillary studies such as electrocardiograms. Unfortunately, a precise diagnosis is not made in a high percentage of cases. It is up to the medical provider to carefully deal with uncertainty, not over-test or over-refer, and provide ongoing care that minimizes anxiety. Most importantly, if a noncardiac etiology is the highest consideration, medical providers should thoughtfully provide extensive reassurance that includes a symptomatic treatment approach and a plan for appropriate follow-up. It is of the utmost importance that providers provide this reassurance and follow-up to avoid a chronic course of chest pain with potential disability. Of note, families should be specifically asked about school absenteeism so that recommendations for returning to school can be given. Treatment plans should be tailored to both the most likely diagnosis and the patient's individual concerns. Musculoskeletal chest pain can be treated with heat, anti-inflammatory medications, or specific exercises. Respiratory causes of chest pain require aggressive therapies for the underlying cause, most frequently reactive airway disease. Psychogenic causes of chest pain are perhaps the hardest to treat, often requiring consultation with behavioral pediatricians, counselors, and/or psychologists. Primary care providers can start this treatment by having their patients keep pain diaries to help facilitate follow-up discussions. Gastrointestinal causes of chest pain can be diagnosed and treated with a trial of H_2-blocking agents or proton pump inhibitors in addition to reflux precautionary behaviors such as avoiding foods that worsen the symptoms, not eating close to bedtime, and elevating the head of the bed at night.

Overall, because etiologies of chest pain are so often multifactorial and require ongoing evaluation and treatment, the primary care physician must stay actively involved in the patient's care over time.

Murmurs

Andrew N. Pelech

Most heart murmurs are normal or innocent, and must be distinguished from pathologic murmurs of congenital or acquired cardiac diseases. Whereas less than 1% of the population has structural congenital cardiac disease, as many as 85% of the population has a heart murmur sometime during childhood. The causes of cardiac murmurs are often influenced by the age of the patient at presentation (Table 8.1). The causes of congenital heart disease are varied and include genetic disorders, syndrome complexes (Table 8.2), metabolic disorders, and teratogenesis. The causes of acquired heart diseases in children include rheumatic fever, endocarditis, and cardiac injury caused by systemic illnesses.

THORAX

Knowing the location of the heart chambers and valves within the thorax helps in the interpretation of heart sounds (Fig. 8.1). The left atrium is located posteriorly, close to the spine. The right atrium and right ventricle are located anteriorly, immediately beneath the sternum. The outflow tract of the right ventricle, which contains the pulmonary valve, rises to the left of the sternum. The parts of the left side of the heart that are close to the chest wall include the left ventricular apex and the ascending aorta as it passes up to the right of the sternum. In other areas, lung tissue lies between the heart and chest wall. This may diminish or distort the intensity of heart sounds.

ORIGINS OF THE HEART SOUNDS

Normal heart sounds originate from vibrations of heart valves when they close and from heart chambers when they fill or contract rapidly. The amount of pressure that forces the valve closure influences the intensity of a heart sound. Other mechanical factors such as valve stiffness, thickness, and excursion have less effect on sound intensity.

Cardiac murmurs are the direct result of blood-flow turbulence. The amount of turbulence and consequently the intensity of a cardiac murmur is directly proportional to both the pressure difference or gradient across a narrowing or defect and the blood flow or volume moving across the site.

As sound radiates from its source, sound intensity diminishes with the square of the distance. Consequently, heart sounds should be loudest near the point of origin. However, other factors influence this relationship. Sound passage through the body is affected by the transmission characteristics of the tissues. Fat has a more pronounced dampening effect on higher frequencies than does more dense tissue such as bone. If the difference in tissue density is significant—for example, between the heart and lungs—more sound energy is lost. Only the loudest sounds may be heard when lung tissue is positioned between the heart and chest wall.

In contrast to intensity, the frequency of a cardiac murmur is proportional to pressure difference or gradient across a narrowing alone.

CARDIAC CYCLE

Cardiac sounds and murmurs that arise from turbulence or vibrations within the heart and vascular system may be innocent or pathologic. It is important to understand the timing of events in the cardiac cycle as a prerequisite to understanding heart murmurs. The relationship between the normal heart cycle and that of the heart sounds is noted in Fig. 8.2.

The cardiac cycle begins with **atrial systole**, the sequential activation and contraction of the 2 thin-walled upper chambers. Atrial systole is followed by the delayed contraction of the more powerful lower chambers, termed **ventricular systole**. Ventricular systole has 3 phases:
1. Isovolumic contraction: the short period of early contraction when the pressure builds within the ventricle but has yet to rise sufficiently to permit ejection
2. Ventricular ejection: when the ventricles eject blood to the body (via the aorta) and to the lungs (via the pulmonary artery)
3. Isovolumic relaxation: the period of ventricular relaxation when ejection ceases and pressure falls within the ventricles

During ventricular contraction, the atria relax (**atrial diastole**) and receive venous return from both the body and the lungs. Then, in **ventricular diastole**, the lower chambers relax, allowing initial passive filling of the thick-walled ventricles and emptying of the atria. Later, during the terminal period of ventricular relaxation, the atria contract. This atrial systole augments ventricular filling just before the onset of the next ventricular contraction.

The sequence of contractions generates pressure and blood flow through the heart. The relationship of blood volume, pressure, and flow determines opening and closing of heart valves and generates characteristic heart sounds and murmurs.

CHANGES IN THE CIRCULATION AT BIRTH

An understanding of the fetal, transitional, and neonatal adaptations of the circulation is important in the evaluation of the pediatric cardiovascular system, because many organic heart diseases are evident in association with the circulatory changes occurring at birth. The majority of significant structural congenital heart disease is recognized in the first few weeks of life. The age at recognition or referral often dictates the nature of the cardiac anomaly and the urgency with which assessment is necessary.

In the fetus (Fig. 8.3), oxygen is derived from the placenta and returns via the umbilical vein and through the ductus venosus to enter the inferior vena cava and right atrium. Preferentially, flow is directed across the foramen ovale to enter the left atrium and, subsequently, the left ventricle. Deoxygenated blood returning from the superior vena cava and upper body segment is preferentially directed by the flap of the eustachian valve to enter the right ventricle and then, via the ductus arteriosus, to enter the descending aorta to return via the umbilical

TABLE 8.1	Causes of Heart Murmurs	
Neonate*	**Infant**	**Older Child**
Transient patency of the ductus arteriosus	Congenital heart disease	Congenital valvular obstruction
Peripheral pulmonic stenosis	(L→R shunt or R→L shunt)[†]	Ejection murmurs (normal)
Cyanotic congenital heart disease	Ejection murmurs (normal)	Repaired congenital heart disease
Congenital valvular obstruction	Anemia	Anemia
Arteriovenous malformation (CNS, hepatic, pulmonary)	Arteriovenous malformation	Mitral valve prolapse
Anemia	Infective endocarditis	Venous hum
Asphyxia-related myocardial ischemia (transient TI	Kawasaki disease	Bacterial endocarditis
or MI)	Hunter syndrome	Rheumatic fever
	Hurler syndrome	Marfan syndrome
	Fabry syndrome	Prosthetic valves
		Obstructive (hypertrophic) cardiomyopathy (subaortic stenosis)
		Carotid or abdominal bruit
		Tumor (atrial myxoma)
		Thyrotoxicosis
		Systemic lupus erythematosus
		Pericardial friction rub

*Common causes of congenital heart disease in low-birth-weight infants include PDA, VSD, tetralogy of Fallot, coarctation of the aorta–interrupted aortic arch, hypoplastic left heart syndrome, heterotaxy, and dextrotransposition of the great arteries, in that order. Common causes of congenital heart disease in term infants include VSD, dextrotransposition of the great arteries, tetralogy of Fallot, coarctation of the aorta, pulmonary stenosis, hypoplastic left heart syndrome, and PDA; other causes represent a smaller percentage.

[†]The relative percentages of congenital heart lesions are VSD (25-30%); ASD (6-8%); PDA (6-8%); coarctation of aorta (5-7%); tetralogy of Fallot (5-7%); pulmonary valve stenosis (5-7%); aortic valve stenosis (5-7%); dextrotransposition of great arteries (3-5%); and hypoplastic left ventricle, truncus arteriosus, total anomalous venous return, tricuspid atresia, single ventricle, and double-outlet right ventricle representing 1-3% each. Other and more complex lesions (forms of heterotaxy) together represent 5-10% of all lesions.

ASD, atrial septal defect; CNS, central nervous system; L, left; MI, mitral insufficiency; PDA, patent ductus arteriosus; R, right; TI, tricuspid insufficiency; VSD, ventricular septal defect.

arteries to the placenta. The pressures within both ventricles are essentially equal, inasmuch as both chambers pump to the systemic circulation. However, in utero, the right ventricle does the majority of the work, pumping 66% of the combined cardiac output. At transition (see Fig. 8.3), with the first breath, pulmonary arterial resistance begins to fall as the lungs begin the process of respiration. Pulmonary venous return to the left atrium closes the flap of the foramen ovale. Through mechanical and chemical mechanisms, the ductus arteriosus begins to close. In the normal full-term infant, this is accomplished by 10-15 hours after birth. Intermittent right-to-left atrial level shunting through the foramen ovale may occur, particularly if pulmonary vascular resistance fails to drop. In addition, structural cardiac abnormalities necessitating patency of the ductus arteriosus for maintenance of either pulmonary blood flow (pulmonary atresia) or systemic blood flow (hypoplastic left heart syndrome) most often manifest within the first few days of life. Thus, the time when a pediatric patient presents for evaluation is influenced by the spectrum of heart diseases. Ductus-dependent abnormalities, such as pulmonary atresia, transposition of the great arteries, coarctation of the aorta, hypoplastic left heart syndrome, or significant outflow obstructions (e.g., critical aortic valve stenosis) manifest in the first few days after birth. In the absence of an associated anomaly, hemodynamically significant ventricular septal defects (VSDs) seldom manifest before 2-4 weeks after birth. Atrial septal defects (ASDs) are seldom symptomatic in infancy.

NORMAL INTRACARDIAC PRESSURES

In the child after birth and successful transition, resistance to flow in the pulmonary circuit is much lower than in the systemic circuit. Therefore, the pressures in the right-sided chambers are lower than those in the left-sided chambers. The higher values (see Fig. 8.3) reflect pressures during ventricular systole in a normal heart. Pressure in the great vessels during systole is identical to that in the corresponding ventricles. This changes if there is outflow obstruction. In ventricular diastole, the semilunar valves (aortic and pulmonary) close. Resistance to blood flow in the vascular bed determines the diastolic pressures in the great arteries. The thin-walled atria generate much lower pressures than do the ventricles, both during the phase of passive atrial filling (**v wave**) and during atrial contraction (**a wave**). Only the mean (m) or average atrial pressure is shown in Fig. 8.3. During ventricular relaxation, the diastolic pressures are lower than those in the atria, enabling filling. Knowledge of the cardiac cycle is important in understanding the more complicated hemodynamics and flow patterns of specific cardiac abnormalities.

PEDIATRIC CARDIOVASCULAR EVALUATION

◆ History

Historical assessment of the pediatric patient referred for evaluation of a cardiac murmur should include questions about the family history, the pregnancy, and perinatal course, in addition to questions about symptoms of cardiovascular disease. An index of exercise or play capacity should be sought, as should an assessment of growth and development. The presence of congenital abnormalities of other major organ systems is associated with structural cardiac problems in as many as 25% of patients.

Structural heart disease is frequently seen in association with recognizable syndromes (see Table 8.2). Children with clearly definable chromosomal disorders known to have a significant incidence of structural cardiac abnormalities, such as Down or Turner syndromes, are usually

(See *Nelson Textbook of Pediatrics,* p. 2799.)

TABLE 8.2	**Syndromes or Syndrome Complexes Associated with Congenital Heart Disease**
Syndrome	**Dominant Cardiac Defect**
Alagille (arteriohepatic dysplasia)	Peripheral pulmonary stenosis
Asplenia	Complex cyanotic heart disease, anomalous veins, pulmonary atresia
Carpenter	Patent ductus arteriosus, ventricular septal defect
Cat eye	Total anomalous pulmonary venous return
Char	Patent ductus arteriosus
CHARGE	Ventricular, atrioventricular, and atrial septal defects
de Lange	Tetralogy of Fallot, ventricular septal defect
Down (Trisomy 21)	Artioventricular septal defects, ventricular septal defect, patent ductus arteriosus
Ellis–van Creveld	Single atrium, endocardial cushion defects
Fanconi	Patent ductus arteriosus, ventricular septal defect
Fetal alcohol	Ventricular septal defect, atrial septal defect, tetralogy of Fallot
Fragile X	Mitral valve prolapse, aortic root dilation
Goldenhar	Tetralogy of Fallot
Holt-Oram	Atrial or ventricular septal defect
Hydantoin/phenytoin embryopathy	Atrial or ventricular septal defect, coarctation of aorta
Infant of diabetic mother	Hypertrophic cardiomyopathy, ventricular septal defect
Laurence-Moon	Tetralogy of Fallot, ventricular septal defect
Marfan	Aortic root dissection, mitral valve prolapse
Mulibrey nanism	Pericardial thickening, constrictive pericarditis
Multiple lentigines (LEOPARD)	Pulmonary stenosis
Noonan	Pulmonic stenosis (dysplastic valve), atrial septal defect
PHACE	Coarctation of aorta, ventricular septal defect, patent ductus arteriosus
Pierre Robin	Coarctation of aorta
Polycystic kidney disease	Mitral valve prolapse
Polysplenia	Complex acyanotic lesions, azygos continuation
Rubella	Patent ductus arteriosus, peripheral pulmonary stenosis
Rubinstein-Taybi	Patent ductus arteriosus
Scimitar	Hypoplasia of the right lung, anomalous pulmonary drainage
Smith-Lemli-Opitz	Ventricular septal defect, patent ductus arteriosus
Thrombocytopenia–absent radius (TAR)	Atrial septal defect, tetralogy of Fallot, ventricular septal defect
Trisomy D	Ventricular septal defect, patent ductus arteriosus, atrial septal defect
Trisomy E	Ventricular septal defect, patent ductus arteriosus, atrial septal defect
Turner	Coarctation of aorta, bicuspid aortic valve
VACTERL (VATER)	Ventricular septal defect, tetralogy of Fallot
Valproate	Coarctation of aorta, hypoplastic left heart syndrome
Velocardiofacial	Ventricular septal defect, right aortic arch
Williams (7q11.23 deletion)	Supravalvular aortic stenosis, peripheral pulmonary stenosis
Wolf-Hirschhorn	Atrial septal defect, ventricular septal defect
22q11.2 deletion syndrome	Tetralogy of Fallot, interrupted aortic arch, ventricular septal defect, truncus arteriosus

CHARGE, coloboma, heart disease, atresia choanae, retarded growth and development or central nervous system anomalies, genital hypoplasia, and ear anomalies and/or deafness; LEOPARD, lentigines, electrocardiographic conduction defects, ocular hypertelorism, pulmonary stenosis, abnormalities of the genitals, retarded growth, deafness; PHACE, posterior fossa malformations, hemangiomas, arterial anomalies, coarctation of aorta, and eye abnormalities; VACTERL, vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, and limb defects; VATER, vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia.

referred for further diagnostic evaluation. Family history of sudden unexplained death, rheumatic fever, sudden infant death syndrome, or a structural cardiac abnormality in a first-degree relative may be relevant. Hypertrophic cardiomyopathy in a first-degree relative is associated with a high incidence of inheritance, and this condition is sufficiently subtle that echocardiographic screening is mandatory.

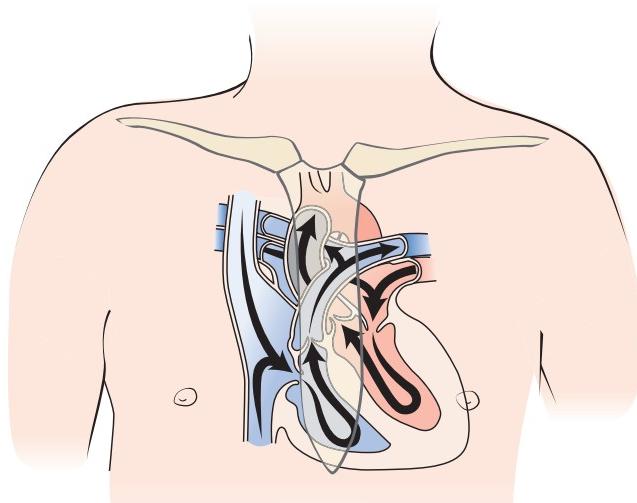
A maternal history of gestational diabetes mellitus may be associated with a transient hypertrophic cardiomyopathy in as many as 30% of infants of these mothers, as well as with definable congenital structural abnormalities. Additional relevant pregnancy history may include the presence of chronic or acute maternal illness, congenital infections, or medication use, any of which may be associated with significant


FIGURE 8.1 Location of the heart within the thorax. The right atrium and right ventricle lie immediately beneath the sternum. The left atrium lies posteriorly against the spine. The left ventricle extends laterally toward the chest wall, whereas the left ventricular outflow tract extends to the right side of the sternum, going upward toward the cardiac base.

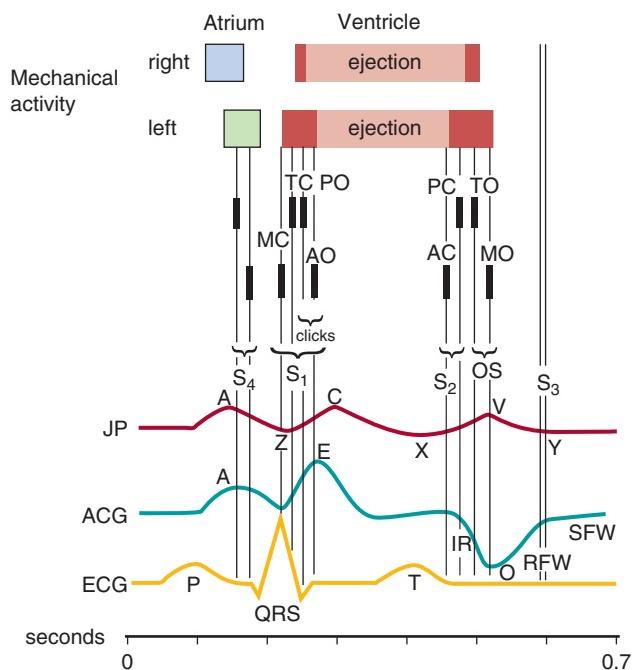

FIGURE 8.2 The cardiac cycle. Relationship among electrical and mechanical events, valvular motion, heart sounds (S_1, S_2, S_3, and S_4), the jugular pulse wave (JP), and the apexcardiogram (ACG). AC and AO, aortic component and opening; ECG, electrocardiogram; IR, isovolumic (isochronic) relaxation wave; MC and MO, mitral component and opening; O, opening of mitral valve; OS, opening snap of atrioventricular valves; PC and PO, pulmonic component and opening; RFW, rapid-filling wave; SFW, slow-filling wave; TC and TO, tricuspid component and opening. (From Tilkian AG, Conover MB. *Understanding Heart Sounds and Murmurs: With an Introduction to Lung Sounds*. 3rd ed. Philadelphia: WB Saunders; 1993.)

structural heart disease. Unexplained fever, lethargy, a history of intravenous drug use, or additional symptoms arising after recent dental work should arouse suspicion of possible endocarditis.

SYMPTOMS AND SIGNS OF HEART DISEASE

The general health of a child with a suspected cardiac malformation is important. Particularly relevant are the rate of growth, development, and history of past illnesses. Although symptoms of **failure to thrive** are nonspecific, patterns of growth reflect duration and severity of the disease and effectiveness of treatment (see Chapter 9). In an infant, feeding difficulties are often the first evidence of congestive heart failure. Feeding problems are common manifestations of cardiac disease and may be evidenced as disinterest, excessive fatigue, long feeding duration, diaphoresis, tachypnea, dyspnea, or a change in the pattern of respiration. It is important to obtain a measure of caloric intake by quantitating the number and/or volume of feedings. Some index of **exertional tolerance** should be sought in all children as an index of cardiovascular fitness and a sign of functional capability. This index should be age relevant and, in an infant, might include assessment of the vigor and duration of feeding and the time period of interactive play. In a toddler, the index might include ability to keep up with peers, climb stairs, or walk for extended periods. In an older child, a comparison with peer sporting interactions, level of function in physical education, and an index of aerobic ability should be sought.

Respiratory rates should be assessed in the quiet infant (Table 8.3). The rate and pattern of breathing should be assessed for a full minute, because rates may vary considerably with activity and feeding. **Tachypnea** may occur as a consequence of increased pulmonary blood flow. With increasing pulmonary congestion, particularly obstruction to pulmonary venous drainage, dyspnea is manifested as an anxious look with grunting, flaring of the alae nasi, and intercostal, suprasternal, and subcostal retractions. Cardiac asthma or exercise-inducible reactive airway disease may occur as a consequence of passive or active pulmonary congestion (see Chapter 3). Compression of airways by plethoric vessels may contribute to the stasis of secretions and atelectasis, which predisposes to respiratory tract infections.

Cyanosis in association with a cardiac murmur suggests a structural lesion with restriction to pulmonary blood flow (Table 8.4). Cyanosis, or a blue discoloration of the skin and mucous membranes, is a consequence of reduced hemoglobin (>5 g/dL), and is evident in one third of infants with potentially lethal congenital heart disease. Central cyanosis is distinguished from acrocyanosis or peripheral cyanosis by involvement of the warm mucous membranes, including the tongue and buccal mucosa. Acrocyanosis or peripheral cyanosis is generally confined to the perioral and perinasal regions, extremities, or nail beds and occurs in the child who is cold, vasoconstricted, or at rest. A distinctive feature is that central cyanosis generally worsens with activity and increasing cardiac output, whereas acrocyanosis generally improves or resolves with increased activity.

◆ Physical Examination
Overall Appearance
Height and weight should be measured and plotted on a growth chart. An assessment of the child's overall growth, appearance, and state of distress serves as a guide to the urgency of further investigation and management. The sick infant often appears anxious, fretful, diaphoretic, pale, or breathless and is seldom consolable. Observe for cyanosis, pallor, digital clubbing, an abnormal pattern of respiration, and possible dysmorphic features, which may suggest specific structural cardiac anomalies.

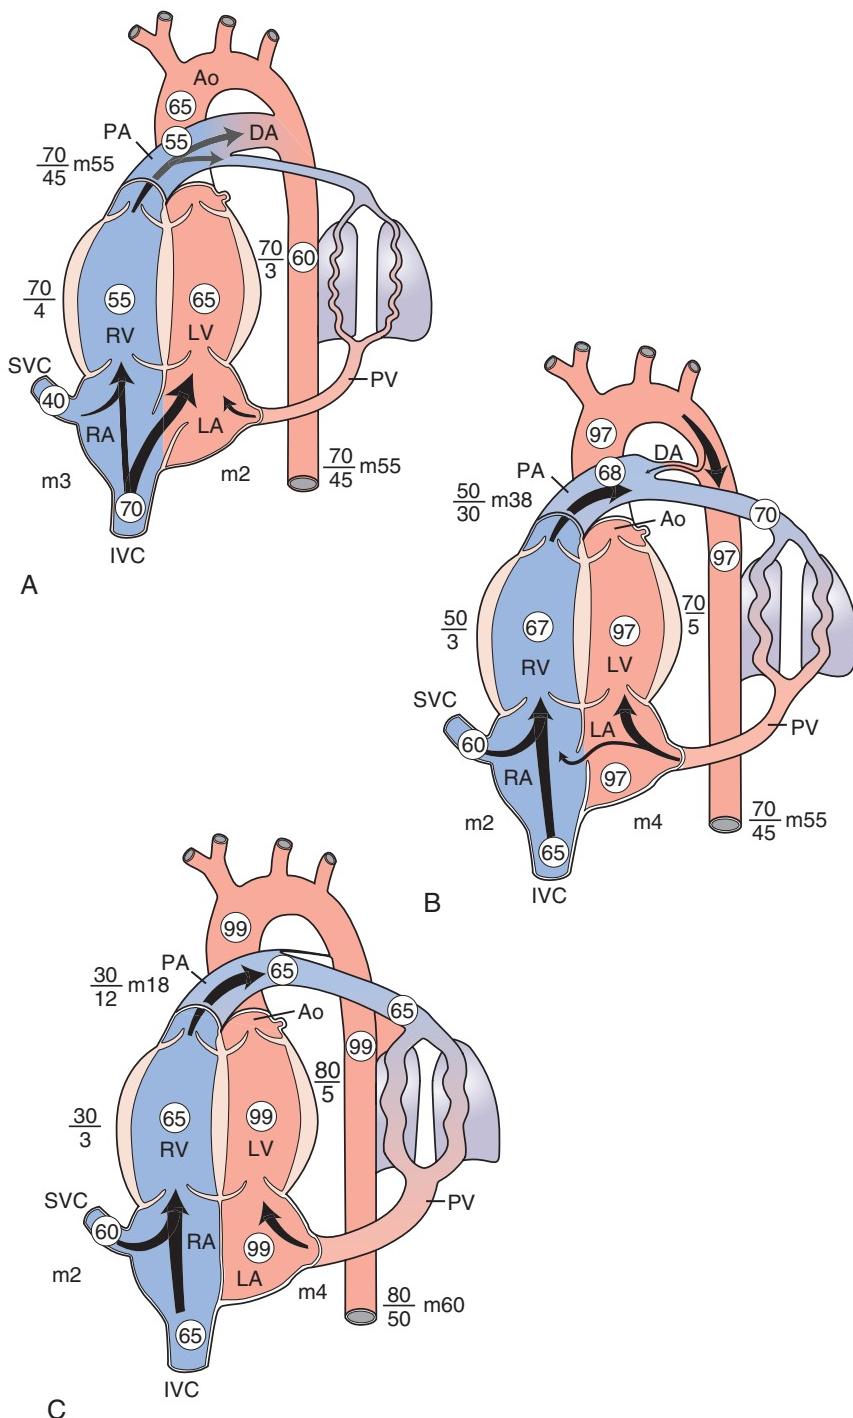
(See *Nelson Textbook of Pediatrics,* p. 2261.)


FIGURE 8.3 Fetal (A), transitional (B), and neonatal (C) circulations. The course of the circulation in the heart and great arteries of the late-gestation fetal lamb, within a few hours of delivery and as a newborn, are presented. The figures in the circles within the chambers and vessels represent percent oxygen saturation. The numbers alongside the chambers and vessels are pressures in mm Hg related to amniotic fluid pressure as zero. Ao, aorta; DA, ductus arteriosus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; m, mean; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Modified from Rudolph AM. Chapters 2 and 3. In: *Congenital Disease of the Heart*. Chicago: Year Book Medical; 1974.)

Vital Signs

Normal resting heart rates and respiratory rate values for age are presented in Table 8.3. Blood pressure should be measured manually using an appropriately-sized cuff. Every child should have a comparison of upper and lower blood pressures on at least one occasion. The lower limb systolic blood pressure is normally 10 mm Hg higher than the upper limb pressure in older children. On occasion, the subclavian arteries may arise aberrantly beyond the site of ductal ligament insertion. Therefore, both upper limb pressures should be measured and compared with the lower limb pressure. Normal values for blood pressure in children are presented in Fig. 8.4.

TABLE 8.3	**Normal Values of Respiratory and Heart Rates in Infants and Children**				
	AGE				
	Birth-6 Weeks	**6 Weeks-2 Years**	**2-6 Years**	**6-10 Years**	**Older Than 10 Years**
Respiratory rate	45-60/min	40/min	30/min	25/min	20/min
Heart rate	125 ± 30/min	115 ± 25/min	100 ± 20/min	90 ± 15/min	85 ± 15/min

TABLE 8.4	**Categories of Cyanotic Heart Lesions in the Neonate**				
Group	**Heart Size**	**Pulmonary Blood Flow**	**Low Cardiac Output**	**Respiratory Distress**	**Examples**
I	Small	Reduced	No	None	Hypoplastic RV with pulmonary atresia Hypoplastic RV with tricuspid atresia Tetralogy of Fallot (severe)
II	Small or slight cardiomegaly	Increased	No	Moderate	Transposition of great arteries with intact ventricular septum
III	Large	Increased	Yes	Yes	Complicated coarctation of aorta with VSD, hypoplastic LV
IV	Small	Pulmonary venous congestion	Yes	Yes	Obstructed total anomalous pulmonary veins

LV, left ventricle; RV, right ventricle; VSD, ventricular septal defect.

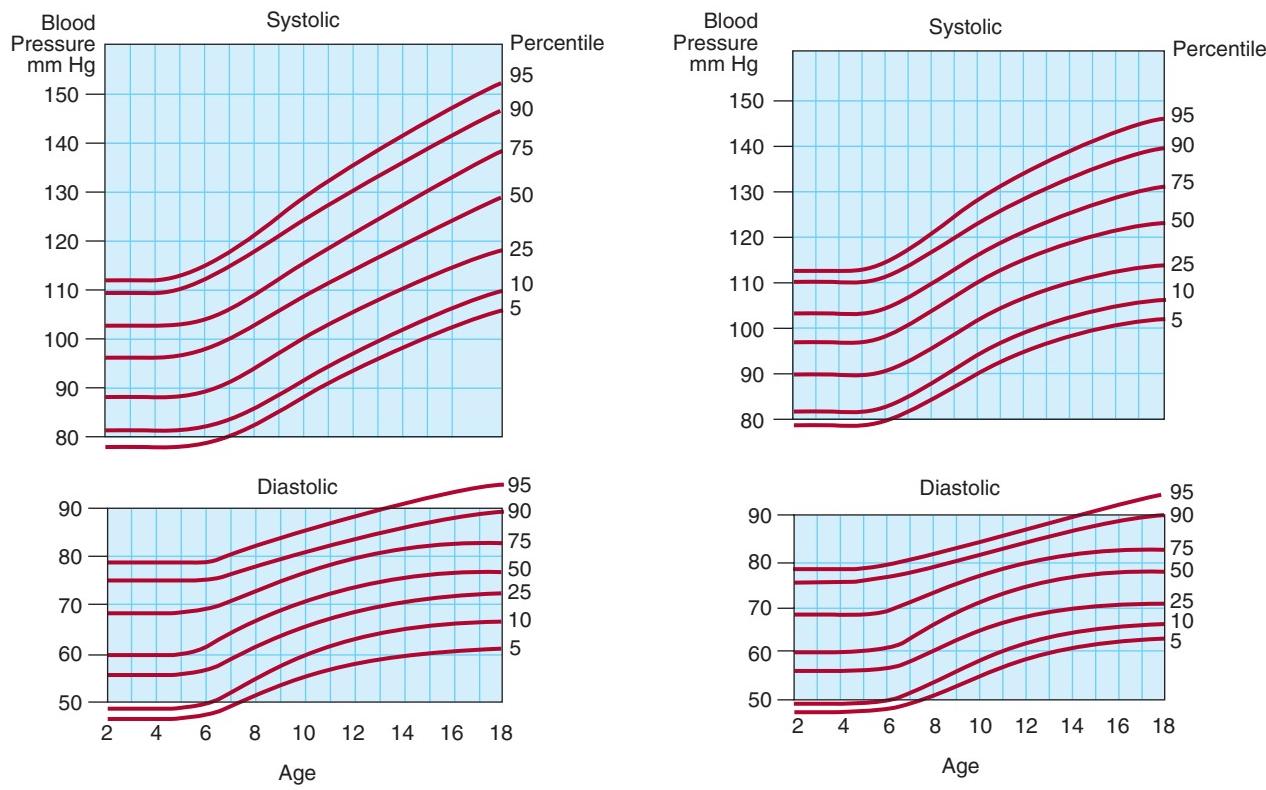

FIGURE 8.4 Normal blood pressure percentiles for boys *(A)* and girls *(B)*, aged 2-18 years. The Korotkoff IV sound is used for diastolic blood pressure. (Modified from the National Heart, Lung, and Blood Institute. Report of the second task force on blood pressure control in children, 1987. *Pediatrics* 1987;79:1.)

Respiratory Assessment

Respiratory distress may suggest cardiac disease. In addition to noting the rate, depth, and effort of respiration, the inspection should include observation for evidence of air trapping, increased chest diameter, or the presence of subcostal Harrison sulci as an indication of chronic upper airway obstruction. An allergic malar facies may also suggest upper airway obstructive disease with predisposition to hypercapnia and pulmonary hypertension. Although crackles in the lungs in infants and even young children usually indicate infection, pulmonary edema should also be a consideration.

CARDIOVASCULAR ASSESSMENT

Arterial Examination

Pulses should be assessed for rate, rhythm, volume, and character. The dynamic character of the pulse may provide information about the cardiac output. A clinical index of cardiac output includes the warmth of the digits and measured capillary refill time. This is obtained by blanching the nail beds or digits and estimating the time to full reperfusion, which is normally less than 2 seconds. Initially, the radial and brachial pulses should be assessed simultaneously in the upper limb. By palpating the pulse at 2 sites and altering the pressure applied by the palpating fingers, a more accurate assessment of the rate of rise, volume, and contour may be obtained. Assessment of the femoral pulse requires that the infant be quiet. Palpating parallel to the inguinal crease and allowing the leg to continue to flex is generally more effective than extending the leg. Blood pressures in the arm and leg should be assessed, and the radial and femoral pulses should be palpated simultaneously. Whenever possible, the radial pulse should be brought in close apposition to the femoral pulse to compare for any delay. This enables a more accurate appreciation of any temporal delay and enables more accurate detection of the presence of **coarctation of the aorta**. The presence of a palpable femoral pulse is by itself an inadequate screen for coarctation because a widely patent ductus arteriosus (PDA) or collateral vessels (particularly in the older patient) may provide delayed perfusion. Previous arterial instrumentation, injury, or congenital variability may account for reduction in palpable peripheral pulses.

Venous Examination

In infants and young children, the liver character and size offer more reliable indicators of right atrial pressure and systemic congestion than does the jugular venous pressure. The position, size, and consistency of the liver should be assessed. The character of the normal liver margin is generally likened to that of the cartilage of the external pinna, and the margin should be sharp and angulated. In the newborn, the liver may be normally palpable at 1.5-2.5 cm below the right costal margin in the midclavicular line. This distance decreases to approximately 1-2 cm by 1 year of age and remains just palpable until school-entrance age. In the presence of congestive heart failure, the liver enlarges and distends downward. The congested liver margin becomes rounded and firm and is often more difficult to feel. An enlarged liver may be tender, and aggressive palpation may cause discomfort and tensing of the abdominal musculature, making accurate assessment difficult. A transverse liver is suggestive of a **heterotaxy syndrome** with abnormal abdominal organ location (situs abnormalities) and complex congenital heart lesions. The spleen should always be sought; enlargement suggests endocarditis in the patient with a heart murmur. Splenic enlargement in association with congestive heart failure is unusual (see Chapter 17).

Precordial Examination

Inspection of the chest may suggest the presence of a precordial bulge of long-standing right ventricular volume overload. The examiner's entire palm and hand should be warmed and then fully applied to the patient's chest wall to maximize ability to detect thrills or heaves. Whereas the examiner's fingertips are best utilized to localize an abnormality, the palmar surface of the metacarpals and first phalanges are more sensitive for the detection of low-frequency events. The fingertips should be used to localize the most lateral displacement of the apical impulse. In patients of all ages, the apical impulse should be confined to one intercostal interspace and would be described as localized; however, if the apical impulse is equally dynamic in 2 or more interspaces then it is best described as diffuse. In the neonate, a right ventricular impulse may be felt close to the sternum. Later in life, the same degree of parasternal activity is likely to suggest pulmonary hypertension, right-sided heart volume overload, or right ventricular outflow obstruction. The lateral displacement of the apex, normally located in the midclavicular line, should be compared to existing landmarks. A dynamic or thrusting character to an apical impulse may be detected in association with an elevated cardiac output or various forms of obstruction to left ventricular outflow. On occasion, an apical filling impulse, coinciding with an audible S_3, may be normally palpable, particularly in the adolescent or athlete with a relative bradycardia and increased stroke volume.

A **thrill** is a palpable murmur and should be sought in the precordial and suprasternal areas. The palmar surface of the examiner's hand is most sensitive in detection of a thrill; however, only the tips of the digits fit in the patient's suprasternal notch. A palpable second heart sound (S_2), indicative of a significant level of pulmonary hypertension, may be detected as a sharp or distinctive impulse in the pulmonary outflow.

Auscultation

Thorough auscultation in the cooperative patient may take as long as 5-10 minutes and should include listening in the principal areas of the precordial auscultation (tricuspid, pulmonary, mitral, and aortic) with both the bell and diaphragm of the stethoscope, with the patient in the supine, sitting, and standing positions. These 4 areas serve as a guide to auscultation of the heart (Fig. 8.5). These are the optimal sites for listening to sounds that arise within the chambers and great vessels:

1. The tricuspid area is represented by the fourth and fifth intercostal spaces along the left sternal edge but extends to the right of the sternum as well as downward to the subxiphisternal area.
2. The pulmonary area is the second intercostal space along the left sternal border. Murmurs that are best heard in this area may also extend to the left infraclavicular area and often lower, along the left sternal edge to the third intercostal space.
3. The mitral area involves the region of the cardiac apex and generally is at the fifth intercostal space in the midclavicular line. This area may also extend medially to the left sternal edge and laterally to the region of the axilla.
4. The aortic area, although centered at the second right intercostal space, may extend to the suprasternal area, to the neck, and inferiorly to the third left intercostal space. The margins of these areas are ill defined, and auscultation should not be limited to these sites and may extend to the axillae, neck, back, or infraclavicular areas.

A step-by-step auscultation—first for heart sounds, subsequently for systolic murmurs, and then separately for diastolic murmurs—is essential. The ability to clearly characterize the S_2 is perhaps more crucial than for any other sound; the effects of respiration are important. The components of the S_2 in childhood are normally split with

Aortic valve stenosis
Supravalvular AS
Subvalvular AS

Pulmonary valve stenosis
Atrial septal defect
Pulmonary ejection murmur, innocent
Pulmonary flow murmur of newborn
Pulmonary artery stenosis
Aortic stenosis
Coarctation of the aorta
Patent ductus arteriosus
PAPVR
TAPVR

Ventricular septal defect,
including ECD
Vibratory innocent murmur
(Still's murmur)
HOCM (IHSS)
Tricuspid regurgitation
Tetralogy of Fallot

Mitral regurgitation
Vibratory innocent murmur
Mitral valve prolapse syndrome
Aortic stenosis
IHSS

FIGURE 8.5 Diagram showing systolic murmurs audible at various locations. Less common conditions are shown in smaller type. AS, aortic stenosis; ECD, endocardial cushion defect; HOCM, hypertrophic obstructive cardiomyopathy; IHSS, idiopathic hypertrophic subaortic stenosis; PAPVR, partial anomalous pulmonary venous return; TAPVR, total anomalous pulmonary venous return. (From Park MK. *Park's Pediatric Cardiology for Practitioners*. 6th ed. Philadelphia: Elsevier; 2014:33, Figure 2-12.)

inspiration and become single on expiration. A loud pulmonary closure sound should suggest the possibility of pulmonary artery hypertension. The S_2 may be widely split and/or fixed in association with right ventricular volume overload or delayed right ventricular conduction. Normal inspiratory splitting of the S_2 should be sought and established in all patients. As timing may be difficult in the infant with a rapid respiratory rate, the presence of splitting at any time during the respiratory cycle may be accepted as normal.

The right ventricle is normally just beneath the sternum. This proximity generally makes sounds emanating from the right heart louder and less diffuse. In addition, right heart sounds and murmurs are more influenced by the effects of respiration.

Heart Sounds

First direct the examination to the normal heart sounds in sequence. Appreciate the effects of inspiration and expiration on the heart sounds. Then address additional heart sounds and murmurs. Describe any variability that occurs with a change of body position.

First Heart Sound

The first heart sound (S_1) (see Fig. 8.2) arises from closure of the atrioventricular (mitral and tricuspid) valves in early isovolumic ventricular contraction and, consequently, is best heard in the tricuspid and mitral valve areas. Mitral valve closure occurs slightly in advance of tricuspid valve closure, and, on rare occasion, near the lower-left sternal edge 2 components (splitting) of the S_1 may be heard. There is usually a single sound. The S_1 is most easily heard when the heart rate is slow because the interval between the S_1 and S_2 is shorter than the interval between the S_2 and subsequent S_1. The intensity of the S_1 is influenced by the position of the atrioventricular valve at the onset of ventricular contraction.

Second Heart Sound

Shortly after the onset of ventricular contraction, the semilunar valves (aortic and pulmonary) open and permit ventricular ejection. This opening does not usually generate any sound. The atrioventricular valves remain tightly closed during ventricular ejection. As ventricular ejection nears completion, the pressure begins to fall within the ventricles, and the semilunar valves snap closed. This prevents regurgitation from the aorta and pulmonary artery back into the heart. The closure of the semilunar valves generates the S_2 (see Fig. 8.2). The S_2 usually consists of a louder and earlier aortic valve closure sound (A_2), followed by a later and quieter pulmonary valve closure sound (P_2). Normal physiologic splitting or variability is appreciated most easily in the pulmonary area during or near the end of inspiration. During expiration, the aortic and pulmonary valves close almost synchronously and produce a single or narrowly split S_2. Normal splitting of S_2 is caused by (1) increased right-sided heart filling during inspiration because of increased blood volume returning via the venae cavae; and (2) diminished left-sided heart filling because blood is retained within the small blood vessels of the lungs when the thorax expands. During inspiration, when the right ventricle is filled more than the left, it takes slightly longer to empty. This causes the noticeable inspiratory delay in P_2 in relation to A_2. *Splitting of the S_2 during inspiration is a normal finding and should be sought in all patients.*

The aortic and pulmonary pressure in diastole closes the semilunar valves. Many forms of congenital or acquired heart disease have an impact on the pulmonary circulation and, consequently, often affect the S_2. Thus, the higher the pulmonary artery diastolic pressure, the more intense and earlier the P_2 is. Pulmonary hypertension in children is suggested when the P_2 is palpable, loud, and narrowly split or cannot be separated from A_2. If the P_2 is audible outside of the pulmonary area, particularly at the apex, then pulmonary hypertension is likely. A single or narrow split S_2 may also be noted in patients with severe pulmonic or aortic valve stenosis, tetralogy of Fallot, truncus arteriosus, pulmonary atresia, hypoplastic left heart syndrome, tricuspid valve atresia, or Eisenmenger syndrome with a VSD. In the presence of moderate to severe pulmonic stenosis, there is low pulmonary artery diastolic pressure. The pulmonary valve closure is therefore delayed and of decreased intensity and is occasionally inaudible.

The S_2 may be widely split and/or fixed in association with right ventricular volume overload or delayed right ventricular conduction.

Third Heart Sound

The third heart sound (S_3) (see Fig. 8.2), which is of very low frequency, occurs about a third of the way into diastole, at the time of the most rapid filling of the ventricles. It is most likely caused by sudden tension of the ventricles, enough to produce sound vibrations within the myocardial wall. Vibrations in the atrioventricular valve itself, as well as in the chordae, may also contribute to the sound. The amplitude of S_3 increases with an increased ventricular filling rate. When heard at the apex, S_3 is considered left ventricular in origin, and when heard at the lower left sternal border, S_3 is likely to be right ventricular in origin. An apical S_3 of soft to moderate intensity is readily heard in most children and young adults. An S_3 in association with tachycardia is termed a **gallop** and may be caused by lesions associated with left or right ventricular diastolic overload or diminished ventricular compliance.

Fourth Heart Sound

The fourth heart sound (S_4) (see Fig. 8.2) is also of low frequency and can be both left-sided and right-sided in origin. It occurs with atrial contraction against a high resistance and is therefore heard just before S_1. It is more difficult to hear than S_3, particularly in children, in whom the PR interval is usually shorter than that in the adult. The S_4 is thought to be caused by a forceful atrial contraction against a poorly compliant left ventricle (e.g., as in diastolic overload). The sound is readily heard in adults with significant chronic hypertension or left ventricular cardiomyopathy and, except for its timing, sounds much like an S_3. In a young baby with total anomalous pulmonary venous return, low pulmonary vascular resistance, and significantly increased right ventricular and pulmonary blood flow, a loud right ventricular S_4 (as well as S_3) may be heard as part of a quadruple rhythm at the lower left sternal border. An intermittent S_4 may be heard in children with complete atrioventricular block. Whereas an S_3 may be heard in a normal adolescent and can be physiologic, the S_4 only occurs in a pathologic condition.

Ejection Click

An audible ejection click (see Fig. 8.2) is abnormal and is either related to the hemodynamics associated with a dilated root of the aorta (**aortic ejection click**) or a dilated root of the pulmonary artery (**pulmonary ejection click**) or the effects of a thickened and immobile semilunar valve. The sound is sharp and of very high frequency. The pulmonary ejection click is best heard at the upper-left sternal border, whereas the aortic ejection click is usually best heard at the apex. It may also be heard at the upper-right sternal border, but if so, it is always louder at the apex or the lower-left sternal border. The click arises either from sudden tension of the semilunar valve or from sudden distention with lateral pressure at the root of the aorta or pulmonary artery. The sound is present in aortic or pulmonary valve stenosis. In such cases, the rapid movement of the stenotic valve is suddenly checked. An aortic ejection click may be heard in the presence of a normal aortic valve (as in severe tetralogy of Fallot with a large aortic root); a pulmonary ejection click may be heard with a normal pulmonic valve (as in Eisenmenger syndrome with a large pulmonary root). The aortic ejection click, best heard at the apex, does not vary with respirations. However, the pulmonary ejection click, best heard at the upper-left sternal border, is better heard on expiration than inspiration.

An ejection click or a sharp sound present at the upper-left sternal border, louder with expiration or heard only on expiration, is characteristic of **pulmonary valve stenosis**. The ejection click follows the period of isovolumic contraction and occurs as a consequence of restricted semilunar (aortic or pulmonary) valve excursion at the onset of ventricular ejection. When the ejection sound occurs at the upper-right sternal border or at the apex, a bicuspid or stenotic aortic valve disease is suggested. In contrast to ejection clicks, right-sided cardiac murmurs are accentuated with inspiration. Left-sided heart auscultatory abnormalities vary little with the respiratory cycle.

In the case of the aortic ejection click, the sound is usually well separated from S_1. However, the pulmonary ejection click is usually closer to S_1 than is an aortic click. In some moderate to severe cases, the pulmonary ejection click occurs at the same time as S_1. If one perceives a split S_1, one is most likely hearing an ejection click as the causes of a true split S_1 are very rare.

Opening Snap

The opening snap, present only in rheumatic mitral valve stenosis when the anteromedial leaflet is immobile, is heard early in diastole, usually above the apex, and is of medium frequency. Because the leaflets are fused, the downward movement of the opening valve is suddenly checked, resulting in the opening snap. This sound is often confused with an S_3. The frequency is somewhat higher and the timing is earlier than those of an S_3. The opening snap and the S_3, although similar in timing, can never occur together in the same patient.

Non-Ejection Click

Non-ejection clicks are heard at the apex and occur one third to half of the way between S_1 and S_2. Thus, they are commonly called **midsystolic clicks**. The sounds are of medium to high frequency. The sound is caused by the sudden tensing of the posterior mitral valve leaflet as it prolapses into the left atrium; in rare cases, there may be multiple mid-systolic clicks. The clicks may be loud, but they may also be soft and easily missed.

CLASSIFICATION OF CARDIAC MURMURS

Heart murmurs are the consequence of turbulent blood flow. Turbulence may arise as a result of
- high flow through abnormal or normal valves
- normal flow through narrow or stenotic valves or vessels
- backward or regurgitant flow through incompetent leaky valves
- flow through congenital or surgical communications
- anemia with high flows and discrete decreased blood viscosity
  Not all cardiac murmurs indicate heart problems.

The clinician should be able to determine and describe the following seven characteristics of heart murmurs:
1. Timing: the relative position within the cardiac cycle relative to S_1 and S_2
2. Intensity or loudness: murmurs are graded as
   - grade I: heard only with intense concentration
   - grade II: faint but heard immediately
   - grade III: easily heard, of intermediate intensity
   - grade IV: easily heard and associated with a thrill (a palpable vibration on the chest wall)
   - grade V: very loud, with a thrill present, and audible with only the edge of the stethoscope on the chest wall
   - grade VI: audible with the stethoscope off the chest wall
3. Location: on the chest wall with regard to
   - area where the sound is loudest (point of maximal intensity)
   - area over which the sound is audible (extent of radiation)
4. Shape: to include the duration (the length of the murmur from beginning to end) and configuration (the dynamic changing nature of the murmur)

5. Pitch: the frequency range of the murmur, generally described as low, medium, or high—pitched
6. Quality: aspect that relates to the presence of harmonics and the overtones
7. Physiologic effects: of different positions, manipulations, or maneuvers

PEDIATRIC MURMUR EVALUATION

After the neonatal period, an innocent murmur may be detected at some time in the majority of children before school age. The clinical diagnosis of a normal ejection or innocent murmur should only occur in the setting of an otherwise normal history, physical examination, and appearance (Table 8.5 and Fig. 8.6).

Thorough auscultation in the cooperative patient should include listening in the principal areas (tricuspid, pulmonary, mitral, and aortic) of the precordium with both the bell and diaphragm of the stethoscope and with the patient in the supine, sitting, and standing positions.

SYSTOLIC MURMURS

Systolic murmurs begin with or follow the S_1 and end before the S_2 (Fig. 8.7).

Holosystolic murmurs, beginning abruptly with S_1 and continuing at the same intensity to S_2, are graphically shown as a rectangle. This murmur begins during the period of isovolumic contraction and thus occurs when there is a regurgitant atrioventricular valve (tricuspid or mitral) or in association with a VSD.

Ejection murmurs are crescendo-decrescendo or diamond-shaped murmurs that may arise from narrowing of the semilunar valves or outflow tracts. The rising-and-falling nature of the murmur reflects the periods of low flow at the beginning and end of ventricular systole.

Innocent murmurs are almost exclusively ejection systolic in nature (see Table 8.5). They are generally soft, are never associated with a palpable thrill, and are subject to considerable variation with positioning changes.

Early systolic murmurs start abruptly with S_1 but taper and disappear before the S_2 and are exclusively associated with small muscular VSDs.

Mid-systolic to late-systolic murmurs begin midway through systole and are often heard in association with the mid-systolic clicks and insufficiency of mitral valve prolapse.

DIASTOLIC MURMURS

Diastole, the period between closure of the semilunar valves (S_2) and subsequent closure of the atrioventricular valves (S_1), is normally silent because of relatively low flow through large valve orifices. Regurgitation of the semilunar valves, stenosis of the atrioventricular valves, or increased flow across the atrioventricular valves all cause turbulence and may produce diastolic heart murmurs (Fig. 8.8).

Early diastolic murmurs are decrescendo in nature and arise from either aortic or pulmonary valve insufficiency (regurgitation).

Mid-diastolic murmurs are diamond-shaped and occur because of either (1) increased flow across the normal tricuspid or mitral valve or (2) normal flow across an obstructed or stenotic tricuspid or mitral valve.

Late diastolic or crescendo murmurs are created by stenotic or narrowed atrioventricular valves and occur during atrial contraction.

CONTINUOUS MURMURS

Flow through vessels, channels, or communications beyond the semilunar valves is not confined to either systole and/or diastole. Thus, there may be turbulent flow throughout some or all of the cardiac cycle (Fig. 8.9). The resulting murmur that extends beyond the S_2 has been classically termed "continuous." The continuous murmur can be heard through part or all of diastole. Continuous murmurs are generally pathologic; the venous hum is an exception.

TABLE 8.5 Common Innocent Heart Murmurs in Children

Type (Timing)	Description of Murmur	Age Group
Classic vibratory murmur (Still murmur) (systolic)	Maximal at MLSB or between LLSB and apex Grade 2 to 3/6 Low-frequency vibratory, "twanging string," groaning, squeaking, or musical	3–6 yr Occasionally in infancy
Pulmonary ejection murmur (systolic)	Maximal at ULSB Early to mid-systolic Grade 1-3/6 in intensity Blowing in quality	8–14 yr
Pulmonary flow murmur of newborn (systolic)	Maximal at ULSB Transmits well to the left and right chest, axilla, and back Grade 1-2/6 in intensity	Premature and full-term newborns Usually disappears by 3–6 mo of age
Venous hum (continuous)	Maximal at right (or left) supraclavicular and infraclavicular areas Grade 1-3/6 in intensity Inaudible in the supine position Intensity changes with rotation of the head and compression of the jugular vein	3–6 yr
Carotid bruit (systolic)	Right supraclavicular area and over the carotids Grade 2-3/6 in intensity Occasional thrill over a carotid	Any age

LLSB, lower left sternal border; MLSB, mid-left sternal border; ULSB, upper left sternal border.

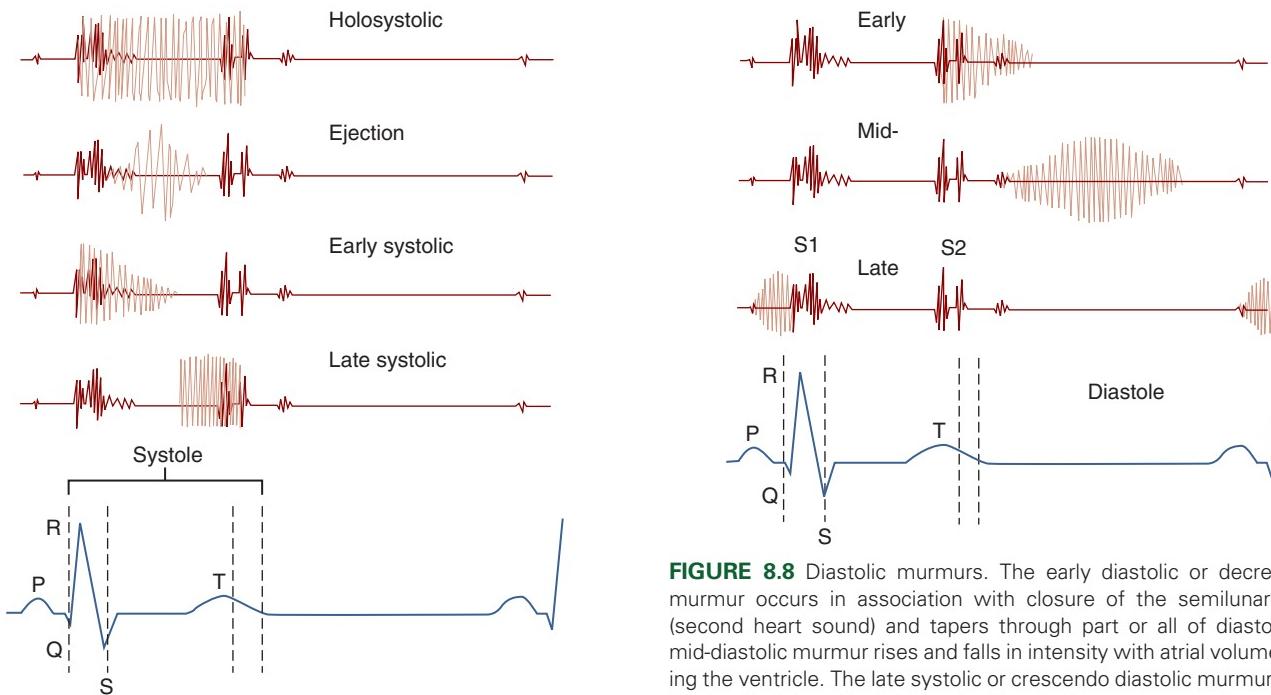

FIGURE 8.7 Four types of systolic heart murmurs. The holosystolic or pansystolic murmur begins abruptly with the first heart sound (S_1) and proceeds at the same intensity to the second heart sound (S_2). The ejection systolic or crescendo-decrescendo murmur begins with the onset of volume ejection from the heart. As the flow increases, the murmur varies both in intensity and frequency and subsequently tapers as the period of ejection ceases, before the S_2. The early systolic murmur begins, as does the holosystolic murmur, abruptly with S_1 but terminates in mid-systole with the cessation of shunt flow. The late systolic murmur begins well after S_1, commencing in mid- to late systole in association with the development of valve insufficiency and proceeds at this intensity to S_2. (From Pelech AN. The cardiac murmur. *Pediatr Clin North Am*. 1998;45:107-122.)

FIGURE 8.8 Diastolic murmurs. The early diastolic or decrescendo murmur occurs in association with closure of the semilunar valves (second heart sound) and tapers through part or all of diastole. The mid-diastolic murmur rises and falls in intensity with atrial volume entering the ventricle. The late systolic or crescendo diastolic murmur occurs late in diastole with atrial contraction, before systole, and ascends to the first heart sound. (From Pelech AN. The cardiac murmur. *Pediatr Clin North Am*. 1998;45:107-122.)

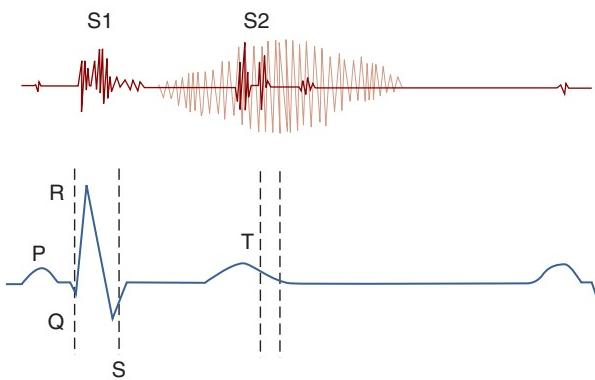

FIGURE 8.9 Continuous murmur. The continuous murmur begins in systole and proceeds up to and through the second heart sound, proceeding through part or all of diastole. (From Pelech AN. The cardiac murmur. *Pediatr Clin North Am*. 1998;45:107-122.)

MURMURS IN CHILDREN WITH NORMAL HEARTS

"Innocent" murmurs occur in the absence of structural or physiologic cardiac disease. Innocent murmurs have been called functional, benign, innocuous, or physiologic but are perhaps best termed normal to accurately convey to parents the favorable impression and outcome that should accompany the diagnosis. After the neonatal period, a normal murmur may be detected in the majority of children at some time before school age.

The normal murmurs of childhood are composed of five systolic and two continuous types but are never solely diastolic (see Table 8.5 and Fig. 8.6). The intensity or loudness of the murmur is grade III or less and consequently is never associated with a palpable thrill. The majority of all murmurs, both innocent and organic, are accentuated by fever, anemia, or increased cardiac output.

Vibratory Still Murmur

The most common innocent murmur in children is the vibratory systolic murmur described by Sir George Still. The murmur is typically audible in children between ages 2 and 6 years, but may be present as late as adolescence or as early as infancy. The murmur is low to medium in pitch, confined to early systole, generally grade II (range I-III), and heard maximally at the lower-left sternal edge and extending to the apex. The murmur is loudest when the patient is in the supine position and often changes in character, pitch, and intensity with upright positioning.

The most characteristic feature of the murmur is its vibratory, musical, harmonious quality described as a twanging sound, very like that made by twanging a piece of tense string. The quality of the murmur can thus never be described as "noisy" or "rough." Quite characteristically, the intensity of the murmur diminishes and the pitch changes with upright positioning; it seldom disappears entirely.

The origins of the murmur are obscure and have been ascribed to vibration of the pulmonary valves during systolic ejection, vibrations arising from the shift in blood mass in the dynamically contracting ventricle, physiologic narrowing of the left ventricular outflow tract, and the presence of ventricular false tendons or bridging bands. Phonocardiographic recordings have shown the innocent murmur to arise from either the right ventricular or left ventricular outflow tracts.

Pulmonary Flow Murmur

An innocent pulmonary outflow tract murmur may be heard in children, adolescents, and young adults. The murmur is a crescendo-decrescendo, loudest in early- to mid-peaking ejection systolic murmur confined to the second and third interspaces at the left sternal border. It is of low intensity (grades II-III) and transmits to the pulmonary area. It is rough and dissonant without the vibratory musical quality of the Still murmur. The murmur is best heard in the supine position and is exaggerated by the presence of a pectus excavatum, a straight back, or kyphoscoliosis, which results in compression or approximation of the right ventricular outflow tract to the chest wall. The murmur is augmented in full exhalation while the patient is supine, rarely resulting in the perception of a palpable thrill, and is diminished by upright positioning and held inspiration.

The murmur of an ASD is attributable to increased flow through the pulmonary outflow tract and may be indistinguishable from the innocent pulmonary flow murmur. However, the hyperdynamic right ventricular impulse, wide splitting of the pulmonary component of the S_2, and presence of a mid-diastolic flow rumble should enable distinction.

The murmur of pulmonary valve stenosis may be distinguished from the innocent pulmonary flow murmur by the frequent presence of a systolic thrill, higher pitch, longer duration, and/or presence of an ejection click. The presence of an ejection click signifies improper opening of a semilunar valve and is usually of pathologic origin. In pulmonary stenosis, the S_2 may be widely split and the P_2, when audible, is of diminished intensity.

Peripheral Pulmonary Arterial Stenosis Murmur

A common murmur heard frequently in newborns and in infants younger than 1 year is the audible turbulence of peripheral branch pulmonary arterial stenosis, angulation, or narrowing. These ejection character murmurs are typically grade I or II, are low to moderate in pitch, begin in early to middle systole, and extend up to and occasionally just after the S_2. These murmurs are most often present in normal newborns but may be associated with viral lower respiratory tract infections and reactive airway disease in older infants. In the fetus, the pulmonary trunk is a relatively dilated, domed structure because it receives the majority of combined cardiac output from the high-pressure right ventricle. Right and left pulmonary artery branches arise from this major trunk as comparatively small lateral branches that receive little intrauterine flow because of high pulmonary artery resistance. When the lungs expand at birth, the relative disparity transiently persists. The branches also arise at comparatively sharp angles from the main pulmonary trunk, accounting for turbulence and a recognized physiologic drop in pressure from the main trunk to the proximal branch pulmonary arteries. In association with a respiratory tract infection, regional vascular reactivity and pulmonary blood flow redistribution may account for the reappearance of the murmur after the neonatal period.

The murmurs are often best heard peripherally in the axillae and back with both regional and temporal variability. Because of the rapid respiratory rate of infants, similar sound frequency composition of breath sounds, and peripheral location of the murmurs, these murmurs are often overlooked. They are often most evident in the recovery phase of a respiratory illness. Of importance is that the murmur of peripheral branch stenosis changes with heart rate variability, increasing in intensity with heart rate slowing as the stroke volume increases and, conversely, diminishing with tachycardia and reduction in stroke volume.

The normal peripheral branch stenosis murmur may be indistinguishable from the peripheral murmur of significant stenosis of the branch pulmonary vessels seen in Williams or rubella syndrome or from accompanying hypoplasia or narrowing of the pulmonary arteries. Murmurs of significant anatomic narrowing may be distinguished by their higher pitch and extension after the S_2 in children after the first few months of life. The pulmonary flow murmur of an ASD may mimic this murmur but is not heard in this age group. Proximal pulmonary valve or right ventricular outflow obstruction may also closely resemble this murmur, but these obstructions are often of louder intensity, possibly associated with an ejection click, and heard maximally lower along the left sternal border.

Supraclavicular or Brachiocephalic Systolic Murmur

A supraclavicular systolic crescendo-decrescendo murmur may be heard in children and young adults. This systolic murmur is audible maximally above the clavicles and radiates to the neck but may be present to a lesser degree on the superior chest. The murmur is low to medium in pitch, of abrupt onset, brief, and maximal in the first half or two thirds of systole. High pitch or extension into diastole is unusual and suggests significant vascular obstruction.

The murmur is present in both supine and sitting positions but varies with hyperextension of the shoulders. The shoulders can be hyperextended with the elbows brought behind the back until the shoulder girdle is taut. When this maneuver is done rapidly, the

murmur diminishes or disappears altogether. Supraclavicular systolic murmurs are thought to originate from the major brachiocephalic vessels as they arise from the aorta.

Aortic Systolic Murmur or "Athlete's Murmur"

Innocent systolic flow murmurs may arise from the outflow tract in older children and young adults. The murmurs are ejection in character, confined to systole, and audible maximally in the aortic area. In children, these murmurs may arise secondarily to extreme anxiety, anemia, hyperthyroidism, fever, or any condition of increased systemic cardiac output.

In trained athletes, slower heart rates with increased stroke volume may give rise to short crescendo-decrescendo murmurs of low to medium pitch. Physical examination may suggest a relatively displaced thrusting apex and a physiologic S_3.

These murmurs must be distinguished from the systolic murmur of hypertrophic cardiomyopathy obstructions of the left ventricular outflow tract. The presence of a family history for hypertrophic cardiomyopathy or a family history of unexplained death in a young individual, particularly if associated with activity, is suggestive of hypertrophic cardiomyopathy. A systolic murmur that gets louder with performance of the Valsalva maneuver is considered almost diagnostic of hypertrophic cardiomyopathy with systolic anterior motion of the mitral valve. A reduction in venous return results in closer apposition of the septum and mitral valve and dynamic narrowing of the left ventricular outflow tract. In contrast, rapid squatting improves venous return; the left ventricular chamber size is enlarged, the mitral valve and septum are farther apart, and the murmur of hypertrophic cardiomyopathy gets softer. It is often difficult to be certain of the cause of this type of aortic murmur, and further investigations may be indicated.

Normal Continuous Murmurs

Venous Hum

The most common type of continuous murmur heard in children is the innocent cervical venous hum, which is most audible on the low anterior part of the neck just lateral to the sternocleidomastoid muscle but often extends to the infraclavicular area of the anterior chest wall. The murmur is generally louder on the right than on the left, is louder when the patient is sitting than when lying down, and is accentuated in diastole. Intensity varies from faint to grade III. Patients are occasionally aware of a loud hum. The murmur is quite variable in character, always low pitched and often described as rumbling, roaring, or whirring.

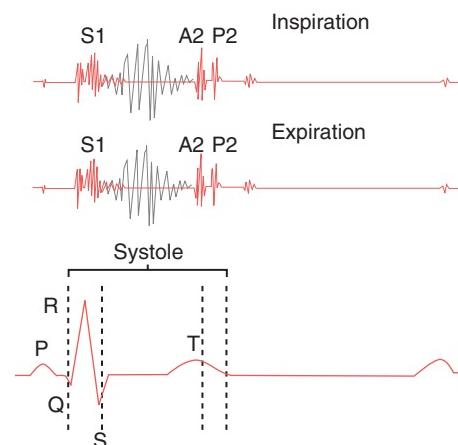
The venous hum is best accentuated or elicited with the patient in a sitting position and looking away from the examiner. The murmur often resolves or changes in character with lying down and may be eliminated or diminished by gentle compression of the jugular vein or turning the head toward the side of the murmur. The murmur is thought to arise from turbulence at the confluence of flow as the internal jugular and subclavian veins enter the thoracic inlet or perhaps from angulation of the internal jugular vein as it courses over the transverse process of the atlas.

Mammary Arterial Soufflé

The mammary arterial soufflé occurs most frequently late in pregnancy and in lactating women but may occur in rare cases in adolescence. The murmur arises in systole but may extend well into diastole, being audible maximally on the anterior chest wall over the breast. There is usually a distinct gap between the S_1 and the origin of the murmur; this gap is thought to relate to the delayed arrival of cardiac stroke volume at the peripheral vasculature. The murmur is generally high pitched and has an unusual superficial character but may vary considerably from day to day. Firm pressure with the stethoscope or digit pressure on the chest wall occasionally abolishes the murmur. The murmur is thought to be arterial in origin, arising from the plethoric vessels of the chest wall. The murmur must be distinguished from the continuous high-pitched murmur of an arteriovenous fistula or a PDA. Characteristically, the mammary arterial soufflé varies significantly from day to day, is present in a most distinctive patient population, and resolves with termination of lactation.

PHYSICAL EXAMINATION OF COMMON LESIONS WITH LEFT-TO-RIGHT SHUNT

Atrial Septal Defects

The most common form of ASD (Fig. 8.10) is the ostium secundum defect in the floor of the fossa ovalis. Blood flow through an ASD in


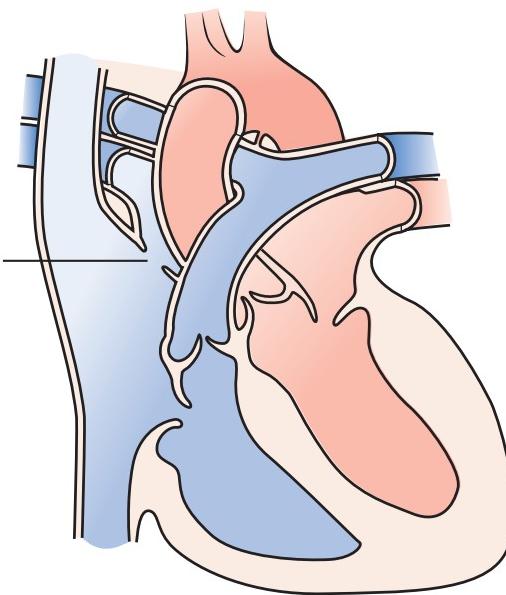


**FIGURE 8.10** Atrial septal defects. The most common type of defect, the secundum atrial septal defect, is shown. Characteristically, in association with a large left-to-right shunt, wide and fixed splitting of the second heart sound occurs. The murmur is that of increased flow through the right ventricular outflow tract. The shunt flow through the defect, which occurs at low pressure, is inaudible.

the low-pressure atria is inaudible. The auscultatory findings in ASD are related to the consequences of increased blood volume that enters the right side of the heart. The right ventricular volume overload is associated with right ventricular overactivity and a right ventricular parasternal tap.

The right atrium and ventricle receive the blood returning from the body plus the blood shunted from left to right through the ASD. This causes a prolongation of right-sided heart emptying. The P_2 of the S_2 is often widely split and fixed (no respiratory variation).

Two types of murmur may be audible:

1. The typical pulmonary flow murmur is ejection systolic in character, generally of low intensity (grade II or III), and of low pitch. The crescendo-decrescendo murmur begins shortly after the S_1 and ends well before the S_2.
2. In patients with a large atrial shunt, there is typically a well-localized, low-pitched mid-diastolic flow rumble in the tricuspid area because of increased flow across the tricuspid valve.

ASDs may lead to pulmonary hypertension in the second and third decades of life. Treatment is surgical or by device closure during cardiac catheterization.

PATENT DUCTUS ARTERIOSUS

In this condition, the connection between the aorta and pulmonary artery that exists prenatally remains open after birth (Fig. 8.11).

The amount of shunt flow is dependent not only on the size of the ductus communication but also on the differential resistances of the systemic and pulmonary circulations. In some children, the PDA may produce significant left-sided heart volume overload and signs of high-output congestive heart failure.

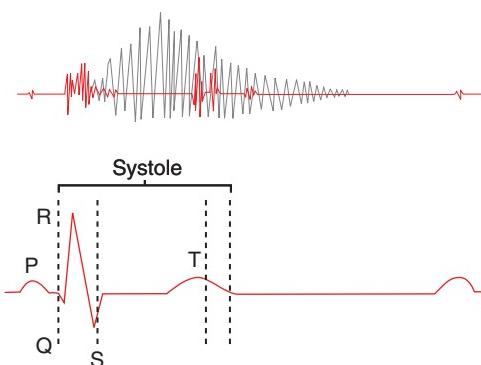
The peripheral pulses associated with significant diastolic runoff to the pulmonary vascular area are bounding. Palpation may reveal a thrill in systole at the upper-left sternal edge (when the murmur is grade IV or greater); an abnormal left ventricular impulse; and, if the left-to-right shunt is large, a hyperdynamic and displaced apical impulse. The majority of patients have an asymptomatic murmur.

Premature infants often have persistence of ductal patency after birth. Initially, in the presence of neonatal lung disease and elevated pulmonary vascular resistance, the shunt volume is not large. After the lung disease improves, the presence of a PDA becomes apparent through the detection of a cardiac murmur and bounding pulses. Preterm infants with a PDA may show signs of heart failure, pulmonary edema, a hyperdynamic precordium, and difficulty in weaning from the ventilator. Treatment in preterm infants includes intravenous indomethacin or ibuprofen and fluid restriction; if these measures are unsuccessful, surgical ligation is generally indicated.

The PDA causes a continuous machine-like murmur, best heard in the pulmonary area. The murmur is generally high pitched, peaks in late systole, and continues well through the S_2. If the PDA is large, a mid-diastolic flow rumble may be heard at the apex because of relative mitral valve stenosis. Beyond the neonatal period, treatment is surgical ligation or device closure during cardiac catheterization.

VENTRICULAR SEPTAL DEFECTS

These common developmental communications between the two ventricles (Fig. 8.12) may be classified as

- perimembranous
- muscular
- atrioventricular or inlet
- subarterial or outlet


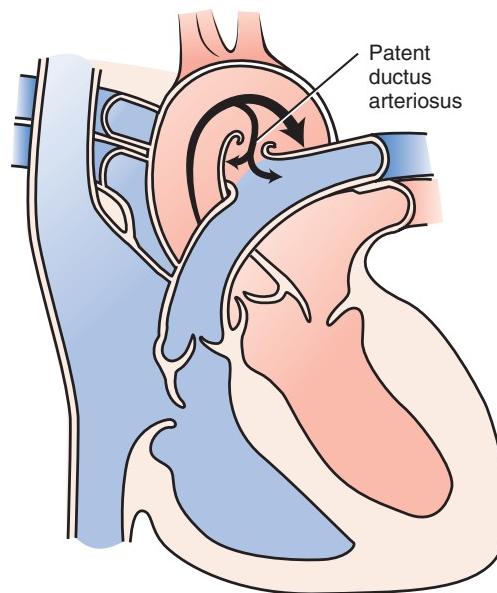


FIGURE 8.11 The patent ductus arteriosus consists of residual patency of a fetal communication between the two great arteries. Because the shunt occurs outside the heart, the murmur is continuous and high pitched if the defect is restrictive and the pulmonary artery pressures are low.

The acoustic findings depend on five factors:

1. Size
2. Location
3. Shunt or defect flow
4. Pulmonary hypertension
5. Associated anomalies

All of these factors need to be addressed in the clinical description of a VSD.

The VSD (Fig. 8.13) causes a left-to-right shunt or, in rare cases, a right-to-left shunt, depending on the resistance to the flow of blood leaving the ventricles. The turbulence and thus the intensity of the murmur are directly proportional to the flow and pressure difference between the ventricles.

Size

A moderate-sized VSD that is restrictive (i.e., a pressure difference exists between the ventricles) causes a harsh blowing holosystolic murmur, which is often very loud and frequently associated with a palpable thrill.

The very restrictive or small VSD creates a high-pitched systolic murmur and causes little or no physiologic disturbance. Muscular

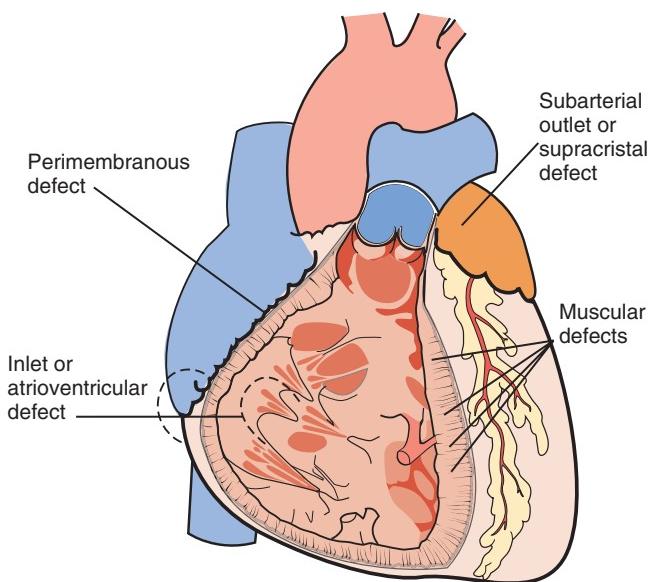
(See *Nelson Textbook of Pediatrics,* Fig. 426-6.)


FIGURE 8.12 Anatomic types of ventricular septal defects. The 4 types of defects of the ventricular septum are shown. The most common type is the muscular defect, which commonly occurs in the anterior trabecular area of the septum. The perimembranous (often called membranous) defect occurs in the regions of the pars membranacea, or the embryonic bulboventricular foramina. The subarterial outlet, or supracristal defect, extends to the fibrous ring of the semilunar valves. The inlet or atrioventricular septal defect is that of the atrioventricular canal or embryonic atrioventricularis communis.
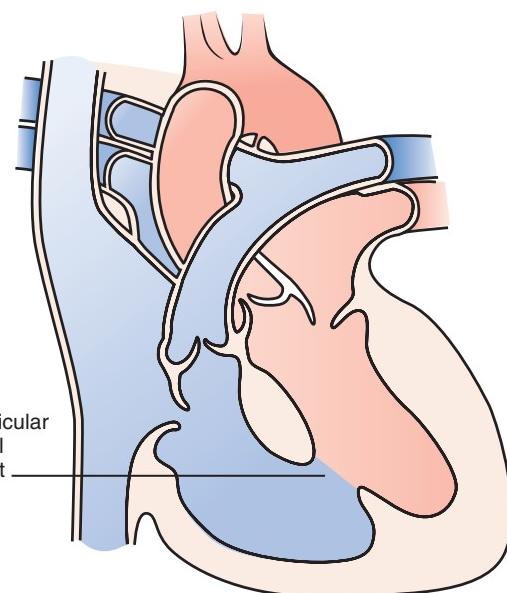


defects may close in mid-systole, which then abruptly stops shunt flow and the murmur before S_2.

In an unrestrictive or large VSD, no pressure difference exists between the two ventricles. This results in less turbulence and therefore a reduced intensity of the murmur.

Location

The perimembranous defect is best heard at the left sternal edge in the third left intercostal space. Muscular defects are heard variably from the sternal edge to the apex. Outlet or subarterial defects are best heard higher along the sternum.

Shunt Flow

If the volume of flow through the VSD (shunt flow) is large (i.e., more than 2-3 times normal ventricular outflow), a low-pitched, mid-diastolic flow rumble may be heard in the mitral area. The extra volume of blood returning from the pulmonary circulation to the left side of the heart creates this murmur of "relative" (not true anatomic) mitral valve stenosis.

Pulmonary Hypertension

High pressure in the pulmonary artery limits left-to-right shunt flow and murmur intensity. The pulmonary closure sound is louder and is either narrowly split or single.

Associated Anomalies

Frequently there are anomalies associated with a VSD, such as right- or left-sided heart outflow obstruction or aortic insufficiency. This may affect the character of the murmur.

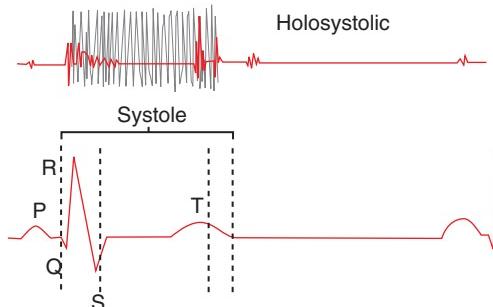
Of importance is that the VSD murmur begins very early with the onset of left ventricular contraction, which may precede right ventricular contraction because the left ventricle is activated earlier. The


FIGURE 8.13 Ventricular septal defects. A ventricular septal defect is a communication between the high-pressure left ventricle and the lower-pressure right ventricle. The shunt flow begins with the onset of ventricular contraction before the period of ejection (isovolumic contraction) and consequently gives rise to a holosystolic murmur that obscures the first and often the second heart sounds. The murmur is high pitched if the defect is restrictive, and the right-sided heart pressures are low; however, the murmur may be low pitched or even inaudible if the defect is large or if the pulmonary artery pressures are high, as occurs in the newborn.

murmur commences during the period of isovolumic contraction and, if it is loud (grade III or greater), often obscures the S_1. Blood is ejected from the left ventricle to the right ventricle throughout systole, giving rise to a classical full-length, or "holosystolic," murmur. On occasion, VSD murmurs may not be full length. This may occur in a small muscular VSD that coapts or closes in mid-systole or, in rare cases, in the presence of heart failure with diminished systolic function.

Analysis of the S_2 in VSD is important and, in conjunction with precordial palpation, enables estimation of the pulmonary artery pressure. The larger the defect, the higher the pulmonary artery pressure and the earlier and louder the P_2 are. Thus, the split of S_2 may become very narrow, or the S_2 may even become single, a finding of great concern. In large defects, a balance exists between delayed P_2, caused by large pulmonary blood flow, and early P_2 caused by high pulmonary artery pressure. The wider the split of S_2, the less the concern is, because pulmonary vascular resistance is then likely to be low.

The intensity or loudness of a murmur relates to the combination of both flow and gradient across the defect. Pitch or frequency relates

to gradient alone. Thus, very small defects with small left-to-right shunt flow may have a soft, high-pitched murmur. In moderate-sized defects, the murmur is loud, often associated with a palpable thrill. In large defects with no restriction between the right and left ventricle, the murmur is low pitched and less intense as the pulmonary artery and right-sided heart pressures equate with the left-sided heart pressure.

In many children, the VSD spontaneously closes, as noted, and the murmur becomes softer and softer until it disappears with defect closure. In patients who develop increased pulmonary vascular resistance and a reduction in shunt flow and who are at risk for progressing to **Eisenmenger syndrome** (irreversible pulmonary vascular disease and cyanosis with right-to-left ventricular level shunt), the murmur also becomes quieter. Thus, a diminishing VSD murmur may be evolving into either a good or bad outcome. The treatment of a VSD includes management of heart failure and surgery.

COMPLETE ATRIOVENTRICULAR SEPTAL DEFECTS

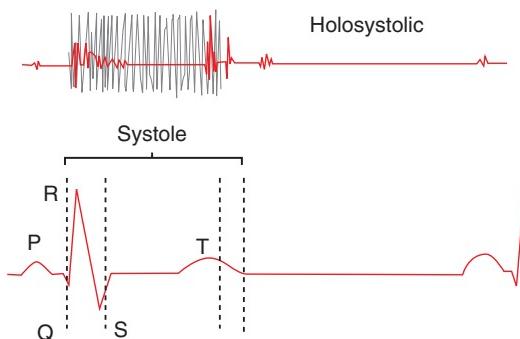
There is great variation in the anatomy of atrioventricular septal defects (AVSDs). AVSDs (Fig. 8.14) occur in complete, partial, and intermediate forms. In the complete AVSD, the intracardiac defect extends between both the atria and ventricles. The atrial or ventricular extent of the defect may be the primary level of shunt flow; consequently, the defect may manifest primarily as either an ASD or VSD. Often the defects are large and unrestrictive. In addition, a common accompaniment of AVSD is a cleft in the left-sided atrioventricular valve, which may cause varying degrees of valve insufficiency. Approximately half of the children born with **Down syndrome** have congenital heart disease, the most common abnormality of which is complete AVSD. Maturation of the pulmonary arteries and small muscular arteries is delayed in children with Down syndrome, and elevated pulmonary vascular resistance early in life is common. Therefore, the lesion may be missed early in life because signs of congestive heart failure may not occur. It is recommended that all children with Down syndrome undergo echocardiographic evaluation. In patients with complete AVSDs, the electrocardiogram demonstrates an abnormally counterclockwise superior vector due to displacement of the AV node. If this finding is present, an echocardiogram should be obtained. Intermediate or partial AVSDs are less likely associated with Down syndrome.

In the partial form of AVSD, absence of the lower part of the interatrial septum, the **ostium primum**, is the major component of the abnormality. In such patients, the manifestation and examination are similar to those described for a secundum type of ASD. Often, mitral regurgitation is present and is apparent as an apical holosystolic murmur that obscures S1. If the amount of mitral valve insufficiency is large, a mid-diastolic flow rumble of increased filling may be heard.

The manifestation and consequently the clinical signs in patients with AVSD vary considerably, depending on the patient's age, pulmonary vascular resistance, size and level of the defects, amount of valve insufficiency, and ventricular function. Patients with an AVSD often manifest the signs of congestive heart failure early in infancy. Surgical repair provides definitive treatment.

PHYSICAL EXAMINATION OF COMMON LESIONS WITH RIGHT-TO-LEFT SHUNT: CYANOSIS

Tetralogy of Fallot

The tetralogy (Fig. 8.15) has 4 anatomic features:
1. VSD
2. Pulmonary stenosis


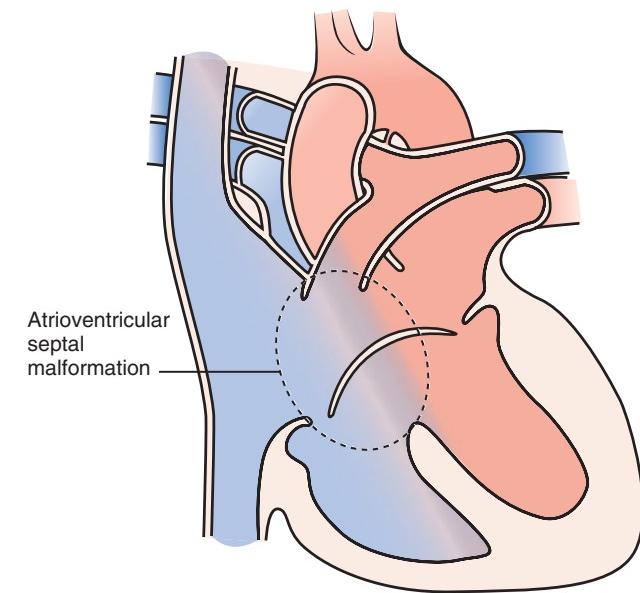


FIGURE 8.14 Complete atrioventricular septal malformation. The atrioventricular septal malformations vary markedly between a large atrial component with a restrictive ventricular communication to a large unrestrictive inlet ventricular septal defect. Consequently, their clinical manifestations also vary from that of an atrial septal defect to that of an unrestrictive ventricular septal defect.

3. Dextroposition or rightward position of the aorta
4. Right ventricular hypertrophy

The functional significance of this anomaly is related to the degree of right ventricular outflow tract obstruction. There is a harsh ejection systolic murmur, heard best in the pulmonary area but also widely transmitted through the chest. The right ventricular outflow obstruction is most frequently a combination of muscular, annular, and valvular narrowing. Consequently, the P2 is soft, delayed and is often inaudible. The VSD is typically large and unrestrictive. The prominent systolic murmur in tetralogy of Fallot is therefore not caused by the septal defect.

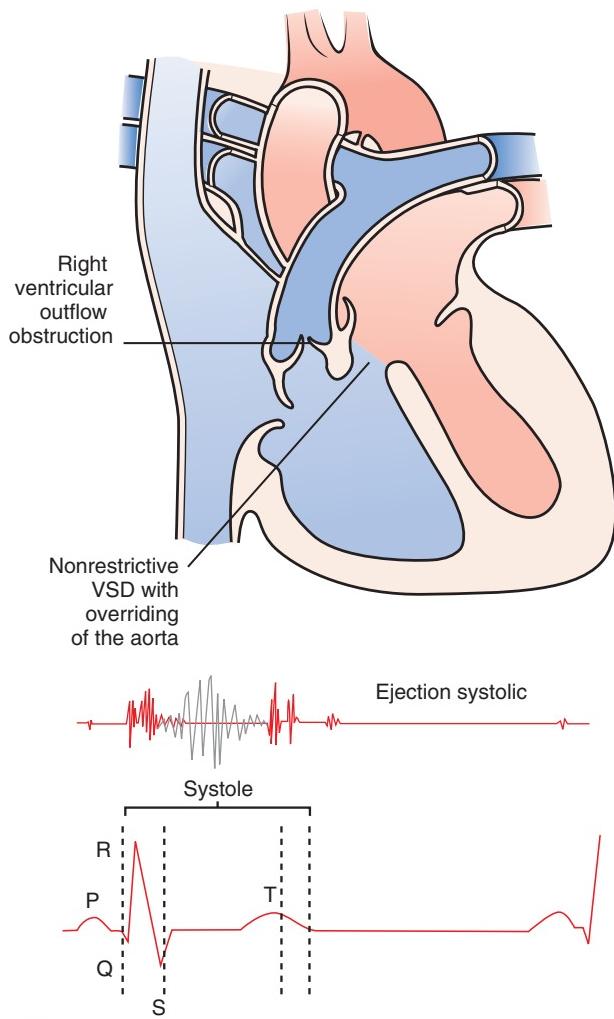
Patients with tetralogy of Fallot may present with moderate to severe degrees of right ventricular outflow obstruction, right-to-left ventricular level shunting, and varying degrees of cyanosis. Alternatively, the outflow obstruction may be mild, providing a predominant left-to-right shunt and causing the "acyanotic" or "pink" form of tetralogy of Fallot. In these patients, the degree of outflow obstruction becomes progressive; bidirectional flow develops and, finally, a dominant right-to-left shunt emerges.


FIGURE 8.15 Tetralogy of Fallot. The 4 anatomic malformations seen in association with tetralogy of Fallot include an unrestrictive perimembranous ventricular septal defect (VSD), overriding of the aorta, right ventricular hypertrophy, and an obstructive right ventricular outflow tract. The cardiac murmur in tetralogy, a harsh loud ejection systolic murmur, arises from the turbulence generated in the right-sided heart outflow. Because the VSD is unrestrictive and the right- and left-sided heart pressures are equal, the VSD generates no sound. The pulmonary closure sound is often soft or inaudible.

FIGURE 8.16 Tricuspid valve atresia. In this condition, the murmur most often detected is a holosystolic murmur of a communicating ventricular septal defect or an ejection systolic murmur related to an obstructing pulmonary outflow.

One aspect of tetralogy physiology is the variable degree of desaturation that may occur as a consequence of the reactive nature of the right ventricular outflow obstruction. The sudden development of severe reactive obstruction in response to temperature, fever, illness, dehydration, or intense crying may precipitate a **hypercyanotic** or **tetralogy spell**. Either increased infundibular reactivity or decreased systemic vascular resistance is responsible for the diminished pulmonary blood flow. This life-threatening event manifests as profound cyanosis, tachypnea, and dyspnea, progressing to acidosis, unconsciousness, and death. During a spell, the outflow tract murmur disappears with the diminution in pulmonary blood flow.

Tetralogy of Fallot is a consequence of developmental anterior displacement of the conal or outlet septum and failure to adjoin with the muscular trabecular interventricular septum. Because conal tissue is needed for closure of the membranous ventricular septum, the anterior displacement and hypoplasia of the conus results in a VSD, which

is characteristically unrestrictive. The aorta extends more to the right, which results in overriding of the aorta.

In cases in which there is a predominant left-to-right shunt, the murmur is a long, loud ejection systolic murmur and may overwhelm and obscure the S_1. The murmur extends up the left sternal border (pulmonary area) and throughout both lung fields. The right ventricle is at systemic pressure, and the pitch of the murmur is quite high. There is a right ventricular parasternal impulse and often a palpable thrill in the pulmonary outflow region.

In cyanotic tetralogy of Fallot, the loudness or intensity of the murmur diminishes as the pulmonary blood flow decreases. The systolic murmur remains high pitched, harsh, and ejection in shape. The S_1 remains loud or normal; the S_2 is single.

In the most severe form of tetralogy, pulmonary atresia with VSD, there is no pulmonary outflow murmur at all. Definitive corrective treatment of tetralogy of Fallot is surgical.

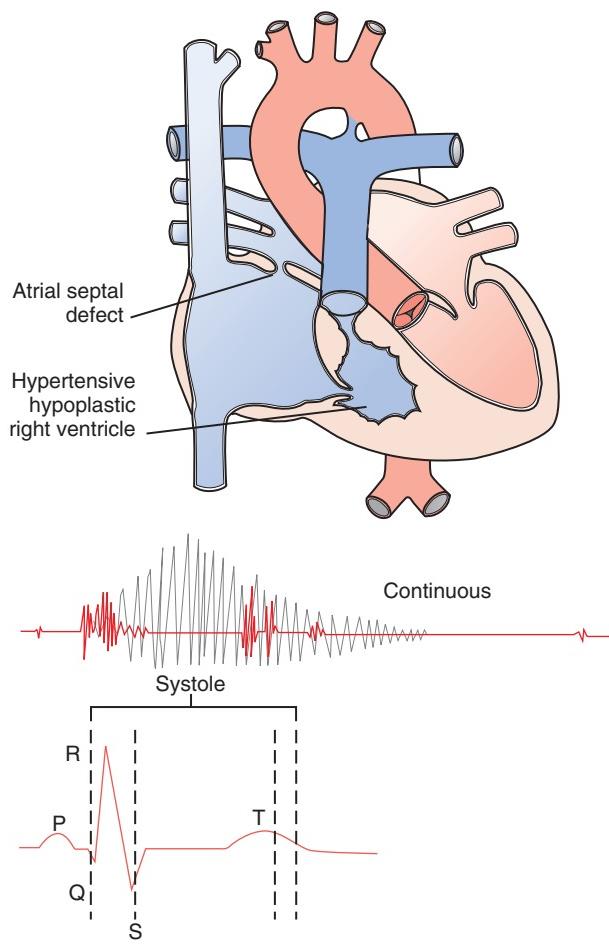
TRICUSPID VALVE ATRESIA

In tricuspid valve atresia (Fig. 8.16), the tricuspid valve does not develop, and in its place there may be an imperforate membrane or a

thick muscle wedge. The right ventricle is usually very small; the left ventricle compensates and is large. A dynamic diffuse left ventricular cardiac impulse is palpable. All systemic venous blood returning to the right atrium must pass across at atrial septal level to enter the left atrium and then the left ventricle. Pulmonary blood flow occurs most often as a consequence of a VSD or, in rare cases, is dependent on the ductus arteriosus. The electrocardiogram reveals an abnormally superior left axis. Examination reveals a VSD murmur. The softer and shorter the murmur, the less the pulmonary blood flow is, so that, just as in tetralogy of Fallot, the softer the murmur, the more severe the cyanosis is. If there is enough pulmonary blood flow, both P_2 and A_2 may be heard. Palliative surgery is required.

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

There are two forms of pulmonary valve atresia. The first is pulmonary atresia with VSD and generally a long fibrous or muscular outflow atresia, which is the most severe malformation on the spectrum of tetralogy of Fallot. The second form occurs in association with an intact interventricular septum (Fig. 8.17), and right-sided heart hypoplasia is usually then present.

The cardiac impulse in hypoplastic right ventricle with pulmonary atresia may be right ventricular even though the dominant ventricle is the left. In contrast to tricuspid valve atresia, a VSD is not part of this lesion. The source of the pulmonary blood flow in the neonate is a ductus arteriosus with left-to-right shunt. A murmur from this ductus may be audible. There is a single S_2 (aortic closure). On occasion, there is tricuspid valve regurgitation, which may be confused with a VSD murmur. The murmur is high pitched, because the right ventricular pressures are very high. The electrocardiogram helps differentiate tricuspid valve and pulmonary atresia. In both disorders, left ventricular hypertrophy is present, but in pulmonary atresia, there is a normal inferior vector. Echocardiography confirms the diagnosis. There is usually profound cyanosis.


Intravenous prostaglandin therapy is required to ensure ductal patency and pulmonary blood flow in the neonatal period. Surgical repair is usually palliative.

TRANSPOSITION OF THE GREAT ARTERIES

In transposition of the great arteries (Fig. 8.18), the aorta arises from the morphologic right ventricle, and the pulmonary artery arises from the morphologic left ventricle. In transposition of the great arteries, desaturated systemic venous blood returns to the right atrium, passes to the right ventricle, and is returned to the aorta and thus to the systemic circulation. Any oxygenation occurring in this setting is the result of mixing of blood with the pulmonary circulation at the ductal, atrial, or ventricular level.

Transposition of the great arteries with an intact ventricular septum manifests in the neonatal period with profound cyanosis in an infant

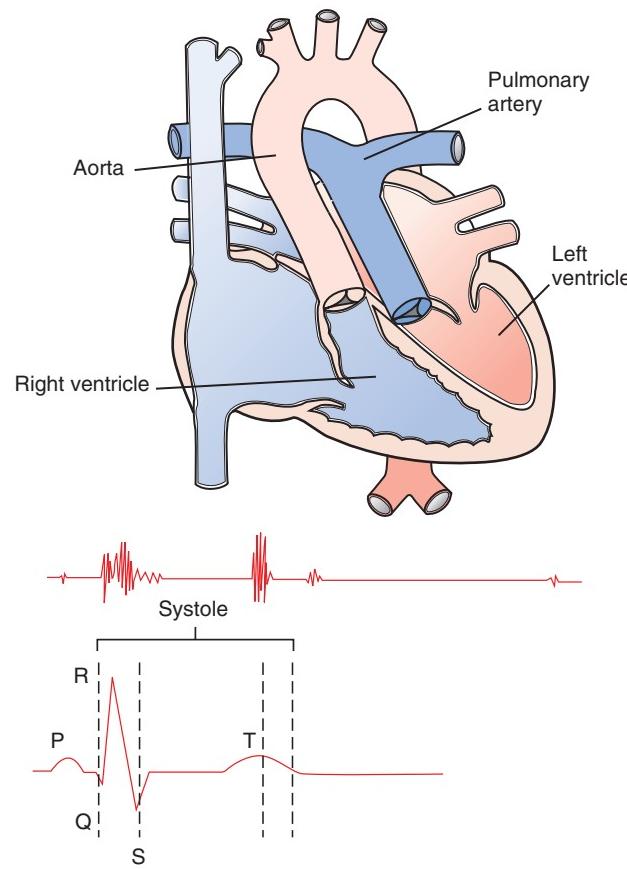
FIGURE 8.17 Pulmonary atresia with intact septum. Characteristically, the defect manifests in the cyanotic neonate. Most often, a continuous murmur of a patent ductus arteriosus is audible. Less often, a high-pitched murmur of tricuspid valve insufficiency may be heard.


FIGURE 8.18 Transposition of the great arteries. The aorta in this condition arises anteriorly, giving rise to a loud, single second heart sound. Many profoundly cyanotic full-term newborns with no audible murmur have transposition of the great arteries.

whose saturations do not improve with oxygen administration; this is the so-called **hyperoxia test**. There is a pronounced right ventricular impulse, and the A_2 is loud because it is anterior. There may be a faint soft short ejection murmur that is audible along the left sternal border as a result of increased pulmonary blood flow. However, there are often no murmurs. Heart failure is not expected. The P_2 is often not heard.

If there is a VSD, the patient may not present in the neonatal period. The minimal cyanosis may be difficult to detect. Such infants usually become ill at 2-3 weeks of age as a result of congestive heart failure rather than hypoxia. The examination findings are very different, because both ventricles are very hyperdynamic. The heart is large; there is often a palpable thrill and a loud systolic murmur.

Treatment consists of corrective surgical switching of the great vessels.

HYPOPLASTIC LEFT HEART SYNDROME

Hypoplastic left heart syndrome (Fig. 8.19) consists of varying degrees of left-sided heart (mitral valve, left ventricle, aortic valve, or arch) hypoplasia or atresia such that the left ventricle cannot support the

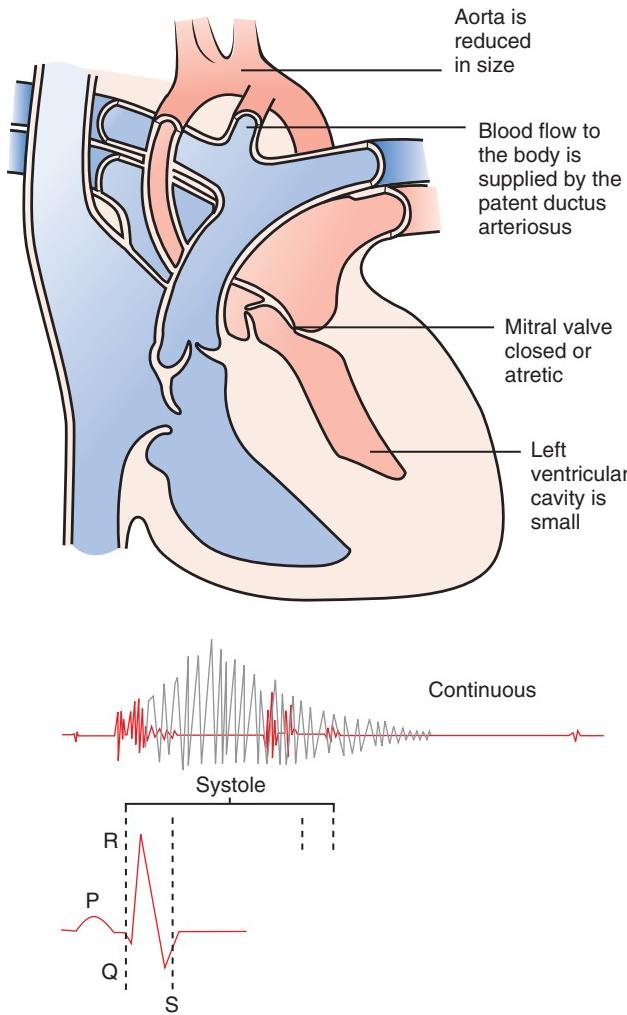

FIGURE 8.19 Hypoplastic left heart syndrome. In this condition, the systemic circulation is supplied from the right ventricle via the ductus arteriosus. The continuous murmur of ductal flow that may be heard is generally low pitched as a result of equal pulmonary and aortic pressures.

systemic circulation. In the first day or two after birth, the neonate may not be recognized as being ill if the ductus arteriosus remains open and the right ventricular output contributes to the systemic output. When the ductus begins to close, perfusion deteriorates, the pulses are diminished, acidosis develops, and death ensues.

The affected infant is often tachypneic, gray, and poorly perfused. There may be considerable pulmonary blood flow and a dynamic right ventricle impulse. An ejection systolic murmur may be audible in the pulmonary area. The heart function may be very poor, and the precordial and auscultatory examination findings may be quiet. A significantly restrictive ASD may cause profound pulmonary venous congestion and poor oxygenation.

After intravenous prostaglandin E_1 has been given, causing opening of the ductus arteriosus, a reasonable systemic output and palpable pulses should return.

Treatment includes the staged Norwood palliative repair to single-ventricle Fontan operation or heart transplantation.

PHYSICAL EXAMINATION OF COMMON LESIONS WITH SIMPLE OBSTRUCTION

In areas of obstruction, the gradient or pressure difference across an obstruction relates to the severity of the narrowing, the flow across the narrowing, and the pressure able to be generated (i.e., the cardiac function).

PULMONARY VALVE STENOSIS

The hemodynamic abnormality in pulmonary valve stenosis (Fig. 8.20) is attributable to increased pressure within a right ventricle that is attempting to eject through a narrowed or obstructed valve. The more severe the stenosis, the higher the intraventricular pressure is until cardiac failure occurs.

This condition is characterized by an ejection systolic murmur, heard best in the pulmonary area. The murmur is diamond-shaped. With increasing valvular obstruction, the murmur becomes louder and higher pitched and peaks later in systole. The P_2 is very helpful because the more severe the pulmonary valve stenosis, the more delayed and less intense the P_2 is.

An ejection click, caused by abrupt arrest of leaflet excursion in early systole, frequently precedes the ejection systolic murmur. The more severe the pulmonary valve stenosis, the earlier and softer the pulmonary ejection click is. In other forms of right ventricular outflow obstruction, such as supravalvular stenosis and subvalvular stenosis, or in the setting of a dysplastic or malformed pulmonary valve, an ejection click is not audible.

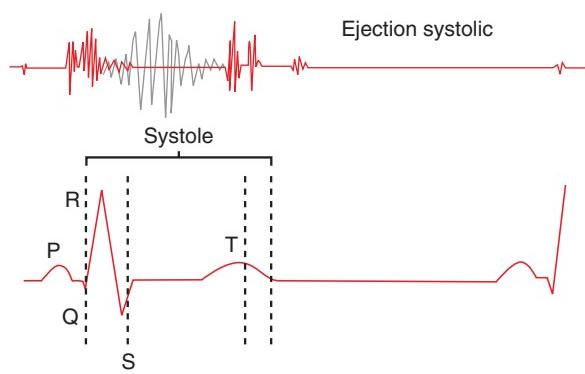
In newborns with very severe critical pulmonic stenosis, cyanosis, and low cardiac output, the examination findings may be quite different. There may be no pulmonary ejection click, and the murmur may be very short, soft, or both.

Palpation in pulmonic valve stenosis may reveal a palpable thrill in the pulmonary area and an abnormal right ventricular impulse (except in mild cases).

Treatment is transcatheter balloon valve dilatation.

AORTIC VALVE STENOSIS

The hemodynamic impact of aortic valve stenosis (Fig. 8.21) is increased pressure in the left ventricle. The more severe the stenosis, the higher the left ventricular pressure is.

The apex beat is of a thrusting character and is not displaced in the absence of left-sided heart failure. Palpation, except in very mild cases,


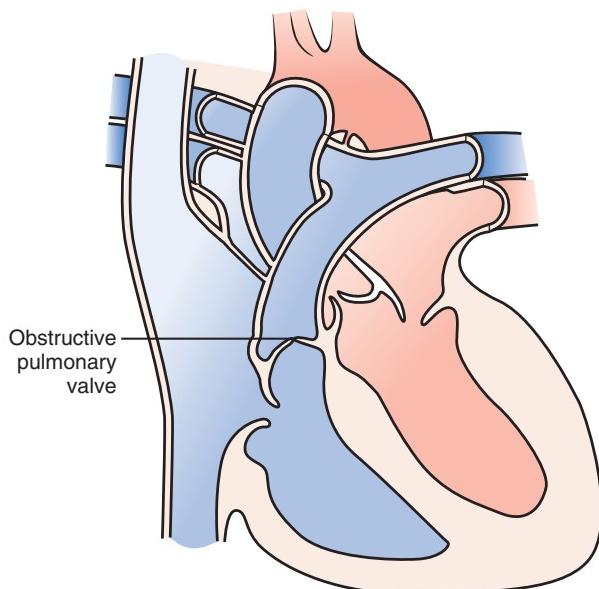


FIGURE 8.20 Pulmonary valve stenosis. Pulmonary valve stenosis gives rise to a rough ejection systolic murmur that is most prominent in the pulmonary area and radiates equally to both lung fields. The presence of an ejection click distinguishes valve obstruction from subvalvular or supravalvular stenosis.

FIGURE 8.21 Aortic valve stenosis. The ejection systolic murmur from aortic valve stenosis is audible both at the apex and in the aortic area. The aortic area extends up to the carotid arteries. There is often a palpable thrill in the suprasternal notch. The pitch and peaking of the murmur allows estimate of the severity of stenosis. Note that a quiet and low-pitched murmur may suggest poor ventricular function and low output.

reveals a suprasternal notch thrill and often a carotid systolic thrill. If the murmur is grade IV or greater, a precordial thrill is also palpable at the upper-right sternal border (aortic area).

The murmur of aortic stenosis is a rough, harsh, diamond-shaped ejection systolic murmur. It is heard best in the aortic area but often extends into the neck and throughout the precordium.

A soft, short ejection murmur that peaks in systole indicates a mild degree of valve obstruction, whereas a loud, long, and late-peaking murmur, often associated with a palpable thrill, reflects more severe stenosis.

An ejection click often precedes the murmur and is heard best at the apex. The click intensity is inversely proportional to the severity of the valve narrowing. A loud aortic valve **ejection click** is often present in patients with a two-leaflet or bicuspid aortic valve even if there is no valve stenosis.

The splitting of the S_2 is normal. The paradoxical split, occurring when there is a large delay of A_2, is quite rare in children and young adults; it is seen in older people with calcific aortic valve stenosis and a failing left ventricle.

In newborns with severe or critical aortic stenosis and low cardiac output, the examination findings may be very different. There is often no aortic ejection click, and, strikingly, the murmur may be short, soft, or both. Significant heart failure and poor perfusion are present in such neonates.

Two other major types of aortic stenosis exist: subvalvular and supravalvular. Neither has an aortic ejection click. In **supravalvular aortic stenosis** (the major cardiac lesion associated with Williams syndrome), the murmur is usually in the aortic area, whereas in **subvalvular aortic stenosis**, the murmur position may extend to the left sternal border or the apex.

The **bicuspid aortic valve** is the most common of all congenital malformations of the heart, found in almost 2% of the general population. The normal aortic valve has three leaflets of equal size. The bicuspid valve has two functional leaflets, one generally larger than the other. The bicuspid aortic valve is often only mildly stenotic or is often unobstructed. The anomaly is recognized from the presence of an aortic ejection click. The ejection click is often mischaracterized as a split S_1, which is a very rare occurrence in children. Asymmetric stresses on the valve leaflets predispose to calcification, dysfunction, and deterioration after many years. The valve is also at risk for the development of infective endocarditis.

Treatment of severe aortic valve stenosis may include surgical or balloon valvotomy and often eventual valve replacement.

COARCTATION OF THE AORTA

Coarctation occurs in association with congenital cardiac anomalies or in isolation. There are fundamentally two forms of coarctation (Fig. 8.22). The more common form has been termed **juxtaductal or adult coarctation** and is typically a discrete area of aortic narrowing or indentation of ductal tissue in relationship to the ductus arteriosus or ligamentum. The second type of coarctation has been termed **infantile coarctation** and includes varying degrees of transverse and isthmic aortic arch hypoplasia.

The hemodynamic abnormality caused by a coarctation of the aorta is a high systolic pressure proximal to the area of narrowing, in the ascending aorta, the brachiocephalic vessels, and the left ventricle.

The diagnosis of coarctation of the aorta is made from recognition of systemic hypertension in the right arm and decreased arterial pulsation in the femoral arteries and the dorsalis pedis in comparison with that in the brachial arteries. The femoral pulses may be absent, or they

FIGURE 8.22 Coarctation of the aorta. The murmur of coarctation is often audible both anteriorly and posteriorly between the scapulae. It is a continuous murmur extending well into diastole.

may be diminished and delayed. In some cases, the left brachial pulse may be diminished as a result of involvement of the left subclavian artery in the site of narrowing. In rare cases, the right subclavian artery may arise aberrantly below the level of the coarctation, causing the pulse in this arm to be diminished. Therefore, brachial pulses must be felt on both sides and compared with the femoral pulses. The blood pressure must be obtained in both arms as well as in one leg. There is seldom any significant or consistent alteration in the heart sounds unless there is associated aortic valve disease. Up to 40% of patients with juxtaductal coarctation of the aorta have an associated bicuspid aortic valve, usually without stenosis. In these cases, there is an aortic ejection click. More complicated heart lesions, often unrestrictive VSDs or AVSDs, are often seen in association with isthmic arch hypoplasia.

The murmur of coarctation is of the ejection or continuous type, is rarely louder than grade III, starts well after S_1, and may peak late in systole or extend into diastole. The point of maximal cardiac activity is variable and is most often palpable in the fifth or sixth intercostal space, extending out to the axillary line. The murmur of coarctation extends to and is often loudest in the interscapular area posteriorly.

As with aortic stenosis and obstruction of the left-heart outflow, the newborn with coarctation may present with signs of low output and heart failure. Prostaglandins have proved useful in this circumstance, alleviating the obstruction by dilating reactive muscle in the aortic wall, which may have extended from the ductus or with opening of the ductus itself, enabling right-to-left ductal flow to the lower body and relieving associated pulmonary hypertension.

Treatment in the neonate is surgical. However, after infancy, aortic coarctation angioplasty with balloon or stent placement may be considered, as may surgery.

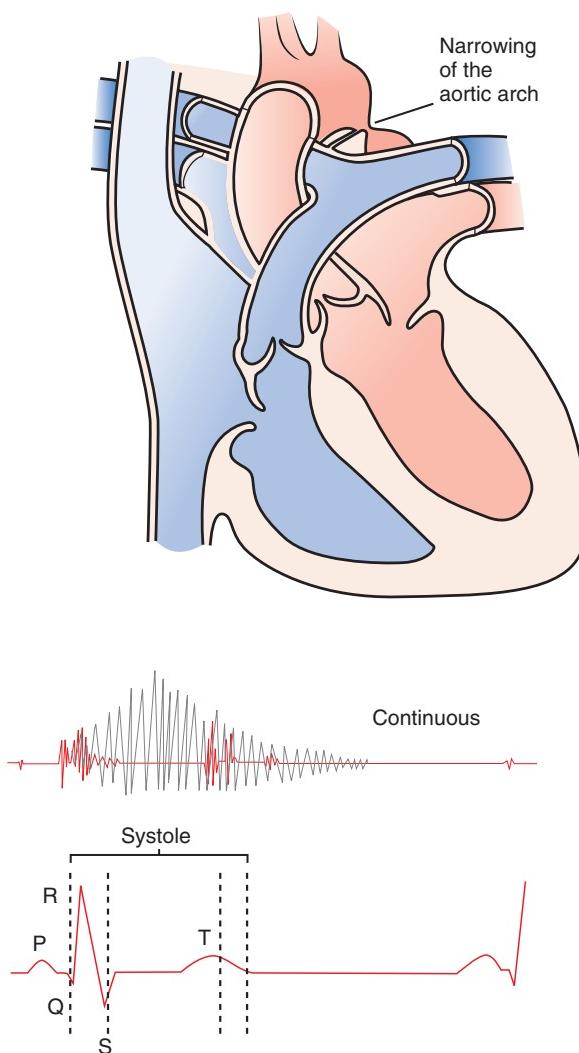
MITRAL VALVE STENOSIS

Congenital mitral valve stenosis (Fig. 8.23) is uncommon; when it occurs, it is usually in association with additional left-sided heart obstructive abnormalities, particularly coarctation of the aorta, which is termed the **Shone complex**. The most common type of significant stenosis is caused by a **single** or **"parachute" papillary muscle**. In its most severe form, it is part of the hypoplastic left ventricle syndrome, in which the valve is small, very stenotic, or atretic. In affected patients, cyanosis, heart failure, and poor perfusion are evident within the first few days after birth.

The leaflets in congenital stenosis are very immobile, and there is seldom the accentuation of the S_1 or an opening snap, which is characteristic of acquired or rheumatic mitral valve stenosis.

The murmur of mitral valve stenosis arises from the increased velocity of blood flow across the relatively immobile mitral leaflets during diastolic filling of the left ventricle. This causes a characteristic low-pitched mid-diastolic flow rumble best heard in the mitral area.

Rheumatic mitral valve stenosis is common in many areas of the world but is uncommon in the United States. As a consequence of mitral obstruction, the left atrial and pulmonary venous pressures are elevated. Often there is a reflex or secondary elevation of pulmonary artery pressures caused by thickening or constriction of small muscular pulmonary arteries. The features of pulmonary hypertension, including a prominent right ventricular tap, single loud or palpable S_2, and high-pitched pulmonary insufficiency may be apparent.

Excursion of the thickened leaflets often causes an early diastolic high-pitched opening snap before the onset of the murmur. In severe stenosis, strong atrial contraction late in diastole may create a late diastolic crescendo murmur. A loud S_1 is often heard in this condition.


(See *Nelson Textbook of Pediatrics,* p. 2208.)

Obstruction to mitral valve inflow

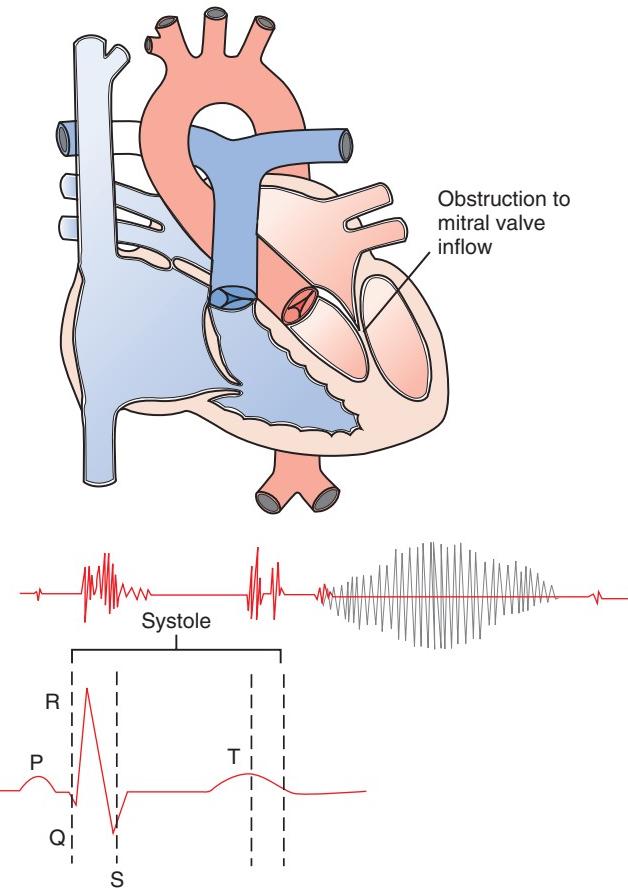
Systole


FIGURE 8.23 Mitral valve stenosis. The murmur of mitral valve steno-sis occurs during the period of passive and active filling of the ventricle as turbulence occurs across the obstructive mitral valve. Pulmonary hypertension often arises as a consequence of the downstream obstruction.

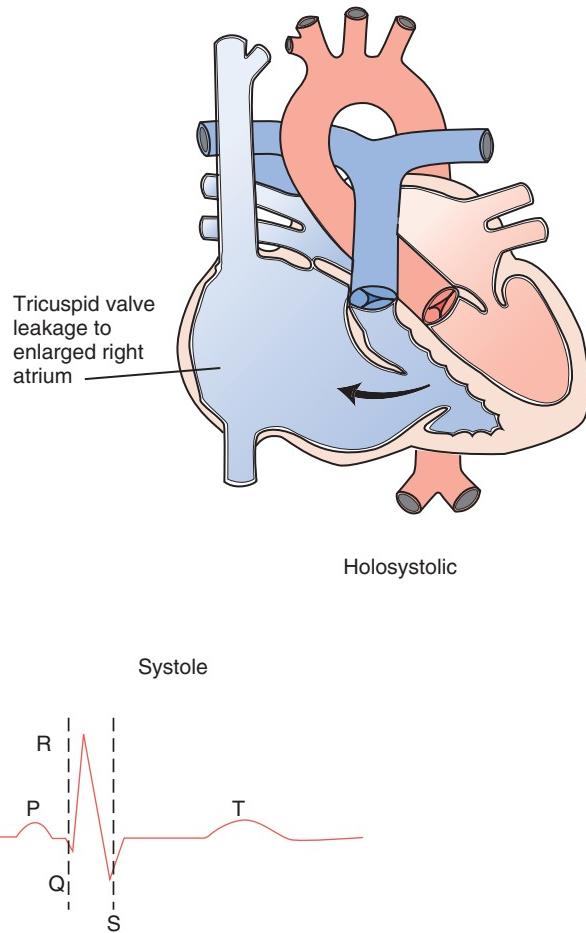
Tricuspid valve leakage to enlarged right atrium

Holosystolic


Systole

FIGURE 8.24 Tricuspid valve insufficiency. The holosystolic murmur of tricuspid valve insufficiency is low pitched in the absence of any pulmonary outflow obstruction. This makes tricuspid valve insufficiency very challenging to hear.

ATRIOVENTRICULAR VALVE AND SEMILUNAR VALVE INSUFFICIENCY

Tricuspid Valve Regurgitation

Tricuspid valve regurgitation (insufficiency) (Fig. 8.24) is uncommon in childhood in the absence of additional abnormalities. It may be a consequence of pulmonary artery hypertension, in which the high-pressure right ventricle contributes to a high-pitched holosystolic murmur at the lower-left or lower-right sternal border (tricuspid area).

Less often, tricuspid valve insufficiency may occur in association with a displaced and malformed tricuspid valve (**Ebstein anomaly**), in which case the pulmonary arterial and right ventricular pressures are not elevated, and the holosystolic murmur is low pitched. The features of right-sided cardiac murmurs vary much more with the respiratory cycle than do left-sided heart murmurs. There may be signs of right-sided heart failure: an enlarged pulsatile liver and, in the older child, a prominent V wave pulsation in the neck veins.

Mitral Valve Insufficiency

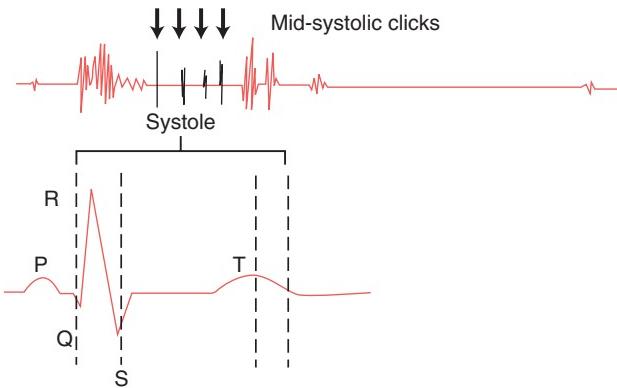
Mitral valve insufficiency (Fig. 8.25) is associated with a diffuse and dynamic apical impulse. If the volume of regurgitant flow is great, a bifid or double apical impulse of a palpable S_3 may be apparent.

The insufficiency jet of blood from the powerful left ventricle to the thin-walled left atrium causes a high-pitched blowing holosystolic murmur that has an abrupt onset. This murmur is heard best with the diaphragm of the stethoscope placed anteriorly in the mitral area. The systolic murmur radiates to the axillae.

The S_1 is usually of normal to increased intensity, but if the valve abnormality is rheumatic in origin, it may be sufficiently deformed that S_1 is quite soft. If the mitral regurgitation is quite significant, an S_3 filling sound is heard, often associated with a mid-diastolic flow rumble of "relative" mitral valve stenosis. Mitral valve insufficiency may be seen as a congenital lesion, in response to dilated annulus secondary to heart failure, during acute rheumatic fever, or as part of the mitral valve prolapse spectrum.

Mitral Valve Prolapse

This common condition of adolescents and young adults manifests as laxity of the mitral valve and results in slippage or displacement of the valve leaflets backward into the left atrium during systole (see Fig. 8.25).

The sudden tensing of the mitral valve often causes a mid-systolic click or sometimes multiple clicks that can be heard best in the mitral area. The click is frequently followed by a late high-pitched systolic murmur of mitral valve insufficiency. The timing of the click or clicks and the intensity of the murmur often vary with body position. When the patient is sitting up (and even more so during standing), the murmur gets louder or may be heard even when no murmur was heard


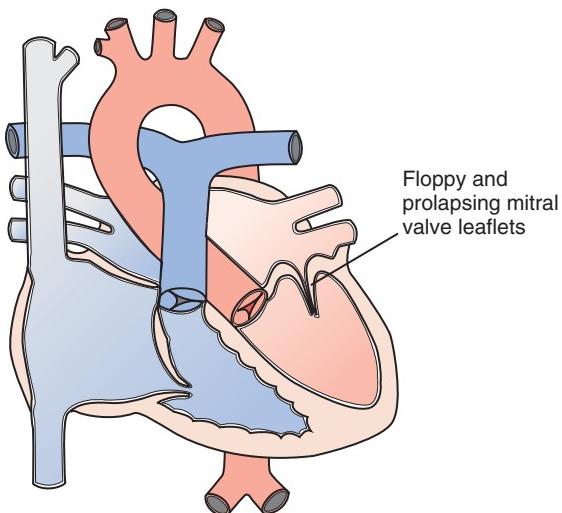


FIGURE 8.25 Mitral valve prolapse. The auscultatory examination findings can be very distinctive, with one or more sharp clicks being heard throughout systole. A late systolic high-pitched murmur may arise if mitral valve insufficiency occurs.

FIGURE 8.26 Pulmonary valve insufficiency. A low-pitched early diastolic murmur is heard just after the second heart sound. The murmur characteristically tapers into diastole.

when the patient was lying down. This is because the left ventricular architecture changes in the upright position. In rare cases, the position change may result in a late systolic murmur's becoming full length, although with late accentuation. The electrocardiogram often shows unusually anterior and superior T waves with prominent U waves, which suggests papillary muscle dysfunction.

Mitral valve prolapse does not usually progress in childhood, but it may be associated with supraventricular tachycardia, chest pain, and possibly endocarditis or cerebrovascular embolism. Ventricular tachycardia and fibrillation may occur in adults, but sudden cardiac death is very unusual during childhood and adolescence. Thickening of the valve, in addition to prolapse, increases the risk of these complications.

Pulmonary Valve Insufficiency

Pulmonary valve insufficiency (Fig. 8.26) rarely if ever occurs in isolation. Most often, congenital regurgitation of the pulmonic valve occurs in association with a pulmonary outflow obstruction such as in the **absent pulmonary valve syndrome**.

When the pulmonary arterial pressure is low, valve insufficiency is recognized by a very low- to medium-pitched early diastolic murmur that starts with P_2. This is heard best in the pulmonary area and extends for a short distance down the left sternal edge.

The more common types of pulmonary regurgitation are acquired, commonly after surgery for severe pulmonary valve stenosis, as occurs with tetralogy of Fallot, when the pulmonary outflow patch is placed and the valve leaflets are deficient or absent. Because no P_2 exists, the murmur often appears to start significantly after S_2. Because these patients often have surgically acquired right bundle branch block, the pulmonary valve closure would be well separated from aortic valve closure if the sound could be heard. The diastolic decrescendo murmur begins at that time.

Pulmonary hypertension, particularly when associated with a high pulmonary vascular resistance, is a common cause of secondary pulmonary insufficiency. Often, a pulmonary ejection click may be present because of the dilated pulmonary root. The S_2 is narrowly split or single because the high pulmonary artery diastolic pressure closes the valve early. A diastolic decrescendo murmur then begins with pulmonary valve closure and is high in frequency because the pulmonary artery pressure is high.

Aortic Valve Insufficiency

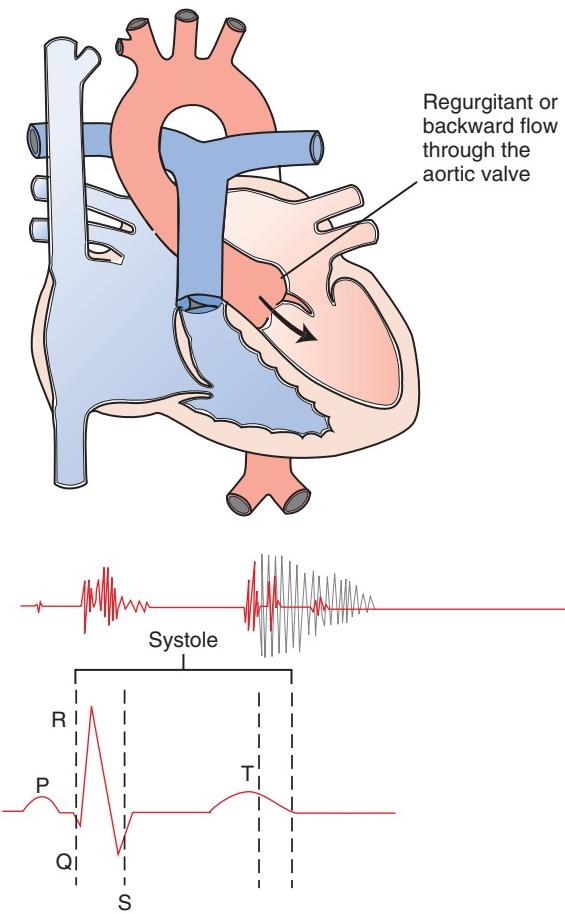
Congenital insufficiency of the aortic valve (Fig. 8.27) is rare and is usually mild and may not be audible. The valve may or may not be bicuspid. There is usually an aortic ejection click that is well separated from S_1, does not vary with respiration, and is usually best heard at the apex. The S_2 split is normal, although the A_2 may be loud and may have a "tambour" quality.


FIGURE 8.27 Aortic valve insufficiency. In contrast to the low-pressure murmur of pulmonary valve insufficiency (in the absence of pulmonary hypertension), the murmur of aortic valve insufficiency is high pitched and audible from the aortic area extending to the apex. The peripheral pulses and the intensity and length of the murmur provide clinical quantification of the magnitude of regurgitant flow.

After closure of the aortic valve (A_2), regurgitation of leakage at this site creates the high-pitched, early diastolic decrescendo murmur of aortic insufficiency. This murmur is heard best at the third left or right intercostal space while the patient is sitting. The pulse pressure is normal if the leak is mild.

The most common form of aortic insufficiency is acquired, most often as a consequence of severe **rheumatic carditis**, and can be present in both acute rheumatic fever and chronic rheumatic heart disease. In acute insufficiency, there is usually no aortic ejection click. The left ventricular impulse is abnormal and hyperdynamic, and a wide pulse pressure is present.

A long, low-frequency musical diastolic rumble beginning one-third of the time into diastole may occur, especially in the left lateral decubitus position in patients with significant valve insufficiency. This is called the **Austin Flint murmur**. It is believed to be related to regurgitant aortic flow passing across the anterior mitral valve and fluttering of the leaflet in conjunction with mitral valve inflow.

MISCELLANEOUS CARDIAC ANOMALIES

Pericardial Disease

Many infectious and noninfectious diseases may cause inflammation of the pericardial sac and surrounding structures. The presence of fluid in the pericardial sac may compromise cardiac filling and result in life-threatening impairment of cardiac output, "pericardial tamponade." The auscultatory findings in these cases often include friction rubs.

These variable sounds are high-pitched, superficial, and scratching noises. They occur in synchrony with cardiac movement and can be heard during the early period after myocardial infarction and most frequently after cardiac surgery (see Chapter 7).

PULMONARY HYPERTENSION

After the neonatal period, pressures in the pulmonary circulation are normally low (approximately 25 mm Hg systolic, or about one fourth of the pressure in the systemic circulation or aorta). Many diseases have profound effects on the pulmonary circulation and can elevate pressures within the pulmonary arteries. These include diseases of lung, pulmonary vasculature, heart, or liver; collagen vascular diseases; and obstruction of the upper airways.

One consistent physical finding detected in pulmonary hypertension is an active right ventricular parasternal tap with a distinctive, sharp palpable P_2. The P_2 is of increased intensity, and there is a single or narrowly split S_2. There may be no audible murmur; a high-pitched murmur of pulmonary valve insufficiency or a high-pitched systolic murmur of tricuspid valve insufficiency may be present.

Recognition of pulmonary hypertension warrants a diligent search for the underlying cause. If the reason for the elevated pulmonary artery pressure remains unclear, the disorder is referred to as **primary pulmonary hypertension**. If an etiology can be found, the disorder is termed **secondary pulmonary hypertension**.

APPROACH TO CONGENITAL HEART DISEASE

Congenital heart disease may produce an asymptomatic murmur, heart failure, cyanosis, cyanosis with heart failure, or severe cardiogenic shock (Fig. 8.28). Malformations associated with profound and fixed cyanosis without heart failure are usually associated with right-sided obstructive lesions and a right-to-left shunt (e.g., pulmonary atresia, tetralogy of Fallot). Transposition of the great arteries with intact ventricular septum also manifests with profound and fixed hypoxia, with mild tachypnea, and with no heart failure. Malformations associated with cyanosis and heart failure have a large mixing lesion (single ventricle, truncus arteriosus, transposition plus a VSD), in which pulmonary oxygenated venous return mixes with desaturated systemic venous return before ejection to the systemic arterial circulation. In addition, obstructed total anomalous pulmonary veins may produce severe cyanosis, pulmonary venous engorgement, and pulmonary hypertension. Lesions associated with left-sided obstruction (critical aortic stenosis, interrupted aortic arch, hypoplastic left heart syndrome) produce significant cardiogenic shock, poor perfusion, and profound lactic acidosis.

The chest radiograph may provide helpful clues to the cause of the lesion, depending on the paucity (pulmonary atresia) or plethora (obstructed total anomalous pulmonary venous return) of the pulmonary vascular markings; the left- or right-sided (tetralogy of Fallot, truncus arteriosus) position of the aorta; the configuration of the heart (boot-shaped, as in tetralogy of Fallot; egg-shaped, as in transposition of the great arteries; or massive enlargement, as in Ebstein anomaly); or the side of the chest (risk of heart disease is higher with dextrocardia, especially if the stomach bubble is on the left side of the abdomen or if the liver is midline). The chest radiograph is of some help in distinguishing heart disease from congenital pneumonia, respiratory distress syndrome, pneumothorax, and congenital diaphragmatic hernia.

FIGURE 8.28 Algorithmic approach to the child with a heart murmur. AV, atrioventricular.

The electrocardiogram in infancy is of help in discriminating atrial and ventricular enlargement or hypertrophy and very helpful when there is an abnormal superior vector (complete atrioventricular canal, tricuspid atresia).

Two-dimensional real-time color Doppler echocardiography is most useful in identifying the anatomy of congenital heart lesions. The echocardiogram enables assessment of the 4 chambers, the interconnecting valves, the great arteries, the pulmonary venous return, and the anatomic relationships between these structures. Furthermore, color Doppler flow studies can determine the presence, direction, and magnitude of right-to-left or left-to-right shunts. Echocardiography has replaced cardiac catheterization for all but the most complex congenital heart lesions.

ACUTE RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Rheumatic fever is a postinfectious, immunologically mediated inflammatory disease of the heart, joints, brain, and skin that is caused by group A streptococcus. Valvulitis, as manifested by specific and new heart murmurs, is often part of the initial clinical picture. The specific heart murmurs are 3: mitral regurgitation, aortic regurgitation, and the rare Carey-Coombs murmur, a mid-diastolic rumble at the apex. Pericarditis, usually associated with valvulitis, may produce a friction rub.

After the acute rheumatic fever has run its course, any remaining murmurs become part of chronic rheumatic heart disease. If the patient has continued permanent reliable penicillin prophylaxis, the severity of the mitral regurgitation often disappears; this happens less

commonly with aortic regurgitation. The development of mitral valve stenosis is part of the natural history of severe repeated episodes of acute rheumatic fever. Pure aortic stenosis does not develop, although in the presence of long-standing rheumatic heart disease with severe aortic regurgitation, some aortic stenosis may be present. In some very severe cases, tricuspid valve regurgitation has been documented, but it is rare.

The diagnosis of acute rheumatic fever is suggested (although not definitively confirmed) by application of the revised Jones criteria, last edited in 2015 (Table 8.6). In addition, evidence of a group A streptococcal pharyngitis must be present, which may include a positive throat culture, positive streptococcal antigen or antistreptococcal antibody, or a history of prior episodes of rheumatic fever. In cases where carditis may be subclinical (no audible murmur), the diagnosis is supported by echocardiographic evidence of subclinical carditis (no audible murmur) by demonstrating significant mitral regurgitation with a regurgitant jet seen in 2 planes with chaotic flow and being holosystolic and extending 1 cm into the left atrium. Criteria for subclinical significant echocardiographic aortic regurgitation include its being seen in 2 imaging planes, being holodiastolic, and extending 1 cm into the ventricle (Table 8.7). The differential diagnosis is limited in the presence of carditis and arthritis (see Chapter 33) but includes systemic lupus erythematosus.

INFECTIVE ENDOCARDITIS

An acute or subacute infection of the cardiac valves produces infective endocarditis. Infection may involve a native, previously normal heart

TABLE 8.6 Guidelines for the Diagnosis of Initial or Recurrent Attack of Rheumatic Fever (Jones Criteria, Updated 2015)

Major Manifestations	Minor Manifestations	Supporting Evidence of Antecedent Group A Streptococcal Infection
Carditis	**Clinical Features**	Positive throat culture or rapid streptococcal antigen test
Polyarthritis	Arthralgia	Elevated or increasing streptococcal antibody titer
Erythema marginatum	Fever	
Subcutaneous nodules	**Laboratory Features**	
Chorea	Elevated acute-phase reactants:	
	Erythrocyte sedimentation rate	
	C-reactive protein	
	Prolonged P-R interval	

1. *Initial attack:* 2 major manifestations, or 1 major and 2 minor manifestations, plus evidence of recent GAS infection. *Recurrent attack:* 2 major, or 1 major and 2 minor, or 3 minor manifestations (the latter only in the Moderate/High-Risk population), plus evidence of recent GAS infection (see text).
2. Low-Risk population is defined as ARF incidence <2 per 100,000 school-age children per year, or all-age RHD prevalence of <1 per 1000 population. Moderate/High-Risk population is defined as ARF incidence >2 per 100,000 school-age children per year, or all-age RHD prevalence of >1 per 1000 population.
3. Carditis is now defined as clinical and/or subclinical (echocardiographic valvulitis).
4. Arthritis (major) refers only to polyarthritis in Low-Risk populations, but also to monoarthritis or polyarthralgia in Moderate/High-Risk populations.
5. Minor criteria for Moderate/High-Risk populations only include monoarthralgia (polyarthralgia for Low-Risk populations), fever of >38°C (>38.5°C in Low-Risk populations), ESR >30 mm/hr (>60 mm/hr in Low-Risk populations).
ARF, acute rheumatic fever; ESR, erythrocyte sedimentation rate; GAS, group A streptococci; RHD, rheumatic heart disease.

valve, a valve or structure (e.g., PDA, VSD opposite an endocardial wall that is subjected to a jet stream) that is anomalous as a result of congenital heart disease, or a prosthetic device (e.g., valve, conduit, patch, graft, shunt, or pacemaker).

Endocarditis may affect congenital heart lesions (most commonly, tetralogy of Fallot, VSD, aortic stenosis, PDA, transposition of the great arteries), valves affected by rheumatic heart disease, and mitral valve prolapse. Endocarditis may develop in congenital heart anomalies in the unoperated and the postoperative state. Furthermore, up to 30% of cases of infective endocarditis occur on previously normal native valves.

Endocarditis is the result of a bacteremia, which in a normal host is usually transient, asymptomatic, and without sequelae. The presence of a damaged valve, a jet stream–injured endocardium, or a foreign body (e.g., central catheter, graft, shunt, or patch) creates a nidus of infection that permits the bacteria to bind, proliferate, and remain sequestered from normal host defense mechanisms. Transient and predisposing bacteremias occur during dental procedures that induce bleeding (even dental cleaning); tonsillectomy or adenoidectomy; intestinal (e.g., gall bladder), urinary (e.g., catheterization, dilatation), prostatic (e.g., cystoscopy), or respiratory surgery; esophageal

manipulation (e.g., sclerotherapy, dilatation), incision and drainage of infected tissue; and gynecologic procedures (e.g., vaginal hysterectomy, vaginal delivery).

Bacterial vegetations grow and produce cardiovascular, embolic, or immune complex–mediated signs and symptoms (Table 8.8). Responsible bacteria are noted in Table 8.9; *Staphylococcus aureus*, α-hemolytic oral mucosa–derived streptococci, and enterococci are the dominant pathogens in native normal and unoperated anomalous valves. *Staphylococcus epidermidis* and *S. aureus* are common pathogens in the postoperative patient and in patients with prosthetic devices.

The definitive diagnosis of infective endocarditis includes recovery of a microorganism from culture or histologic study of a heart, an embolized vegetation, or an intracardiac abscess. Vegetations may be demonstrated by the sensitive technique of transesophageal echocardiography but are usually seen on transthoracic echocardiography. In the absence of direct definitive evidence, the following are important diagnostic factors: persistently positive blood cultures with a pathogen compatible with the diagnosis (see Table 8.9); echocardiographic evidence of an intracardiac mass, vegetations, perivalvular abscess, or new partial dehiscence of a prosthetic valve; and a new valvular murmur (regurgitation, or worsening or changing of a preexisting murmur).

Elevated temperature
Tachycardia
Embolic phenomena (Roth spots, petechiae, splinter nail bed hemorrhages, Osler nodes, CNS or ocular lesions)
Janeway lesions
New or changing murmur
Splenomegaly
Arthritis
Heart failure
Arrhythmias, heart block, conduction disturbances
Metastatic infection (arthritis, meningitis, mycotic arterial aneurysm, pericarditis, abscesses, septic pulmonary emboli)
Digital clubbing

Laboratory
Positive blood culture
Elevated erythrocyte sedimentation rate (may be low with heart or renal failure)
Elevated C-reactive protein level
Anemia
Leukocytosis
Immune complexes
Hypergammaglobulinemia
Hypocomplementemia
Cryoglobulinemia
Rheumatoid factor
Hematuria
Azotemia, high creatinine level (glomerulonephritis)
Echocardiographic evidence of valve vegetations, prosthetic valve dysfunction or leak, or myocardial abscess

CNS, central nervous system.
Modified from Behrman RE, ed. *Nelson Textbook of Pediatrics*. 14th ed. Philadelphia: WB Saunders; 1992.

TABLE 8.9 Bacterial Agents in Pediatric Infective Endocarditis

Common: Native Valve or Other Cardiac Lesions
Viridans group streptococci *(Streptococcus mutans, Streptococcus sanguinis, Streptococcus mitis)*
Staphylococcus aureus
Group D streptococci *(Streptococcus bovis)*
Enterococcus faecalis

Uncommon: Native Valve or Other Cardiac Lesions
Streptococcus pneumoniae
Haemophilus influenzae
Coagulase-negative staphylococci
Abiotrophia defectiva (nutritionally variant streptococcus)
Coxiella burnetii (Q fever)*
Neisseria gonorrhoeae
*Brucella**
*Chlamydia psittaci**
*Chlamydia trachomatis**
*Chlamydia pneumoniae**
*Legionella**
*Bartonella**
Tropheryma whipplei * (Whipple disease)
HACEK group[†]
*Streptobacillus moniliformis**
*Pasteurella multocida**
Campylobacter fetus
Culture negative (6% of cases)

Prosthetic Valve
Staphylococcus epidermidis
Staphylococcus aureus
Viridans group streptococci
Pseudomonas aeruginosa
Serratia marcescens
Diphtheroids
Legionella species*
HACEK group[†]
Fungi[‡]

*These fastidious bacteria plus some fungi may produce culture-negative endocarditis. Detection may require special media, incubation for more than 7 days, polymerase chain reaction on blood or valve for 16S rRNA (bacteria) or 18S rRNA (fungi), or serologic tests.
[†]The HACEK group includes *Haemophilus* species *(H. paraphrophilus, H. parainfluenzae, H. aphrophilus), Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* species.
[‡]*Candida* species, *Aspergillus* species, *Pseudallescheria boydii, Histoplasma capsulatum.*
From Bernstein D. Infective endocarditis. In: *Nelson Textbook of Pediatrics*. 20th ed. Elsevier; 2016.

Blood cultures are helpful if 2 or more drawn 12 hours apart are positive or if a majority (e.g., 3 or 4) of separate cultures drawn in 1 hour are positive. More than 85% of first blood cultures are positive; the yield approaches 95% with the second blood culture. Sufficient blood must be inoculated into the media to detect the low-grade bacteremia of infective endocarditis; excessive blood inoculation may inhibit bacterial growth by continued activity of leukocytes unless the technique involves centrifugation lysis. The cultures should be incubated for more than the routine 72 hours (often 1-2 weeks), and the laboratory should be notified of the possible diagnosis so that laboratory personnel can enrich the media to encourage the growth of fastidious nutrient-dependent organisms.

Additional criteria for diagnosing infective endocarditis include fever, predisposing heart lesions and procedures (many patients have undergone no identifiable procedure), vascular phenomena (embolism, Janeway lesions, petechiae, septic pulmonary infarcts, intracranial hemorrhage), immune lesions (glomerulonephritis, Roth spots, Osler nodes), a suggestive but not definitive echocardiogram, and microbiologic criteria (positive blood culture but not as defined earlier; serologic evidence of active infection).

To prevent infective endocarditis, high-risk patients, procedures, and factors that predispose to bacteremia need to be identified (Table 8.10). Patients needing infective endocarditis prophylaxis include those with intracardiac foreign bodies (prosthetic valve, grafts), prior episodes of infective endocarditis, a heart transplant with abnormal valve function, and certain congenital heart abnormalities including the following: (1) cyanotic congenital heart disease that has not been fully repaired, including children who have had surgical shunts and conduits; (2) a congenital heart defect that has been repaired with prosthetic material or a device for the first 6 months after the repair procedure; and (3) repaired congenital heart disease with residual defects, such as persisting leaks or abnormal flow at or adjacent to a prosthetic patch or prosthetic device.

TABLE 8.10   2007 Statement of the American Heart Association (AHA): Cardiac Conditions Associated with the Highest Risk of an Adverse Outcome from Infective Endocarditis for Which Prophylaxis with Dental Procedures Is Reasonable
Prosthetic cardiac valve or prosthetic material used for cardiac valve repair Previous infective endocarditis
Congenital Heart Disease (CHD)* Unrepaired cyanotic CHD, including palliative shunts and conduits Completely repaired CHD with prosthetic material or device, whether placed by surgery or catheter intervention, during the 1-6 mo after the procedure[†] Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch, or prosthetic device (which inhibits endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

*Except for the conditions listed here, antibiotic prophylaxis is no longer recommended by the AHA for any other form of CHD.
[†]Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 mo after the procedure.

SUMMARY AND RED FLAGS

Murmurs may be caused by cardiac or noncardiac lesions and may be congenital or acquired. Murmurs in the neonatal period are often transient, as a result of the changing hemodynamics of the transitional circulation between fetal and neonatal life, or as a result of the common occurrence of a small VSD, which usually closes in the first 1-5 years of life. Most murmurs at all ages are not caused by cardiac disease and are not associated with symptoms or increased risk for disease.

Red flags in the neonatal period include cyanosis or heart failure with or without the presence of other congenital anomalies or syndromes, such as trisomy 21. Such syndromes often manifest with multiple congenital anomalies, including those involving the cardiovascular, gastrointestinal, and central nervous systems. In the neonatal period, things not to miss include ductus-dependent lesions, in which systemic blood flow (as in interrupted aortic arch, hypoplastic left heart syndrome) or pulmonary blood flow (as in pulmonary atresia) is through the PDA. Sudden deterioration, cyanosis, or heart failure with increasing metabolic acidosis and a reduction in the murmur suggests closure of the ductus arteriosus. Another thing not to miss is the murmur associated with an arteriovenous malformation, such as the cerebral vein of Galen malformation, which manifests with heart failure and a cranial bruit. Finally, obstructed total anomalous venous return may be confused with persistent fetal circulation, and it may be difficult to establish the diagnosis. Total anomalous venous return is associated with fixed, profound cyanosis (PaO_2 <35 mm Hg), severe pulmonary venous congestion, and a small heart.

Acquired murmurs or symptomatic murmurs that change in quality should suggest acute or recurrent rheumatic fever, or infective endocarditis. Systemic symptoms and peripheral signs associated with these disorders are suggestive of the diagnosis. Arthritis (associated with rheumatic fever or endocarditis-induced immune complexes), fever, anemia, leukocytosis, cutaneous manifestations (erythema marginatum and subcutaneous nodules in rheumatic fever; Osler nodes, Janeway lesions, petechiae, and splinter hemorrhages in infective endocarditis), and evidence of prior infection (streptococcal antibodies) or current infection (positive blood cultures) help identify the nature of the acquired heart disease. Finally, heart murmurs in a normal heart may be caused by hemodynamic factors, such as severe anemia or thyrotoxicosis.

9

Failure to Thrive

Susan Feigelman and Virginia Keane

Calories from food provide energy for the body's maintenance functions of repair, regulation, metabolic functions, replacement of losses, and daily activity. Children have additional caloric requirements because they must also grow. Children under the age of 3 years whose caloric needs are not met do not grow according to published norms and are said to have failure to thrive (FTT) or growth faltering. FTT raises serious concerns. It is important to have a systematic, stepwise approach to the diagnosis and management of poor growth in young children and to follow growth over time.

The term **failure to thrive** is used to describe growth failure that accompanies many pathologic conditions as well as psychosocial causes. Differentiation between organic (biomedical) and nonorganic (psychosocial/environmental) is not always useful; children often have a combination of psychosocial and biomedical problems. Children with medical conditions will often have psychosocial issues related to eating and dysfunctional feeding patterns with caregivers. Children with primarily social or emotional issues around eating may develop medical consequences of undernutrition.

There is a poor yield from exhaustive laboratory evaluations of most children with FTT. Testing should be based on clues from the history and physical examination. Children with biomedical and/or psychosocial causes of FTT may or may not gain weight in institutional settings, and this short-term outcome is not always diagnostic.

The best diagnostic tool available to the clinician is a comprehensive history, including diet, family, growth (over time) and social histories, and a complete review of systems; and a complete physical examination. Further work-up should be directed by results from this initial evaluation.

NORMAL GROWTH

Newborns typically lose up to 10-12% of their birthweight during the first few days of life and regain this weight by the age of 2 weeks. Subsequently, they gain weight at a steady pace of about 1 oz per day for the first 3 months; gain at half to two thirds that rate for the next 3 months and half to two thirds again for the next 6 months. This results in a doubling of birthweight by the age of 4-6 months and a tripling before 1 year. Height and head circumference grow at similar well-defined rates. These three growth parameters should be plotted on appropriate growth charts and monitored for adherence to standard growth rates. Children grow in a stepwise manner, but on average their growth pattern follows the accepted curves (see Chapter 43). Online

tools are available to assist with the determination of growth status (peditools.org).

Between the ages of 1 and 3 years, if caloric intake is normal, the child's growth adjusts to his/her genetic potential. Ultimate height is determined by additional factors, among them rates of bone maturity and pubertal development (see Chapter 43). Considerable energy from ingested food is required to achieve this growth. The energy balance can be described by the following equation, in which E equals energy:

$$E_{IN} = E_{OUT} + E_{growth} + E_{stored}$$

E_{OUT} is the sum of basal metabolic rate, energy expended in physical activity, and the energy needed for food digestion. Children should be in a positive energy balance for growth. Any imbalance in this energy equation (losing or using more calories than are ingested) results in abnormal growth patterns. Weight is usually affected first, followed by height and finally head circumference if the energy imbalance is severe and prolonged in young children.

DEFINITIONS

FTT is a sign, not a diagnosis. FTT is generally used to describe children younger than 2 or 3 years who meet any of the following criteria:

1. Growth under the third percentile on World Health Organization (WHO) weight for age growth charts (<3% = less than 3 standard deviations below mean)
2. Weight for height or body mass index (BMI) less than the 5th percentile
3. Growth patterns that have crossed two major percentiles downward on the weight for age charts within 6 months
4. Growth velocity less than normal for age

There are inherent problems with these definitions. Three percent of the population is at or below the 3rd percentile, and so those who are growing appropriately per their genetic potential must be differentiated from those with growth problems. The child who has been obese and is now approaching normal weight for height, crossing major weight percentiles in the process should not be considered a child with FTT. Some children are naturally slim. The clinician must exercise considerable judgment before raising the concern of poor growth.

Additional terms are used to describe children who are not growing well. A child has **wasting** if the weight for length or weight for height is below −2 standard deviations (or −2 z-scores which is equal to

(See *Nelson Textbook of Pediatrics,* p. 250.)

TABLE 9.1	**Three Major Anthropologic Categories of Failure to Thrive**			
	Weight	**Height**	**Head Circumference**	**Associated Diseases**
Type I	Decreased	Decreased/normal	Normal	Malnutrition of organic or nonorganic etiology, usually secondary to intestinal, pancreatic, liver diseases or systemic illness or psychosocial factors
Type II	Decreased	Decreased	Normal	Endocrinopathies, bony dystrophy, constitutional short stature
Type III	Decreased	Decreased	Decreased	Chromosomal, metabolic disease, intrauterine and perinatal insults, severe malnutrition

From Shashidar H, Toila V. Failure to thrive. In: Wyllie R, Hyams JS, Kay M, eds. *Pediatric Gastrointestinal and Liver Disease.* 4th ed. Philadelphia: Elsevier; 2011:137.

<3 centile). **Stunting** is defined as a child whose height or length is less than −2 z-scores due to chronic undernutrition. In the third year of life, children are described as underweight if weight/age is <5% or if BMI is <5% or 10%. Short stature or microcephaly alone is not due to nutritional deficiencies (Table 9.1).

INTERPRETATION OF GROWTH CHARTS

The evaluation for any child who is not growing well includes a careful analysis of growth charts. A review of the growth pattern over time is the most useful. Measurements of length are the most susceptible to error; standard procedures should be used (see Chapter 43). Possible errors in weight, head circumference, date of birth, or plotting on the growth chart should all be considered. Once the correct data are available, the charts should be examined to answer the following questions:

- Are the measurements of length and weight proportionate?
- Has the head grown proportionately?
- How severe are the deficits of each measurement, relative to what is expected?
- When did the problem start and progress?
- Is the problem acute or chronic?
- What environmental factors were present at the start of this process (weaning, introduction of new foods)?

Although weight is usually the most readily available measurement, measurement of length is particularly critical, because it serves as the point of reference for other diagnostic considerations. The best way to obtain accurate length measurements is to use a specially calibrated length board with a fixed headpiece and a movable footpiece. In the absence of such a device, the examiner can use a table or desk with the infant's head pressed against the wall and a firm square box or thick textbook for the sliding footer. Measurements obtained with the infant lying on a mattress and marked with a pen on the sheet are not accurate (see Chapter 43).

The choice of growth curves is important. In the United States, the recommendation is to use the WHO charts from birth through the second year of life (http://www.cdc.gov/growthcharts/who_charts.htm) (see Chapter 43). Some children previously classified as FTT now fall into the normal range. Their health status may be worse than those classified as within normal range on both charts. The 2000 age- and gender-specific National Center for Health Statistics growth charts published by the Centers for Disease Control and Prevention combined data across geographic and ethnic populations and are appropriate to use for children over 24 months of age.

Conventions differ in whether to plot age in relation to actual birth date or to use corrected gestational age. Growth charts following children prenatally to infancy are available (see Fenton and Olsen at pedi-tools.org). Beyond the equivalent of 40 weeks of gestation, standard charts can be used, keeping in mind that premature infants may not catch up on all parameters for 2 or 3 years.

TABLE 9.2	**Classification of Degree of Malnutrition**		
BMI z-Score	**Weight for Length Percentile**	**Weight Deficit (for Current Length)**	**Degree/Risk of Malnutrition**
0	50%	90–100%	Normal
−1	2.4–15.9%	80–90%	Mild
−2	0.2–2.3%	70–80%	Moderate
−3	<0.2%	<70%	Severe

Because infants with FTT no longer follow their growth curves, the usual convention of expressing growth measurements in relation to normal percentiles is not always useful. Researchers use weight/length or BMI z-scores to better define and assess degree of malnutrition (Table 9.2).

Some conventions classify the severity of wasting or "malnutrition" by the weight deficit for the current length. Loss of about 40% of expected weight for length (actual weight divided by expected weight for length <60%) is the extreme of wasting that is compatible with survival. Therefore, 80-90% actual weight divided by expected weight for length corresponds to mild, 70-80% is moderate, and 60-70% is severe. These calculations are critical for planning nutritional rehabilitation and therefore essential to the overall diagnostic and treatment processes.

It is important to note the following points:

1. Infants and toddlers who are short in proportion to weight should be considered to have primary growth problems, including various endocrine and skeletal disorders (see Chapter 43) (see Table 9.1).
2. Infants who have had inadequate caloric intake will be abnormally thin. If the problem developed at some time after birth, weight will drop off before changes in length or head circumference.
3. Infants with disproportionately small heads may have primary neurologic problems affecting brain growth because head growth is the last to be affected by malnutrition and is not characteristic of primary skeletal growth problems (see Table 9.1). An alternative diagnosis is craniosynostosis, or early closure of skull growth plates.

Several examples of how these patterns may be interpreted are presented in Figs. 9.1 to 9.4. Growth charts adjusted for abnormal head size (micro- or macrocephaly) are not available. This factor becomes of relatively less importance as the child ages, but during infancy may significantly affect the weight percentile and requires clinical judgment to assess.

Disease-specific growth charts have been developed for certain populations (e.g., trisomy 21, skeletal dysplasias). Their use is most

appropriate for conditions that affect muscle and bone development (e.g., Russell-Silver syndrome). Any other disease -specific charts should be used in conjunction with the WHO charts.

EPIDEMIOLOGY

FTT is found in all populations, but has a higher prevalence among children of low socioeconomic status compared to those in higher socioeconomic groups. FTT accounts for up to 5% of all hospitalizations; up to 10% of children may have FTT at some point in time. Most affected children with nutritional problems present before the age of 3 years.

CLINICAL PRESENTATION

Parents often voice concerns about their young child's weight gain. They may complain that their child is a picky eater or seems not to drink enough formula, or they worry that breast milk supply is inadequate. Very commonly, parents complain that their child is not as big as a similar-aged child or a sibling at that age. Many such children are growing normally. Plotting the child's growth and reviewing it with the parent is usually reassuring, or it may serve to confirm the parents' concerns. When families raise concerns about growth, regardless of whether a problem exists, the child and the weight have already become a focus of concern for that family. Often parents have already put a great deal of effort into changing the child's eating patterns. The child's real or perceived weight or appetite problem may cause intrafamily conflict. In this setting, conversations about the child's growth may carry a high emotional charge.

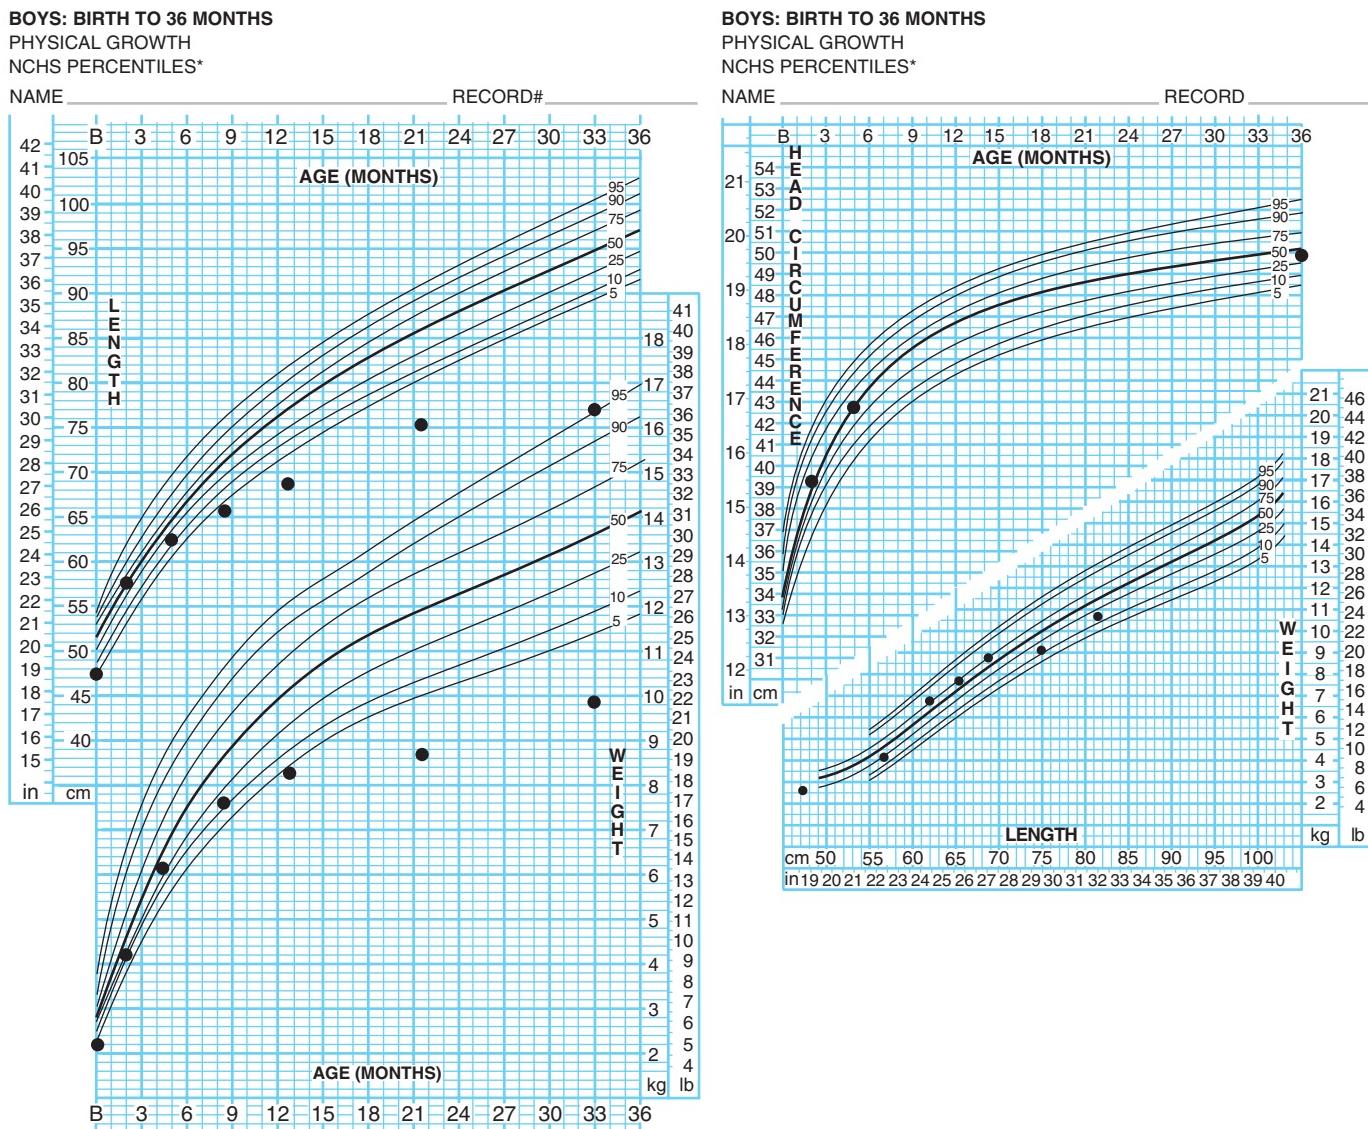
However, it is often the physician who is first to raise concerns. These suspicions can be confirmed by carefully plotting the growth parameters. The clinician must then prioritize the clinical issues and decide whether the FTT should be addressed immediately or deferred


FIGURE 9.2 Growth curve of an infant boy with untreated growth hormone deficiency. Note that weight and length remain proportionate, whereas head growth is less affected. (Modified from National Center for Health Statistics: NCHS growth charts. *Monthly Vital Statistics Report.* 1976;25:76-1120. Rockville, MD: Health Resources Administration, June 1976. Data from The Fels Research Institute, Yellow Springs, Ohio. Copyright 1976, Ross Laboratories.)

for evaluation and management at another time in the very near future. In rare cases, the growth failure is so severe (child is <60% of ideal body weight for height) that immediate hospitalization must be instituted to begin nutritional rehabilitation. In this case, the evaluation can take place over several days, while therapeutic nutritional interventions are ongoing.

APPROACH TO DETERMINING ETIOLOGY

Clinicians need to have a broad approach to determining etiology of FTT for each child. Many children with FTT, particularly those with chronic diseases, have a mixed pattern of increased needs or losses attributable to organic causes, along with environmental causes leading to calorie deprivation.

There are several growth conditions that result in smaller than normal size but that are not due to calorie insufficiency. Children with constitutional delay usually grow normally over the first year, but weight and height decelerate to near or below the 5th percentile followed by growth at normal rates along their new curve (see Chapter 43). The symmetric deceleration of height and weight is a clue that the child does not have calorie insufficiency. Infants who are born small for gestational age and are *symmetrically* small are believed to have a reduced number of somatic cells in relation to their normal-sized peers as a result of an early intrauterine event. Infants who are *asymmetrically* small for gestational age, with sparing of the head circumference and possibly length, suffered a late intrauterine event, such as poor maternal nutrition or placental insufficiency. These infants often eat voraciously and experience catch-up growth early in life. Children with genetic short stature have short height for age with appropriate low weight.

Children with FTT caused by calorie insufficiency typically have decreased weight gain, at first with sparing of height and head circumference (wasting). Long-standing calorie insufficiency results in height deceleration (stunting). Height or length is the best predictor of

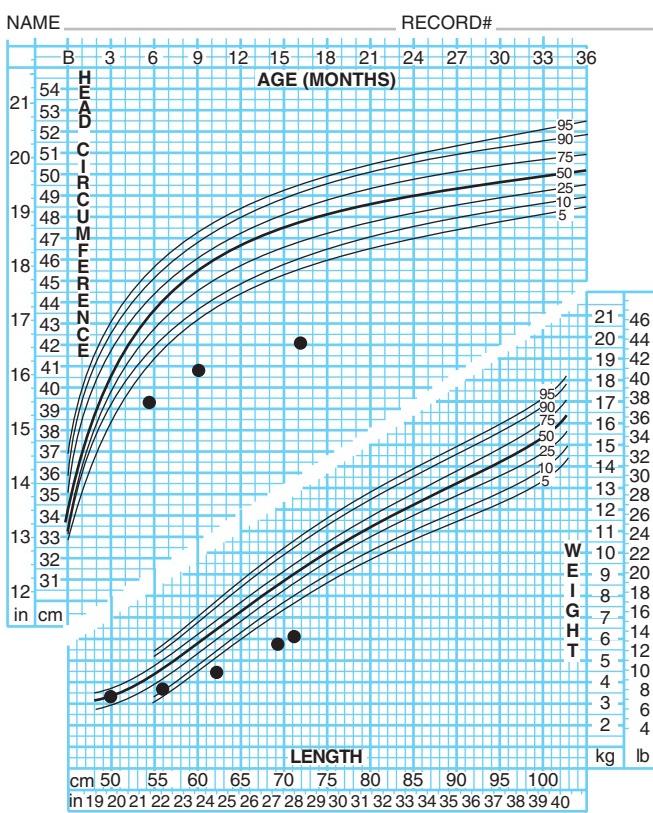

FIGURE 9.3 Growth curve of an infant boy with severely impaired head growth, poor weight gain, and less impairment of length. Most obvious is the marked microcephaly associated with developmental delay, suggestive of an underlying neurologic disorder. (Modified from National Center for Health Statistics: NCHS growth charts. *Monthly Vital Statistics Report*. 1976:25:76-1120. Rockville, MD: Health Resources Administration, June 1976. Data from The Fels Research Institute, Yellow Springs, Ohio. Copyright 1976, Ross Laboratories.)

chronic malnutrition. Only in the worst, long-standing cases is head growth decreased. This typical pattern suggests calorie insufficiency and informs the clinician of the chronicity of the problem.

There are several approaches to the differential diagnosis. The functional approach determines whether there is a problem with increased calorie requirement or utilization, inadequate calorie intake, or increased calorie loss (Table 9.3). The systems approach focuses on the identification of the organ system or systems that might be responsible for the poor growth. A careful history can point the clinician toward a particular system to consider for further diagnostic evaluation (Table 9.4).

Another approach is to consider the age at onset, the child's developmental level, and the conditions likely to manifest at that stage of development. The causes of prenatal growth problems include environmental toxins, maternal drug and alcohol use, prenatal infection, congenital syndromes, placental insufficiency, and poor prenatal

nutrition. Poor growth immediately after birth can be associated with maternal postpartum depression, bonding and attachment disorders, incorrect formula preparation, failure to establish breast-feeding, and congenital anomalies or metabolic conditions. In children older than 9 months, issues of separation and autonomy may result in power struggles over eating resulting in insufficient intake. For toddlers, poor food choices (empty calories found in juice drinks and snack foods), dysfunctional feeding interaction (restriction of self-feeding or lack of structure around meals), and distraction (chaotic home environment, television and electronic devices) may interfere with adequate food intake.

◆ History

The history is the most important part of the evaluation of the child with FTT and guides the evaluation.

NCHS PERCENTILES*

NAME _____ RECORD# _____
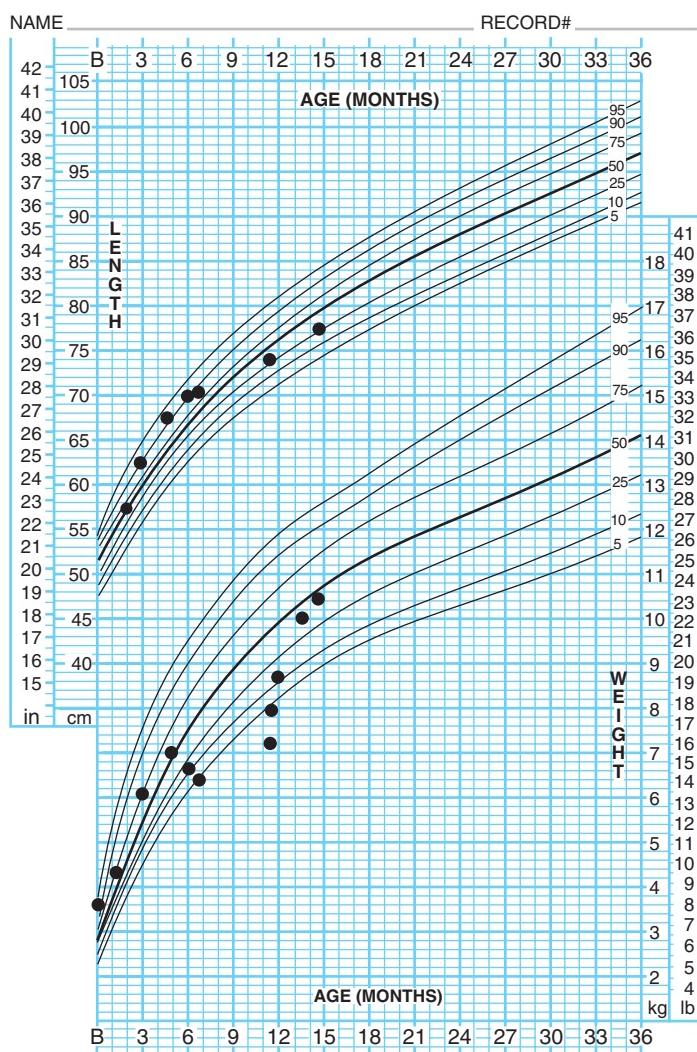

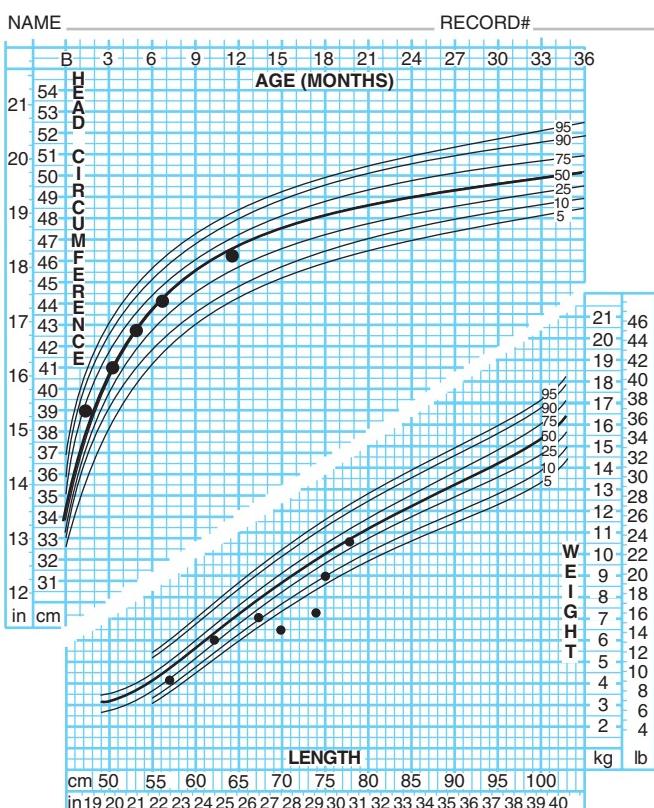

FIGURE 9.4 Growth curve of an infant boy with acute weight loss and catch-up weight gain. Before the age of 4^1/$_2$ months, there was normal growth while he was breast-feeding. After a change to an inadequate weaning diet, severe weight loss developed, but less impairment of length occurred. Head size was not affected. An acute episode of diarrhea led to multiple dietary changes that resulted in further weight loss. With a proper diet history, nutritional rehabilitation with a balanced diet resolved this child's problem. This may also be a pattern of a child with celiac disease. (Modified from National Center for Health Statistics: NCHS growth charts. *Monthly Vital Statistics Report.* 1976:25:76-1120. Rockville, MD: Health Resources Administration, June 1976. Data from The Fels Research Institute, Yellow Springs, Ohio. Copyright 1976, Ross Laboratories.)

History of the Present Illness

If poor growth is first noted by the clinician, the clinician should identify whether the family perceives a problem. What is the family members' perception of the child's food intake? When, if ever, did they first notice a problem? What changes have they made to address the problem? Asking these questions in a nonjudgmental manner will reassure the family that the clinician regards them as partners in the task of improving the child's growth.

A detailed feeding history should start with infant feeding; dietary sources and growth patterns should be chronologically reviewed. Was the child breast- or formula-fed? If breast-fed, were there any problems with milk sufficiency? How did each parent feel about breast-feeding? Did the mother feel emotionally supported in her choice to breast-feed? If the child was formula-fed, what was the formula; how was it mixed; was there ever any reason to change formula? Was feeding a pleasurable or a difficult experience for the parent and child? These questions may give insight into early parent-child interaction problems.

If the child is beyond infancy, when and how were solid foods introduced? Were there any specific food refusals that might indicate an allergy or intolerance? How did the child accept solids? What are the child's food preferences? When did the child start to self-feed? Where does the child eat? Is there a high chair or secure place to eat? Are there family meals, or does the child eat alone? What is going on in the immediate environment when the child is eating? These

TABLE 9.3 Differential Diagnosis by Functional Category

Excessive Calorie Needs
Diabetes mellitus
Cystic fibrosis
Chronic respiratory or cardiovascular disease
Hyperthyroidism
Cerebral palsy/spasticity
Chronic infection or inflammatory diseases

Inadequate Calorie Intake
Family education and mental health: maternal depression, psychosis, substance abuse, lack of parental knowledge of child nutrition needs
Parent-child interaction: parental emotional distance, parental anxiety, mealtime distractions (i.e., television), lack of family mealtime, overindulgent or overcontrolling parent, parental inability to read hunger, and satiety cues
Poor food choices: allows grazing, excessive juice intake
Child factors: neuromuscular disease, poor oral/motor coordination, chronic disease with easy tiring, and failure to complete meals, difficult temperament, hyperactivity, inability to display hunger cues
Economic factors: family not able to afford adequate food, diluting formula, early conversion from formula to cow's milk
Food aversion: impaired swallowing, oropharyngeal or esophageal inflammation, anorexia causing conditions, psychosocial factors

Increased Calorie Loss/Failure to Incorporate Ingested Calories
Diabetes mellitus
Malabsorption syndromes (celiac disease, lactose intolerance, cystic fibrosis, other causes of pancreatic insufficiency, chronic cholestasis)
Metabolic disorders
Chronic diarrhea including IPEX and IPEX-like syndromes
Gastroesophageal reflux and other conditions with chronic vomiting, eosinophilic gastroenteritis
Short gut syndrome

IPEX, immune dysregulation polyendocrinopathy enteropathy X-linked.

questions can reveal dysfunctional eating behaviors that can affect the child's intake.

Questions about unusual eating habits or pica may indicate nutritional deficiencies, such as iron deficiency (Table 9.5). Children with difficult temperaments may have problematic eating behaviors.

Does the child have difficulty taking or manipulating food in the mouth? Is there frequent choking on food? Does the child drool? Is there food refusal or aversion suggesting **dysphagia**? If the response to any of these questions is confirmatory, consider difficulty with oral motor control. This is common among children with neurologic problems.

What is the child's usual daily pattern of activity? Who prepares the food and feeds the child? Is there more than one caregiver? Do the parents know what other caregivers feed the child, or if the child has vomited or defecated while in the care of another adult? Is there a difference in how the child eats or eliminates when the child is with the parents in comparison to other caretakers?

A careful *dietary* history is imperative. The 24-hour recall is standard, although some authorities question its validity. The clinician asks the parent to remember everything the child ate in the past 24 hours and whether that was a typical day. It is helpful to start with the present and work backward. Alternatively, the parent may keep a 3-day food diary. The diary should be structured so that the type of food, quantity, method of preparation, and amount eaten are recorded; beverages should be included. The caregiver should receive prior instruction regarding how to estimate portions and to include only what the child actually eats.

Diet review is a good opportunity to explore parental beliefs about food and the feeding of children (e.g., children must drink water, they need lots of milk, juice is good for them, fat should be restricted to prevent obesity and heart disease). It may be useful to explore parent assumptions about food based on their own experiences or beliefs. The parent who sees the child as vulnerable may be overanxious and rigid about food intake. Cultural norms may dictate certain food choices, which may not provide optimal nutrition. Vegetarian diets may provide insufficient protein, vitamin B_{12}, and iron. Rice and almond milks have inadequate protein for young children. Some parents may substitute goat's milk or rice milk for cow's milk–based nutrition. Goat's milk is deficient in folate while rice milk is extremely low in protein and has caused severe protein deficiency.

Medical History

The prenatal and perinatal history begins with the mother's age, general health, and parity. Was this pregnancy planned? What was the mother's reaction to the pregnancy? How did the father and other family members react? Was mother emotionally prepared for a child? Did the mother have any emotional problems during or before her pregnancy? What was her alcohol, tobacco, and drug intake during pregnancy? When did she start prenatal care? Did she have sufficient visits to monitor the pregnancy? How much weight did she gain? Were there any complications during the pregnancy? Was prenatal testing for sexually transmitted and other infections obtained, and what were the results? Was she hoping for a boy or a girl?

The perinatal history includes problems with labor, method of delivery, and the newborn's growth parameters at birth (i.e., appropriate [AGA], small [SGA], or large [LGA] for gestational age). Is this an SGA infant who needs extra calories for catch-up growth or a newborn with intrauterine growth restriction who is small in all growth parameters? Did the baby have any problems in the nursery? A nursery stay more than 2-3 days may indicate a problem with the newborn. Did the baby have feeding problems after birth? Was breast-feeding begun immediately?

The child's medical history should be reviewed for chronic conditions and recurrent, acute conditions, such as recurrent emesis, diarrhea, constipation, neurologic symptoms, or recurrent infections. Hospitalizations, surgical procedures, medications, and allergies should be explored. Immunization status should be ascertained. It is essential to document neurodevelopmental progress, because motor or cognitive delays could be associated with neurologic dysfunction that increases calorie requirements and/or decreases feeding efficiency.

Family History

The clinician should ascertain the growth of siblings and other family members. Are there patterns of growth in the family that might result in a child growing less than expected in the early years? What, if any, differences do the parents notice between this child and their other children? What were the growth patterns and ultimate sizes of the parents and grandparents? What was the age at menarche and puberty in parents and siblings? Creating a two-generation genogram that includes the height and weight of each family member may provide clues to the growth potential of the patient. Plotting the mean parental height on the child's height curve will help to predict ultimate stature.

Is there any history of heart, renal, or gastrointestinal disease in the family? Have there been any early childhood deaths? Is there any sickle

cell disease or other anemic condition? Are there any family members with genetic or metabolic conditions? Is there a family history of mental illness that might affect the child or the caretakers? Is there consanguinity?

Social History

Many cases of FTT do not have a primary medical etiology, and thus the social history is vital. The examiner should start with the family constellation and who takes care of the child. What is the relationship of the adults in the household, and how do they get along? Are the parents working, and if they work simultaneously, who cares for the child? Are food stores accessible? Do the parents have adequate storage, refrigeration, and food preparation space? Are there adequate eating facilities and implements? Are there siblings who might eat the child's food? Is the child enrolled in the Women, Infants, and Children (WIC) program? Families should be screened for food insecurity. What is the cultural context of food selection and eating behavior?

More difficult social issues must be approached carefully, with a statement to the family that all patients with this problem are asked these routine questions. Is there any substance abuse in the home that might result in use of food money for tobacco, alcohol, or drugs? Have the child protection authorities ever been involved with the family?

Is the child in group daycare, or has the family traveled to an area where a chronic infection such as a parasite might have been acquired? Although the social history can be the most revealing part of the history, it can be the most difficult to elicit. Often the clinician must establish trust with the family before they can reveal the source of their inability to meet their child's nutritional needs.

Review of Systems

A thorough review of systems can help to reveal organic conditions. A few areas merit special attention: Are there sources of calorie loss? Does the child vomit or spit up frequently? What is the stool pattern and quality? What is the pattern and frequency of urination? Does

TABLE 9.5	**Characteristics of Mineral Deficiencies**			
Mineral	**Function**	**Manifestations of Deficiency**	**Comments**	**Sources**
Iron	Heme-containing macromolecules (e.g., hemoglobin, cytochrome, myoglobin)	Anemia, spoon nails, reduced muscle and mental performance	History of pica, cow's milk, gastrointestinal bleeding, excessive milk in diet	Liver, eggs, grains
Copper	Redox reactions (e.g., cytochrome oxidase)	Hypochromic anemia, neutropenia, osteoporosis, hypotonia, hypoproteinemia, poor growth	Inborn error, Menkes kinky hair syndrome, occipital horn syndrome, long term TPN	Liver, oysters, meat, nuts, grains, legumes, chocolate
Zinc	Metalloenzymes (e.g., alkaline phosphatase, carbonic anhydrase, DNA polymerase; wound healing)	Acrodermatitis enteropathica; poor growth, acro-perioral-perianal rash, alopecia, delayed sexual development, hypogeusia, infection	Protein-calorie malnutrition; weaning; malabsorption syndrome	Meat, grains, cheese, nuts
Selenium	Prevents oxidative damage	Keshan cardiomyopathy in China, poor growth	Endemic areas; long-term TPN	Meat, vegetables
Chromium	Insulin cofactor	Poor weight gain, glucose intolerance, neuropathy	Protein-calorie malnutrition, long-term TPN	Yeast, breads
Fluoride	Strengthens dental enamel	Caries	Supplementation during tooth growth, narrow therapeutic range, fluorosis may cause staining of the teeth	Seafood, supplemented water
Iodine	Thyroxine, triiodothyronine production	Simple endemic goiter Myxedematous cretinism: congenital hypothyroidism Neurologic cretinism: mental retardation, deafness, spasticity, normal T_4 level at birth	Endemic in New Guinea, the Congo; endemic in Great Lakes area before iodized salt available	Seafood, iodized salt, most food in nonendemic areas

T_4, thyroxine; TPN, total parenteral nutrition.

urination seem excessive or inadequate? Affirmative answers may indicate a gastrointestinal, metabolic, or renal problem. Are there sources of increased calorie need? Has the child been sick? Has the child had fevers? Does the child tire when feeding? Is there decreased activity?

Constitutional: The examiner should ask whether there are any fevers, night sweats, or changes in activity. Assess sleep hygiene, amount of sleep, and whether sleep is disrupted by snoring or awakenings.

Gastrointestinal: The examiner should inquire about choking, swallowing, dysphagia, vomiting, and spitting up. Night waking and coughing may indicate reflux. Diarrhea, constipation, abdominal pain, distention, or discomfort may indicate organic disease. Pocketing food, or retaining food in the mouth, may indicate oral-motor dysfunction that impedes adequate intake.

Cardiopulmonary: The examiner should ask about coughing, wheezing, night waking, shortness of breath, exercise intolerance, and early tiring during feeding.

Renal: The examiner should inquire about dysuria, hematuria, increased urinary frequency or volume, secondary enuresis, and urine that seems unusually dilute.

◆ Physical Examination

The examination should start with accurate measurements of height or length, weight, and head circumference; these parameters should be plotted on a standard growth curve. Weight for height or BMI (if >2 years of age) should also be plotted. Historical events should be obtained and plotted to identify patterns of growth.

As part of a complete physical examination, the following signs should be sought:

General: degree of emaciation, state of fat distribution and muscle mass, dysmorphic features, vital signs (including blood pressure)

Head, eyes, ears, nose, and throat: fontanel size, evidence of chronic ear infections, allergic stigmata, patency of upper airway

Cardiorespiratory: respiratory effort, lower airway sounds, cardiac sounds, pulses, edema

Gastrointestinal: organomegaly, abdominal distention, rectal fissures or prolapse

Genitourinary: renal masses, Tanner staging

Musculoskeletal: joint swelling, bone deformities

Skin: hydration, evidence of chronic inflammation, bruising or scarring, rashes, hair quality and distribution, nails

Lymph nodes: local vs. generalized (see Chapter 36)

Neurologic: muscle volume, tone (hypo or hypertonic), strength, coordination, swallowing and drooling, assessment of development and interaction with the examiner.

Abnormalities associated with pathologic biomedical conditions should prompt a search for a specific diagnosis (see Table 9.4). On occasion, growth failure as well as other physical findings can be associated with specific nutrient deficiencies (Table 9.6; see Table 9.5).

◆ Laboratory Evaluation

Almost any serious chronic illness may result in FTT; therefore the examiner must have a broad diagnostic screening approach and simultaneously consider the more likely possibility that nonmedical

(See *Nelson Textbook of Pediatrics,* p. 343.)

TABLE 9.6 Characteristics of Vitamin Deficiencies

Vitamin	Function	Manifestations of Deficiency	Comments	Sources
Water-Soluble				
Thiamine (B$_1$)	Coenzyme in ketoacid decarboxylation (e.g., pyruvate →acetyl-CoA transketolase reaction)	Beri-beri: polyneuropathy, calf tenderness, heart failure, edema, ophthalmoplegia	Inborn errors of lactate metabolism; boiling milk destroys B$_1$	Liver, meat, milk, cereals, nuts, legumes
Riboflavin (B$_2$)	FAD coenzyme in oxidation-reduction reactions	Anorexia, mucositis, anemia, cheilosis, nasolabial seborrhea	Photosensitizer	Milk, cheese, liver, meat, eggs, whole grains, green leafy vegetables
Niacin (B$_3$)	NAD coenzyme in oxidation-reduction reactions	Pellagra: photosensitivity, dermatitis, dementia, diarrhea, death	Tryptophan is a precursor	Meat, fish, liver, whole grains, green leafy vegetables
Pyridoxine (B$_6$)	Cofactor in amino acid metabolism	Seizures, hyperacusis, microcytic anemia, nasolabial seborrhea, neuropathy	Dependency state; deficiency secondary to drugs	Meat, liver, whole grains, peanuts, soybeans
Pantothenic acid	Coenzyme A in Krebs cycle	None reported	—	Meat, vegetables
Biotin	Cofactor in carboxylase reactions of amino acids	Alopecia, dermatitis, hypotonia, death	Bowel resection, inborn errors of metabolism, and ingestion of raw eggs	Yeast, meats; made by intestinal flora
B$_{12}$	Coenzyme for 5-methyl-tetrahydrofolate formation; DNA synthesis	Megaloblastic anemia, peripheral neuropathy, posterior lateral column disease, vitiligo	Vegans; fish tapeworm; transcobalamin or intrinsic factor deficiencies	Meat, fish, cheese, eggs
Folate	DNA synthesis	Megaloblastic anemia	Goat milk deficient; drug antagonists; heat inactivates	Liver, greens, vegetables, cereals, cheese
Ascorbic acid (C)	Reducing agent; collagen metabolism	Scurvy: irritability, purpura, bleeding gums, periosteal hemorrhage, aching bones	May improve tyrosine metabolism in preterm infants	Citrus fruits, green vegetables; cooking destroys it
Fat-Soluble				
A	Epithelial cell integrity; vision	Night blindness, xerophthalmia, Bitot spots, follicular hyperkeratosis, poor growth	Common with protein-calorie malnutrition; malabsorption	Liver, milk, eggs, green and yellow vegetables, fruits
D	Maintains serum calcium, phosphorus levels	Rickets: reduced bone mineralization, poor growth	Prohormone of 25- and 1,25-vitamin D; malabsorption	Fortified milk, cheese, liver
E	Antioxidant	Hemolysis in preterm infants; areflexia, ataxia, ophthalmoplegia	May benefit patients with G6PD deficiency; malabsorption	Seeds, vegetables, germ oils, green leafy vegetables
K	Posttranslation carboxylation of clotting factors II, VII, IX, and X and proteins C, S	Prolonged prothrombin time; hemorrhage; elevated PIVKA (protein induced in vitamin K absence)	Malabsorption; breast-fed infants	Liver, green vegetables; made by intestinal flora

FAD, flavin adenine dinucleotide; G6PD, glucose-6-phosphate dehydrogenase; NAD, nicotinamide adenine dinucleotide.
Modified from Tershakovec A, Stallings VA. Pediatric nutrition and nutritional disorders. In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics.* 2nd ed. Philadelphia: WB Saunders; 1994:74.

processes are the cause. In most cases of chronic "organic" illness, there is likely some indication in the history, physical examination, or selected diagnostic screening tests (Table 9.7). The few cases of organic FTT not detected by these screening tests may become evident when the infant does not respond to nutritional rehabilitation. If, however, the examiner attempts to pursue every conceivable diagnostic test for organic causes of FTT before implementing vigorous nutritional rehabilitation, he or she is likely to run out of time, patience, and resources and to come to no conclusion. Some unusual cases may take months or years before a diagnosis is made.

The choice of the appropriate initial laboratory tests may include several general screening tests (complete blood count, urinalysis, serum electrolyte levels, blood urea nitrogen level) to detect treatable conditions. A complete blood cell count can reveal clinically inapparent anemia, which, although usually secondary to the poor nutritional state, can sometimes contribute to the poor dietary intake or suggest anemia of chronic disease. A urinalysis and urine culture can reveal evidence of an occult urinary tract infection or renal tubular acidosis. An erythrocyte sedimentation rate or C-reactive protein may provide evidence of chronic inflammation or infection. The examiner may need to test for celiac disease, in which poor weight gain may be the only symptom for many years. Other specific tests are directed by the history and physical examination (Table 9.8). For example, for a child with developmental delay and FTT, a blood lead test, metabolic

TABLE 9.7 **Clinical Clues to Differentiate Predominant Organic Disease from Predominant Organic Disease Not Present**

Predominant Organic Disease Not Present	Predominant Organic Disease Present
Spoon or bottle refusal	Accepts spoon or bottle first
Presence of anticipatory gagging and "pocketing" of food in mouth	Absent
Picky about texture or type of food	Accepts a variety of foods
Presence of abnormal feeding practice (nocturnal feeding, force feeding, prolonged meals)	Absent
Onset after a trigger or traumatic event (e.g., choking episodes, prolonged nasogastric feeding)	Usually absent
Vivacious infant	Lethargic infant
Poor appetite	Interest in eating
Absence of organic symptoms	Diarrhea or abdominal distention

From Shashidar H, Toila V. Failure to thrive. In: Wyllie R, Hyams JS, Kay M, eds. *Pediatric Gastrointestinal and Liver Disease.* 4th ed. Philadelphia: Elsevier; 2011:141.

screening tests, a karyotype or other genetic testing, imaging of the head, or human immunodeficiency virus screening may be necessary, whereas a child with apparent malabsorption is evaluated completely differently (such as for cystic fibrosis or celiac disease). If height growth is affected, a bone age can be useful to determine if an endocrine evaluation is necessary.

OVERALL APPROACH TO MANAGEMENT

The evaluation of a child with FTT should proceed in a stepwise manner (Fig. 9.5). Once the clinician has arrived at a working diagnosis, treatment can be instituted. It is important to develop a therapeutic alliance with family members. Parents whose children are not growing according to expectation may be feeling guilty or may have a sense of failure. A nonjudgmental approach, avoiding the assignment of blame, is important. Although the clinician can make suggestions, it is the family that must feel empowered to implement the plan.

Providing specific information that can be easily implemented in the family's home environment will be more successful than giving general advice. Suggestions that a parent feed more food to a child may be disregarded, particularly when the family members believe they are already doing their best. Pressuring parents may increase caregiver guilt, frustration, and anxiety if the child does not grow as expected.

Even with the strong suspicion of a biomedical cause, it is reasonable to give specific advice on enhancing calorie intake while further evaluation and treatment is ongoing. If the condition is chronic, the child may need long-term nutritional supplementation. If the condition is acute and treatable, the child needs extra calories for catch-up growth.

Steps to Improve Calorie Intake
Mealtime Behavior
A pleasant, safe setting should be created for mealtime. An infant seat is appropriate for the first several months. Once a child can sustain a sitting position, a high chair is advantageous. The high chair allows the child to feel safe from falling, frees up his or her hands for feeding, and keeps the child confined in one place to focus on the meal. A bib prevents the need for frequent changes of clothing. For an older child, a booster seat is appropriate along with child-sized utensils. Parents who feed an infant or toddler while holding the child in their laps find that the meal is a struggle; this also prevents the child from developing the skills needed for self-feeding.

To promote the important social aspect of mealtime, family members should be seated and eating with all children whenever possible. Use of a small, child-sized table and chair prevents the child from observing and learning from siblings and adults during family meals. Toddlers and older infants are usually interested in the food served to other family members, and this encourages experimentation with new foods. There should be conversation during the meal, but the child's food intake should not be the focus of the conversation.

Distractions should be minimized during meals. The television and other electronic media should be off. There should not be other commotion in the kitchen. However, for the infant, a small washable toy on the tray or table may help keep attention on the meal.

Parents should understand that experimenting with food is part of the natural curiosity of older infants and toddlers. If the parent is constantly wiping the child and berating him or her for getting messy, the child cannot learn that eating can be a fun experience. If a parent has particular difficulty with messiness, the examiner can suggest spreading newspaper or a plastic sheet under the high chair. Another simple technique is the "two-spoon method" of feeding the child. The parent should provide a spoon to the child to dip into the food, and the parent has the second spoon, which provides most of the feeding.

Once the child has communicated that the meal is finished, the parent can offer one or two more bites but then should accept that the child is no longer hungry, and the meal should be ended. The duration of the meal for a toddler is typically not more than 15 or 20 minutes. Food should not be brought out until the next regular meal or snack.

Beverages
Exclusive breast-feeding is the preferred nutritional source for infants from birth to 6 months. Formula-fed infants should be held during a feeding until they are able to sit on their own and hold the bottle. Bottles should never be propped. After 1 year of age, cow's milk should be consumed. Although 1-2% milk is acceptable, whole milk is preferred for underweight toddlers. The volume of formula or whole cow's milk consumed should be about 24 ounces per day. If a child is drinking an excessive amount of formula, review the preparation procedures to ensure that the proper dilution is used.

All children naturally enjoy sweet foods. However, if they are introduced early or used instead of more nutritionally complete foods, children may develop a preference for sweets, especially juices. In particular, toddlers who are allowed to have bottles with sweetened juices throughout the day eat little at mealtime, resulting in undernutrition. In addition, because of limited absorption of dietary sugars, particularly in juices with high fructose-to-glucose ratios (such as apple and pear juice), children with excessive juice intake may suffer from bloating, excessive flatulence, abdominal pain, and chronic diarrhea because of undigestible carbohydrate malabsorption. Juice should not be introduced until after children are 6 months of age. When introduced, only 100% fruit juice should be offered in a cup. Intake should be limited to 4-6 ounces per day for children aged 1-6 years and to 8-12 ounces per day for older children and adolescents.

Various methods are available to enhance the calorie density of infant dietary beverages for nutritional supplementation. Formulas can be made with less water. Polycose and vegetable oils can be added. Pumped/expressed breast milk can be enhanced with breast milk fortifier (premature infants) or powdered formula (full-term infants).

TABLE 9.8	**Some Causes of Failure to Thrive and Screening Tests**
Cause	**Screening Tests**
Environmental and Psychosocial*	
Inadequate caloric intake	History; observation in hospital
Emotional deprivation and disruptions	History; observation in hospital
Rumination; chronic diarrhea, gastroesophageal reflux	History; observation in hospital
Anorexia nervosa and bulimia	History; examination
Secondary to impact of organic disease	History and observation
Organic	
Central nervous system abnormalities, infection	Neurodevelopmental assessment; brain MRI
Gastrointestinal system	
Malabsorption, cystic fibrosis, inflammatory bowel disease, parasites, aganglionic megacolon; liver disease; food intolerance; celiac disease; gastroesophageal reflux, eosinophilic esophagitis	Examination of stools: stool fat, sweat test, stool ova and parasites; tissue transglutaminase antibodies; liver function tests; barium swallow, erythrocyte sedimentation rate, food challenge, esophageal and intestinal biopsy
Partial cleft palate	Physical examination; observation of feeding
Chronic heart failure	Physical examination; chest x-ray; echocardiography
Endocrine disorders	Growth chart; thyroid function tests; bone age, cortisol level GH testing
Pulmonary disease	
Bronchopulmonary dysplasia; bronchiectasis; cystic fibrosis	Physical examination; chest roentgenography; tuberculin test, pulmonary function tests, sweat test
Renal disease

Food Selection

Including older children in food shopping and preparation will increase interest in eating. At mealtime, older toddlers and preschool-aged children may be permitted some flexibility in food selection from two or three choices. Providing choices allows the child to assume some control over the feeding. Each choice must be nutritionally sound and acceptable to the parent. Parents should not become bound by social constraints when it comes to foods served at certain meals.

Infants and young toddlers may have preferences for certain food textures, temperatures, and presentations. These preferences are often short-lived. Normal children may become "picky" eaters in the second and third years of life. New foods should routinely be introduced but not forced on the child. With repetition and modeling, children will try new foods. For some children, food preferences may be strong and cyclic. For example, a child may go through a cycle in which he or she requests peanut butter and jelly sandwiches for nearly every meal. If a variety of fruits or vegetables are given along with the sandwich, this may be a reasonable compromise.

Although it is the caregiver's responsibility to provide appropriate food, it is the child's responsibility to decide on the quantity of food to be eaten. "Force feeding" will convince the child that mealtime is

FAILURE TO THRIVE (AND WEIGHT LOSS)

Perform H and P, accurate documentation of serial measurements

Signs or symptoms suggestive of developmental delay or neuromuscular disorder present

YES → Carefully review feeding history / Assess caloric intake / Consider TORCH titers, microarray, speech pathology consult

something to be feared. Parents must learn to read a child's cues for hunger and satiety.

Daily Routines and Snacks

Once children are receiving solid foods, they should be on a regular schedule of meals that are served at predictable times during the day. This may mean three meals and two or three snacks per day for infants and toddlers. The practice of "grazing"—having food available to the child throughout the day—should not be allowed. Frequent snacking allows the child to be satiated, preventing interest in standard meals.

This may lead to poor nutritional intake. Planned snacks afford the opportunity to supplement the child's diet with high-quality foods with good nutritional content. For toddlers and preschool-aged children, beverages should be introduced only after a good portion of the meal has been eaten.

Calculating Caloric Need

In order to calculate the minimal daily caloric requirements needed for catch-up growth, the examiner should determine the weight age (age at which current weight would be at 50%) and recommended

TABLE 9.9 **Normal Calorie Requirements and Weight Gain by Age**

	Calorie Requirement (kcal/kg/day)	Weight Gain* (g/day)
Premature	150	20-40
Full-term to 3 months	100-120	25-39
3-6 months		14-20
6- 9 months	90-100	9-13
9-12 months		7-10
Toddler	75-85	6-9

*Based on WHO growth charts (5% and 95%).

calories for weight age (Table 9.9). The ideal weight for current height (50% weight for current height) should also be determined. Calories needed for catch-up growth are calculated as:

$$\frac{(\text{kcal/kg for weight age}) \times (\text{ideal weight for height in kilograms})}{\text{actual weight in kilograms}}$$

For most children, calories needed for catch-up growth can be easily calculated as:

$$\frac{(120\,\text{kcal/kg}) \times (\text{ideal weight for height in kilograms})}{\text{actual weight in kilograms}}$$

Most infants will achieve catch-up growth on 160-180 kcal/kg/day. Some infants may need considerably more, up to 1.5-2 times the daily requirements for catch-up. Caloric intake can be estimated from the diet history.

NUTRITIONAL SUPPLEMENTATION FOR THE OLDER INFANT AND CHILD

Several products are available for nutritional supplementation. The complete liquid formulations are excellent products; very similar nutritional value can be found in packaged instant-breakfast drinks when mixed with whole milk, at much lower cost. These nutrient-dense beverages should supplement the child's diet, not supplant other foods.

Many food products (powdered milk, margarine, cheese, wheat germ, peanut butter) can be added to acceptable foods in order to increase calories. It is easier to increase caloric density than increase the amount of food eaten. Attention should be paid to maximizing protein intake needed for growth.

If a child does not seem to be taking an adequate variety of foods, a supplement of multivitamins with minerals may be indicated. Particularly during periods of rapid catch-up growth, additional vitamins and minerals can be beneficial. Iron and zinc deficiencies may impede normal growth (see Table 9.5). Supplementation of zinc and other trace minerals has been shown to enhance catch-up growth in malnourished children. A trial of an appetite stimulant, such as cyproheptadine, can be effective in some children.

Referral Resources and Other Options
Multidisciplinary Team
Children with FTT have complex medical and psychosocial issues. As a result, a biomedical model of care may be insufficient for managing the child and family. A multidisciplinary approach may be beneficial in complicated cases by relieving the medical provider of the responsibilities of investigating the home situation, reviewing the family's finances and resources, and observation of mealtime.

The team might include a physician, social worker, psychologist, nutritionist, nurse, child life specialist, and home visitor. Each team member evaluates the patient and family according to his or her discipline. The team then discusses the case and develops a plan for ongoing management. Children treated by teams have been found to have better outcomes than do children receiving routine care.

The psychological evaluation may identify children with developmental delays, and can assess family stressors and help identify strengths and weaknesses in the family. In some families, the child may be the indicator that there is an underlying disturbance, such as depression or marital stress. The psychologist can also offer support and reassurance as the family goes through a difficult period caused by potential long-term nutritional rehabilitation of the child. In addition, the psychologist can help the caregiver understand that improving the feeding situation takes a great effort on the part of the parent as well as the child and that new strategies are required for successful weight gain.

The nutritionist's expertise is essential for a thorough evaluation and follow-up plan. When taking a complete nutritional history, the nutritionist can analyze the nutritional and caloric values of the foods eaten. Alternative meal plans can then be developed to maximize calories and nutritional content.

A social worker's contribution to the team is an assessment of the child's environment and factors that may be contributing to the child's poor growth. Areas for investigation include social supports, housing conditions (crowding, space for food storage, proper refrigeration), and financial hardships. Families may need assistance with arranging work leave, rearranging work schedules, transportation, or respite care. Families can be directed to community-support services that focus both on social/emotional and material/financial issues. Participation in the WIC program ameliorates food insecurity. If child maltreatment is suspected, the social worker assists with communication with the appropriate social service agency.

When feasible, home observation provides a wealth of information to the clinician about the environment in which the child resides and eats meals. Does the child have an appropriate place in which to eat? Is there a supply of appropriate foods in the home? What are the other environmental factors that may be impeding the child's growth? Studies of home interventions have had mixed success, but young children with highest risks have improved developmental outcomes with home intervention.

Recording or Direct Observation
Observation or recording of a meal provides an opportunity to assess the child's willingness and ability to participate in the meal, the parenting style, and the interaction between the child and parents. Parent feeding style can be classified as responsive/authoritative, controlling/authoritarian, indulgent/permissive, or neglectful/rejecting. Parent and child strengths should be pointed out to the parent. Problematic communication, both verbal and nonverbal, should be reviewed. Difficulties that are observed should be discussed and become the basis for further intervention.

Involvement of Social Service Agencies
Clinicians caring for children with FTT often find themselves working in conjunction with other agencies, including *social service agencies.* Children who are refused food or are abused in any way must be reported. It may, however, be difficult to determine what constitutes

neglectful care. Families that are disorganized and overwhelmed, have other pressing social issues, or refuse to follow recommendations, resulting in lack of sufficient progress in the child's growth, must be reported to the local agency. This may include parents with cognitive deficits or mental health problems. It is important for all agencies to work together and articulate a plan, so that the families involved do not receive conflicting instructions and messages.

Behavioral Strategies

In some situations, behavior-modification programs are used. These may include strategies to determine specific parameters in the feeding environment that will improve the child's intake. These may include colors, textures, tastes, etc. In more difficult cases, a strict behavior modification program may be used.

Non-Oral Enteral Feeding

For some children, maximizing oral intake may nonetheless provide insufficient calories for catch-up growth. The clinician may consider other forms of enteral feeding. This intervention is needed if, despite all other attempts to maximize oral feeding, the child's growth is falling further below the 5th percentile or if the child is showing signs of severe malnourishment (e.g., hypoalbuminemia, or low prealbumin levels).

Initially, nasogastric (NG) feeding can be used for night feedings. The child should be encouraged to eat orally during the day. If the need for the NG tube is extended for a longer duration (some authorities use 3 months), then a referral should be made for placement of a percutaneous gastrostomy tube (G-tube). This is used for supplemental nutrition for most children and is not a substitute for oral intake. Children receiving supplemental alimentation should be monitored very closely. Once the weight for height is near the 50th percentile, the supplement should be adjusted to prevent obesity. The G-tube is removed when the child can sustain an adequate growth rate eating orally.

It is very important that some oral stimulation continue even if the G-tube is the main source of nutrition. If children are denied the chance to develop competence in age-appropriate feeding behaviors, they are likely to develop food aversions. This makes reintroduction of oral intake extremely difficult.

CHILDREN WITH SPECIAL HEALTH CARE NEEDS

This category encompasses a variety of children: children with isolated dysphagia for whom eating represents more work than pleasure, children with sensory issues for whom food tastes and textures can be experienced as adverse, and children who are technology dependent and not able to self-regulate caloric intake.

During the medical assessment, if a child is found to have drooling, coughing, gagging, pocketing of food in the cheek, retention of food in the mouth, or oral aversion, consider oral motor problems. An assessment by a speech therapist or occupational therapist with specific training in oral motor therapy can help reveal specific problems that are amenable to therapy. A modified barium swallow may be recommended to assess the risk of aspiration. Some children with oral motor dysfunction develop oral aversion, as if it is not worth the effort to put anything in their mouths. Oral motor therapy or involvement in an intensive feeding program that addresses feeding therapy in a multidisciplinary fashion may be indicated for these children.

Children with autism often have sensory issues that cause feeding aversion. Again oral motor evaluation and therapy may be of help, but the therapy may need to focus on oral desensitization rather than motor skills. These children will sometimes accept only a very limited number of foods, or a single color, or texture. The clinician can ensure adequate micronutrient intake with vitamins and other supplements, but may need to disguise them in the accepted foods.

Technology-dependent children represent a very different challenge. Here, it is necessary to monitor growth regularly, and adjust caloric intake as necessary. Increased activity or work, due perhaps to improved motor skills, or decrease in respiratory support, can abruptly increase a child's caloric need and cause weight loss if caloric intake is not increased. In general, increases of 10% are well tolerated, and can be adequate to improve growth. This can be done by increasing volume or caloric density depending on the particular patient's clinical situation. Follow-up weight checks in 2-4 weeks can inform the clinician if the increase was adequate, or excessive, and additional adjustments can be made. Failure to gain weight appropriately even with additional calories should prompt further evaluation for increased utilization or improper home feeding.

CRITERIA FOR HOSPITALIZATION

Decisions about when to hospitalize an infant with FTT are inevitably influenced by practical considerations of the availability and quality of hospital services, cost, and distance from the family's home. The medical issues are whether hospitalization will facilitate further diagnostic steps and whether the affected child is malnourished enough to create a sense of urgency about nutritional rehabilitation. Loss of more than 30% of the average weight for length (to less than 70% of expected weight for length) constitutes severe malnutrition, which most physicians would be reluctant to treat on an outpatient basis unless there is no satisfactory alternative. In addition, hospitalization is indicated if there is a concern about **factitious disorder (Munchausen syndrome)** by proxy. In this situation, a parent may be purposefully manipulating the child in order to produce FTT or other symptoms.

Most children with FTT gain weight in the hospital within 1-2 weeks, but obtaining a weight gain in a short amount of time does not prove that the home environment was the problem. Alternatively, even a 1- to 2-week hospitalization in a child without an organic cause of the growth failure may not produce a sustainable weight gain. The foreign surroundings and lack of familiar faces might prevent the child from eating appropriately. Parents may not be able to remain with the child in the hospital if they have other small children to attend to at home.

Sufficient time must be anticipated in the hospital for substantial recovery; in severe cases, full recovery requires about 6 weeks. After initial stabilization and reassurance that the infant is doing well, the child can spend much of this recovery period in a less expensive, nonintensive supervised medical care facility that emphasizes nutritional support and psychosocial stimulation. Creative approaches to well-organized outpatient day programs or frequent home visiting by properly trained health care workers may provide an attractive alternative to hospitalization.

MONITORING

Long-term follow-up is required to ensure that initial weight gains are sustained. At the follow-up visits, the 24-hour diet recall is assessed, or a 3-day diet history is brought by the family. At all visits, the child's growth parameters must be plotted. Dividing weight gained by the number of days since the last measurement provides a mean growth rate. This can be compared with the normal growth rate in children by age group (see Table 9.9). A child in need of catch-up growth should exceed the expected growth rate for normal children. Periodically, the family can be observed or recorded during a feeding session to determine improvement from prior sessions.

LONG-TERM OUTCOMES

Children with early FTT may suffer long-term consequences in growth, cognitive development, and social functioning. Outcomes depend on cause, age at intervention, and associated risk factors and may not be as ominous as early studies suggested. Parental self- perceived competence and child adaptability have been associated with good outcomes.

Children with FTT who experience other social stressors are at higher risk for adverse outcomes. Poverty and associated family and environmental problems may exacerbate the negative effects of FTT. Children with FTT who experience neglect are more likely to have poor outcomes. However children who are diagnosed early and given appropriate treatment and family support services have better recovery than those who are treated later.

FTT may have long-term effects on growth. It may affect ultimate stature and possibly brain growth and development. Children in whom the FTT has an organic cause that can be successfully managed often do well. For those with undetermined causes or persistent FTT, outcome can be poor. Growth may continue to be delayed. Ultimate stature may be shorter than that predicted from mean parental heights (see Chapter 43). Similarly some children who were SGA at birth may remain small for their life span; nutritional enhancement will have minimal effect.

Of interest is that with long-term follow-up, some children with FTT have been observed to develop obesity. Starvation followed by aggressive nutrition rehabilitation may lead to the development of insulin resistance. The factors that lead some children to develop these consequences of overnutrition are not fully understood.

Poor developmental and cognitive outcomes have been found in many children with FTT. However, studies of these children have multiple confounding factors, and it is difficult to ascribe outcomes solely to the nutritional deficiencies. Some of the children who fare poorly may have had initial mild deficits that were undetected. Those who were symmetrically small for gestational age and those with microcephaly are particularly at risk for diminished cognitive potential. Children who are stunted in the first 2 years of life have poor long-term outcomes. Home intervention by child development specialists may lessen the impact of FTT on cognitive skills. Children should be referred for early intervention services as soon as deficits are detected. Better success will be achieved if intervention is started early.

Children with FTT may manifest behavioral problems, even after the nutritional issues appear to be resolved. If the behaviors are particularly difficult to manage, the services of a psychologist or behavior specialist are warranted.

SUMMARY AND RED FLAGS

FTT (or growth faltering) is a complex condition encompassing biomedical and psychosocial causes. In the United States, it is most often associated with various psychosocial attributes of the parents, family, or child. The keys to determining the cause are a thorough history and physical examination, including assessment of the growth pattern over time. Red flags include refusal to eat, poor response to feedings, an inappropriately small head size, and abnormal physical signs. Clinicians should be vigilant in identifying chronic disease as well as indicators of child abuse and neglect (see Table 9.4). Episodes of recurrent emesis, altered mental status, metabolic acidosis, and hypoglycemia should raise suspicions of an inborn error of metabolism. Microcephaly, seizures, developmental delay or developmental regression, and hypotonia or hypertonia should lead to suspicions of a chronic neurologic problem. Specialists should be consulted for suspected conditions or specific questions. Identifying and treating the medical and psychosocial causes while enhancing calorie intake can result in good outcomes.

Abdominal Pain

Adrian Miranda

Acute abdominal pain is usually a self-limiting, benign condition that is commonly caused by gastroenteritis, constipation, or a viral illness. The challenge is to identify children who require immediate evaluation for potentially life-threatening conditions. Chronic abdominal pain is also a common complaint in pediatric practices, as it comprises 2-4% of pediatric visits. At least 20% of children seek attention for chronic abdominal pain by the age of 15 years. Up to 28% of children complain of abdominal pain at least once per week and only 2% seek medical attention. The primary care physician, pediatrician, emergency physician, and surgeon must be able to distinguish serious and potentially life-threatening diseases from more benign problems (Table 10.1). Abdominal pain may be a single acute event (Tables 10.2 and 10.3), a recurring acute problem (as in abdominal migraine), or a chronic problem (Table 10.4). The differential diagnosis is lengthy, differs from that in adults, and varies by age group. Although some disorders occur throughout childhood (constipation, gastroenteritis, lower lobe pneumonia, urinary tract infections), others are more common in a specific age group (see Table 10.2).

PATHOPHYSIOLOGY OF ABDOMINAL PAIN

Abdominal pain results from stimulation of nociceptive receptors and afferent sympathetic stretch receptors. The pain is classified as visceral or parietal (somatic).

Visceral Pain

Visceral pain receptors are located on the serosa surface, in the mesentery, within intestinal muscle, and mucosa of hollow organs. Pain is initiated when receptors are stimulated by excessive contraction, stretching, tension or ischemia of the walls of hollow viscera, the capsule of a solid organ (liver, spleen, kidney), or of the mesentery. Increased contraction of the smooth muscle of hollow viscera may be caused by infection, toxins (bacterial or chemical agents), ulceration, inflammation, or ischemia. Increased hepatic capsule tension may be secondary to passive congestion (heart failure, pericarditis) or inflammation (hepatitis).

Afferent fibers involved in processing visceral pain are unmyelinated C-fibers that enter the spinal cord bilaterally, resulting in dull, poorly localized pain. Visceral pain is often of gradual onset, and although localization may be imprecise, some general rules may be helpful (Fig. 10.1).

Parietal Pain

Parietal pain arises from direct noxious (usually inflammation) stimulation of the contiguous parietal peritoneum (e.g., right lower quadrant at the McBurney point, appendicitis) or the diaphragm (splenic rupture, subdiaphragmatic abscess). Parietal pain is transmitted through A-delta fibers to specific dorsal root ganglia and thus is usually sharp, and more intense. It can usually be exacerbated by movement or cough, is accompanied by tenderness over the site of irritation, and lateralizes to one of four quadrants. Because of the relative localization of the noxious stimulation to the underlying peritoneum and the more anatomically specific and unilateral innervation (peripheral-nonautonomic nerves) of the peritoneum, it is usually easier to identify the precise anatomic location that is producing parietal pain (Fig. 10.2).

ACUTE ABDOMINAL PAIN

The clinician evaluating the child with abdominal pain of acute onset must decide quickly whether the child has a "surgical abdomen" (a serious medical problem necessitating treatment and admission to the hospital) or a process that can be managed on an outpatient basis. Even though surgical diagnoses are fewer than 10% of all causes of abdominal pain in children, they can be life-threatening if untreated. Approximately 55% of children evaluated for acute abdominal pain have a specific medical diagnosis; in another 45%, the cause is never defined.

◆ History

Obtaining an accurate history is critical for making an accurate diagnosis but is dependent both on the ability and willingness of the child to communicate and on the skill of the parent or guardian as an observer. The person providing an infant's care is the best source of information about the current illness; the examining physician should try to elicit as much information from the child as possible. Some children give a good account of their illness when they are simply asked to describe it; most children must be asked open-ended, non-leading questions. To determine the presence of anorexia, the physician must ask questions about food intake, the time the food was eaten, and how that behavior compares to the child's normal intake. The answers are often quite different from the responses to the more general questions "Are you hungry?" and "Have you eaten today?"

During the history taking, the child should remain in the parent's arms, at play, or comfortably seated beside the parent, as appropriate for the child's age. While the history is obtained, there is no particular reason that the child should be undressed. The clinician must resist the urge to speed things up by examining the child while taking the history. On occasion, when seeing a seriously ill child, the physician may need to abbreviate the diagnostic process, but taking short cuts may lead to inaccurate conclusions.

Essential Components of the History

Time of onset of pain. Pain of fewer than 6 hours' duration is accompanied by nonspecific findings, and observation is often needed to determine the nature of the illness. Pain lasting from 6-48 hours is more apt to have a cause that warrants medical intervention, although delays in presentation and diagnosis in children are not unusual. Timing of the progression of symptoms must be detailed.

(See *Nelson Textbook of Pediatrics,* p. 1764.)

TABLE 10.1	Distinguishing Features of Abdominal Pain in Children				
Disease	**Onset**	**Location**	**Referral**	**Quality**	**Comments**
Functional: irritable bowel syndrome	Recurrent	Periumbilical	None	Dull, crampy, intermittent, duration 2 hr	Caused by unknown physiologic factors; diarrhea/constipation are symptoms
Gastroenteritis	Acute or gradual	Periumbilical, rectal-tenesmus	None	Crampy, dull, intermittent	Emesis, fever, watery diarrhea or dysentery (mucus and blood)
Esophageal reflux	Recurrent, after meals, bedtime	Substernal	Chest	Burning	Sour taste in mouth, Sandifer syndrome
Duodenal ulcer	Recurrent, before meals, at night	Epigastric	Back	Severe burning, gnawing	Relieved by food, milk, antacids; family history
Pancreatitis	Acute	Epigastric/hypogastric	Back	Constant, sharp, boring	Nausea, emesis, marked tenderness
Intestinal obstruction	Acute or gradual	Periumbilical–lower abdomen	Back	Alternating cramping (colic) and painless periods	Distention, obstipation, bilious emesis, increased bowel sounds
Appendicitis	Acute or gradual (1-2 days)	Initially periumbilical or epigastric; later localized to the right lower quadrant	Back or pelvis if retrocecal	Sharp, steady	Nausea, emesis, local tenderness with/without fever; patient is motionless
Meckel diverticulitis (mimics appendicitis)	Recurrent or constant	Generalized diffuse with perforation: periumbilical–lower abdomen	None	Sharp	Hematochezia: painless unless intussusception, diverticulitis, or perforation
Inflammatory bowel disease	Recurrent	Depends on site of involvement		Dull cramping, tenesmus	Fever, weight loss, with/without hematochezia
Intussusception	Acute	Periumbilical–lower abdomen	None	Cramping, with painless periods	Guarded position with knees pulled up, "currant jelly" stools
Lactose intolerance	Recurrent with milk products	Lower abdomen	None	Cramping	Distention, gaseousness, diarrhea
Urolithiasis	Acute, sudden	Back	Groin	Severe colicky pain	Hematuria; calcification on KUB x-ray study, CT scan
Pyelonephritis	Acute, sudden	Back	None	Dull to sharp	Fever, costochondral tenderness, dysuria, pyuria, urinary frequency
Cholecystitis/cholelithiasis	Acute	Right upper quadrant	Right shoulder, scapula	Severe colicky pain	Hemolysis with/without jaundice

CT, computed tomography; KUB, kidney, ureter, and bladder.
Data from Andreoli TE, Carpenter CJ, Plum F, et al. *Cecil Essential of Medicine*. Philadelphia: WB Saunders; 1994:326; Behrman R, Kliegman R. *Nelson Essentials of Pediatrics*. 2nd ed. Philadelphia: WB Saunders; 1994:396.

Location of pain. The location of the pain at its onset and any change in location are very important (Table 10.5; see also Table 10.1). Most intraperitoneal visceral pain is a response to the stimulation of stretch fibers in the bowel wall and is mediated through the spinal nerves. This pain is sensed as a deep, aching periumbilical pain. Pain caused by inflammation of the parietal peritoneum (acute appendicitis) is localized to the area of the inflamed organ or is diffuse if the inflammation is extensive and involves more of the peritoneal cavity. Pain resulting from obstruction of an organ is localized to the area of that organ and radiates to the commonly innervated region (e.g., stones in the ureter cause intense flank pain with radiation into the groin). Pain that is migratory or fleeting in location is rarely suggestive of a problem requiring operative intervention.

Character of pain. The character of the pain is often difficult for the child to describe. Some older children may be able to differentiate cramping, aching, and burning sensations, but most children do not do this well. Children can relate whether the pain comes and goes or is continuous and unrelenting. The character of the pain is usually unknown in the toddler and infant, although the parent can determine whether the discomfort is constant, cramping, or intermittent. If the child intermittently draws the legs up in a flexed position and cries, the clinician can assume that intermittent pain is present.

Child's activity level. The effect of the pain on the child's activities is an important indicator of the severity of the underlying disease. If the pain is sufficiently severe to awaken the child from a sound sleep, it is of much more significance than pain that occurs only at school and never on weekends. If a child has had to avoid a favorite activity, the pain is more apt to have a defined organic cause. This applies only to children with acute abdominal pain because children with chronic functional abdominal pain may wake up from sleep and may miss favorite activities due to pain and disability. Asking whether motion worsens the pain helps differentiate peritoneal irritation or musculoskeletal diseases from more nonspecific problems. The child with acute appendicitis lies motionless, whereas the child with a renal stone, gallstone, gastroenteritis, or pancreatitis may toss and turn and writhe in discomfort. Localized, superficial, tender trigger points in the

Peptic ulcer disease	Mesenteric adenitis
Sickle cell anemia: vasoocclusive crisis	Urinary tract infection
Pancreatitis	Muscle strain (exercise, coughing)
Pneumonia (lower lobe)	DKA
Abdominal tumors	Testicular torsion
Pyelonephritis/cystitis	Idiopathic*
Testicular torsion	
Torsed cryptorchid testis	

*Most commonly seen problem.
†Gastroenteritis indicates intestinal infection with viral, bacterial, protozoal, or parasitic agents. Giardiasis and cryptosporidiosis are particularly common and may produce acute or chronic pain.
DKA, diabetic ketoacidosis.

abdominal wall may suggest abdominal wall (muscle, cutaneous) pain. The localized pain results from entrapment of cutaneous terminal branches of intercostal nerves (7th-12th) penetrating the rectus abdominis muscle and can easily be missed without the proper history or exam.

Gastrointestinal symptoms. The presence or absence of gastrointestinal symptoms may differentiate intestinal problems (acute appendicitis, gastroenteritis, acute cholecystitis) from those arising from other intraabdominal organs (urinary tract infection, ovarian disease, abdominal wall pain).

Anorexia and nausea are difficult symptoms for a small child to describe. Often, if simply asked whether he or she is hungry, a child will respond in the affirmative. Questions about recent food intake, normal eating habits, the last normal meal, and the current desirability of a favorite food often provide more accurate information about the

Testicular torsion	

presence or absence of anorexia and nausea than do direct questions about appetite or nausea.

Vomiting associated with acute pain is usually related to intestinal disease, such as ileus, gastroenteritis, or acute problems of the gastrointestinal tract that warrant surgery. However, vomiting may occur as a response to severe non-intestinal pain such as in testicular torsion;

this vomiting is usually not recurring and is not a prominent feature. Vomiting may be a sign of increased intracranial pressure, which may or may not be accompanied by associated headache or vital sign changes (bradycardia, hypertension, irregular respirations), a bulging fontanel, an altered level of consciousness, or neurologic findings (3rd or 6th cranial nerve palsies). Care should be taken to determine whether the pain occurs before or after the onset of the vomiting. With acute surgical lesions (those caused by intestinal obstruction, acute appendicitis, acute cholecystitis), the pain usually occurs before or during the vomiting. If the vomiting occurred before the onset of pain, the clinician should suspect gastroenteritis or another nonspecific problem. The appearance of the vomited material is also important. Feculent or dark-green material suggests intestinal obstruction. Dark brown or frankly bloody material indicates gastritis, prolapse gastropathy, or peptic ulcer disease as the source of pain.

Diarrhea occurs commonly in intestinal diseases of viral, parasitic, or bacterial origin. The stool volume is large, and defecation is usually preceded by cramping pain that is alleviated by the passage of the diarrheal stool. Diarrhea may also occur in the presence of acute appendicitis or other pelvic infections (such as those resulting from pelvic inflammatory disease, tubo-ovarian abscess); in these cases, diarrhea is caused by inflammation and irritation of an area of colon adjacent to an inflammatory mass. The diarrhea in this instance is of small volume and is frequent. It is important to obtain an estimate of the volume and consistency of stool. Diarrhea may also occur in lesions that cause partial obstruction of the bowel, such as strictures, adhesions, and Hirschsprung disease. In this situation, the patient also has some degree of abdominal distention. **Constipation** alone can cause acute abdominal pain and may also indicate other gastrointestinal dysfunction. Some constipated children present with a picture very similar to that seen in acute appendicitis but have a large amount of stool filling the entire colon. It is therefore important to obtain a good history of not only bowel movement frequency but also consistency as well (see Chapter 16). The history and exam is sufficient to make the diagnosis of constipation, and imaging is usually not necessary. Once the diagnosis is made, appropriate treatment should start with a proper clean-out followed by maintenance therapy. The clinician should not be fooled by the symptom of tenesmus, where the patient has a feeling of constantly needing to pass stools despite having an

Ureteral colic (stones) radiates to testis, upper leg or groin
Pancreatitis radiates to back

empty colon. Tenesmus can be seen in the setting of proctocolitis or inflammatory bowel disease and is often misinterpreted by the patient as constipation.

Associated symptoms. The presence of headache, sore throat, and other generalized aches and pains moves the examiner away from a diagnosis of an acute problem warranting surgery and strongly suggests a viral flu-like illness. Asking the child to point to the area of worst pain sometimes results in the child pointing to the head or throat. The examiner must be careful to remember the whole child and not to focus on the abdomen just because that is the area of the presenting complaint. Many systemic diseases directly or indirectly produce abdominal pain and must be considered in the differential diagnosis (Table 10.6).

Family history and personal medical history. Viral gastroenteritis, other viral syndromes, and food poisoning may affect the patient's family or schoolmates; it is important to ask about other family members, classmates, or playmates who have recently had similar symptoms. Certain systemic and inherited diseases, such as sickle cell anemia, diabetes mellitus, celiac disease, spherocytosis, familial Mediterranean fever, and porphyria, are associated with episodes of abdominal pain. A strong family history of migraine headaches in a child with several previous episodes of intense abdominal pain that have resolved, who presents with a new "attack," suggests the possibility of abdominal migraine. The family must be asked about familial diseases and any previous episodes of pain in the child. Previous intraabdominal operations may result in adhesions that can cause pain, intestinal obstruction, or both. A history of previous intraabdominal surgeries suggests the possibility of bowel obstruction. Some specific medical illnesses result in identifiable or predictable causes of abdominal pain (Table 10.7).

◆ Physical Examination

The physical examination begins when the clinician enters the room and observes the child's activity and demeanor while obtaining the history. Does the child appear ill? Is the patient lethargic, rolling about in discomfort, alert but lying very still, or bouncing all over the room? Each of these activities conveys a message. The listless, lethargic child may be in shock, dehydrated, and very ill. The child who is crying out

loudly and generally dominating the scene probably does not have a problem that warrants surgery and may have mild pain that is self-resolving. The child who seems only mildly ill but moves with great care, if at all, is assumed to have an inflammatory process until it is proven otherwise.

Physical examination techniques and findings are age dependent. Younger children may have difficulty cooperating because of fear or discomfort. Younger children may be more cooperative if kept on their parent's lap. Older children should be asked to get onto the examination table with as little assistance as possible. If the child does this easily, the probability of an acute intraabdominal inflammatory process is quite low. Outer bulky clothing should be removed to allow good exposure of the abdomen without the child having to feel vulnerable.

The examination must be performed in a relaxed, friendly manner with attention fully focused on the child. An accurate examination depends on the child's trust and cooperation. A conversation with the child about family, friends, pets, school, sports, music, or other specific interests of that child diverts attention (distraction) from the examination and increases cooperation. The examiner should never surprise the child and should never lie. The first surprise or untruth, such as the statement "This won't hurt," destroys any trust that has developed.

Low-grade fever (<38.3°C) is seen in early appendicitis but is also common in many other diseases. The absence of fever does not exclude the diagnosis of acute appendicitis or other problems necessitating surgical intervention. Tachycardia may reflect anxiety or may be caused by dehydration, shock, fever, or pain. Tachypnea suggests a metabolic acidosis (shock, diabetes mellitus, or toxic ingestion), an intrapulmonary process, sepsis, or fever. The vital signs must be viewed in context but may be the first clue to a serious illness.

Examination of the head, neck, chest, and extremities may precede the abdominal examination. In children too young to describe the location of the pain, a careful examination of the ears is important, but can be performed at the end of the examination. Streptococcal pharyngitis or mononucleosis is sometimes accompanied by severe abdominal pain. Affected children will present with fever, appear ill, and have tender cervical adenopathy and an obvious tonsillitis, pharyngitis, or both.

Decreased breath sounds and/or rales in a lower-lung lobe, especially on the right side, may indicate pneumonia. Children with lower lobe bacterial pneumonia present with severe abdominal pain, high fever, tachypnea, and, on occasion, vomiting. This presentation could mimic that of a child with peritonitis; however, the abdominal findings are not consistent with the diagnosis of an acute intraabdominal process, and examination of the lungs should demonstrate the pneumonia.

The abdominal examination should be performed systematically and with the child as comfortable as possible. Before the examiner actually touches the child's abdomen, he or she should observe it, looking for distention, inguinal masses, peristaltic waves, and scars from old injuries or surgical incisions. Inguinal and femoral hernias are often overlooked but a common cause of abdominal pain. Next, the child should be asked to indicate with one finger the point of greatest pain. The point may be a vague circle in the area of the umbilicus, but if the child specifies a defined spot, the examiner should avoid that area until the remainder of the abdomen has been palpated.

Gentleness is essential to successful palpation of the abdomen. The examiner must warm both hands and the stethoscope before touching the patient. The stethoscope is an excellent tool for palpation of the abdomen. Auscultation of the chest can simply be extended to the abdomen, with the examiner assuring the child that the stethoscope did not hurt on the chest. The initial examination of the abdomen with

TABLE 10.6   Systemic Causes of Acute Abdominal Pain

Metabolic, Hematologic	Drugs, Toxins
Acute porphyria	Heavy metal poisoning
Familial Mediterranean fever	Lead
Hereditary angioedema	Arsenic
Sickle cell crisis	Mercury
Leukemia	Mushroom ingestion
Acute hemolytic states	Narcotic withdrawal
Diabetic ketoacidosis	Black widow spider bite
Hemolytic uremic syndrome	
Addison disease	**Infectious, Inflammatory**
Uremia	Acute rheumatic fever
Electrolyte disturbances	Infectious mononucleosis

Brain tumor	Pulmonary embolism
Multiple sclerosis	Functional
Radiculopathy	Aerophagia
Neuropathy	
Herpes zoster	
Dysautonomia (Riley-Day syndrome)	

the stethoscope should be just for listening, with no pressure exerted, so that no discomfort results.

Bowel sounds are usually nonspecific in most children with abdominal pain; however, in certain processes, they are helpful. High-pitched tinkling sounds or rushes are usually associated with an obstructive process. Bowel sounds in gastroenteritis are ordinarily very active and loud but may be normal. Acute appendicitis is accompanied by normal sounds in the early stages, but bowel sounds disappear with diffuse peritonitis.

Watching the child's reaction to the auscultation may be a valuable clue to areas of true tenderness. As the examiner continues to listen over the entire anterior abdomen, the pressure on the head of the stethoscope increases until the examiner is, in fact, palpating with the stethoscope. This often is a much more reliable method of eliciting true tenderness and guarding than is the palpating hand.

Palpation is begun as far away from the area of pain identified by the child as possible. The examiner's hand should be softly placed flat (in parallel) on the child's abdomen. Directing fingers into the abdomen (perpendicular) as a method of palpation is unnecessary and often frightening. The clinician should watch the child's face, not the abdomen, during the palpation. Some children are extremely stoic, and only the slightest grimace betrays the discomfort they are experiencing. Attention is paid during palpation to the presence of masses. The examiner should focus on finding the location of pain and the presence or absence of guarding or rebound tenderness. **Guarding** refers to the voluntary or involuntary (often referred to as rigidity) contraction of the abdominal musculature. Fear of pain, rather than actual pain elicited by palpation, is the most common cause for voluntary guarding while involuntary guarding results from reflexive spasms of the abdominal musculature in the setting of peritoneal irritation. A **rigid** or **board-like** abdomen is the result of involuntary guarding and cannot be overcome by distraction. Voluntary guarding usually starts before the palpation starts and can be overcome by asking the child to take deep breaths, flexing the knees and hips, or by using other distractions appropriate to the child's age and temperament. When encountering tenderness, the examiner should palpate only deeply enough to elicit the complaint of pain and some guarding. There is no need to bring on unnecessary pain by deep palpation.

Rebound pain is an indicator of peritoneal irritation and is elicited during examination of the anterior abdominal wall. It occurs when an

TABLE 10.7   Current or Past Aspects of Medical History That May Suggest Cause of Abdominal Pain

Historical Factor	Cause of Pain
Cystic fibrosis	Pancreatitis, diabetes mellitus, meconium ileus equivalent, appendicitis, intussusception, biliary or urinary stones
Sickle cell anemia	Vasoocclusive crisis, cholelithiasis, hepatitis, hemolytic crisis, renal infarction, splenic sequestration
Diabetes mellitus	Pancreatitis, gastric neuropathy
Cirrhosis, nephrotic syndrome	Primary bacterial peritonitis
SLE, other autoimmune disorders	Vasculitis, pancreatitis, serositis, infarction
Corticosteroids	Gastric ulceration, pancreatitis
NSAID	Ileal perforation, gastric ulceration, renal-papillary necrosis
HIV	Gastroenteritis, hepatitis, pancreatitis, esophagitis, lymphoma
Mononucleosis	Hepatitis, splenic rupture
Henoch-Schönlein purpura	Mucosal hemorrhage, intussusception
Hemolytic uremic syndrome	Colitis
Upper respiratory tract infection	Pneumonia, mesenteric adenitis
Pneumonia	Mesenteric adenitis
Prior surgery	Abscess, adhesions, obstruction, stricture, pancreatitis, ectopic pregnancy
Inborn errors of metabolism, hypertriglyceridemia, hypercalcemia	Pancreatitis
Drugs (valproic acid)	Pancreatitis

HIV, human immunodeficiency virus; NSAID, nonsteroidal antiinflammatory drug; SLE, systemic lupus erythematosus.

FIGURE 10.3 *A,* The obturator sign. Pain occurs when the hip is flexed and rotated. Internal rotation is most likely to cause pain as a result of pelvic or retroperitoneal disease or both. *B,* The psoas sign. The test may be performed passively or actively. The hip is passively extended, thus stretching the psoas muscle *(solid arrow)*. The hip is actively flexed usually against resistance, thus tensing the psoas muscle *(dotted arrow)*. (From Reilly BM. Abdominal pain. In: *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:714.)

inflamed focus within the abdomen is compressed and the pressure is then quickly released, resulting in sudden and sometimes severe pain. The standard method to elicit rebound is to palpate deeply, then suddenly remove the palpating hand. *Although this sign aids in the determination of the presence of an intraperitoneal inflammatory process, it is not necessary to cause extra discomfort or stress, particularly in younger children; it is not recommended.* Peritoneal irritation can also be detected by maneuvers such as asking the child to jump, cough, or tapping the feet while observing for facial signs of discomfort.

Other areas of inflammation can be detected by maneuvers that move muscles adjacent to the inflammation. A positive **Carnett test** occurs when pain is unchanged or increased when the supine patient tenses the abdominal wall by lifting the head and shoulders off the examining table. Carnett sign is a sensitive tool to discriminate *abdominal wall* pain from visceral pain. The psoas sign occurs when elevation and extension of the leg against the pressure of the examiner's hand causes pain. An inflammatory mass, such as an inflamed appendix, a psoas abscess, or a perinephric abscess, in contact with the psoas muscle is the cause of this pain. Likewise, the **obturator sign** is pain with flexion of the thigh at right angles to the trunk and external rotation of the same leg while the patient is in the supine position. This

sign results from contact of an inflammatory mass with the obturator muscle (Fig. 10.3).

The flanks and back must be inspected and palpated. Percussion at the costovertebral angle elicits pain in the presence of renal or perinephric inflammation. Vertebral body and disk disease may be detected by palpitation of the spine. The perineum and genitalia must be inspected and palpated as necessary. External examination of the genitalia in prepubertal girls is adequate. If a more thorough examination or an intravaginal examination is needed in prepubertal girls, it should generally be performed with the patient under anesthesia. In postpubertal girls, a pelvic examination may be valuable, regardless of the patient's sexual activity history.

The need for a **rectal examination** is controversial. If a diagnosis is already obvious, the rectal examination may be deferred. If an imaging study or colonoscopy is planned, a rectal examination may be unnecessary. If constipation is suspected as the cause for pain, rectal examination should be performed but should be the last part of the physical examination and should be performed only once. The child should be relaxed and should be given an honest explanation of the procedure. The examiner should use plenty of lubricant and should perform the rectal examination very gently. If the child strongly resists, it is pointless to perform a forceful examination. This is when the rectal examination may truly be deferred. Lateralizing pain, masses, and the presence and character of stool in the rectum are assessed. The stool should always be tested for blood except in children with gastrostomy or nasogastric tubes since it will invariably be positive and can be misleading.

Clues to an organic and at times more serious cause of abdominal pain are noted in Table 10.8. Furthermore, peritoneal signs, which suggest a "surgical abdomen," most often caused by peritonitis are noted in Table 10.9. In addition, the presence of shock suggests other serious diseases (see Table 10.9).

TABLE 10.8 **Red Flags and Clues to an Organic Cause of Abdominal Pain**
Age <4 years old
Localized pain in nonperiumbilical site
Referred pain
Pain awakes child from sleep
Sudden onset of excruciating pain
Crescendo nature of pain
Sudden worsening of pain
Fever (high fever >39.4°C suggests pneumonia, pyelonephritis, dysentery, cholangitis, more than perforation or abscess)
Jaundice
Distention*
Dysuria
Emesis (especially bilious)
Anorexia
Weight loss
Positive family history (metabolic disorders, peptic ulcer disease)†
Change in urine or stool color (blood, acholic) or frequency
Vaginal discharge
Sexual activity
Delayed sexual development (chronic pain)
Anemia
Elevated erythrocyte sedimentation rate
Specific physical findings (hepatomegaly, absent bowel sounds, adnexal tenderness, involuntary guarding, focal or diffuse tenderness, positive rectal examination results, perianal disease, joint swelling)

*Consider 5 Fs: fat, feces, flatus (aerophagia, obstruction), fluid (ascites, hydronephrosis, cysts), fetus (pregnancy or fetal-like abnormal growth [e.g., tumors]).
†Family history is also positive for dysfunctional pain syndromes (constipation, irritable bowel, dysmenorrhea, and lactase deficiency).

TABLE 10.9 **Peritoneal Signs of a "Surgical Abdomen"**
Severe pain
Patient's eyes anxiously open during examiner's palpation
Patient is motionless
Absent bowel sounds
Extreme tenderness to palpation
Voluntary guarding with gentle palpation
Involuntary guarding: board-like rigidity
Rebound tenderness (do not intentionally elicit)
Pain with movement or cough
If Shock Is Present, Consider:
Severe pancreatitis
Trauma: intraabdominal hemorrhage
Ruptured spleen (trauma, mononucleosis)
Spontaneous bacterial peritonitis
Secondary peritonitis (appendicitis, intussusception, perforated ulcer)
Urosepsis
Associated severe gastrointestinal bleeding
Rupture of fallopian tube from ectopic pregnancy
Pulmonary embolism
Aortic dissection
Volvulus
Child abuse
Addisonian crisis (adrenal insufficiency)

◆ Laboratory Evaluation

After a careful history is obtained and thorough physical examination is performed, the diagnosis or a short list of possible diagnoses should be apparent. Laboratory data are supportive in confirming or ruling out suspected disease.

Complete Blood Cell Count

The hemoglobin and hematocrit levels can reveal anemia caused by acute or chronic blood loss (as with ulcers, inflammatory bowel disease, Meckel diverticula) or the anemia of chronic disease (as with systemic lupus erythematosus, inflammatory bowel disease). The white blood cell count indicates the possibility of infection or blood dyscrasias. In uncomplicated acute appendicitis, the white blood cell count ranges from normal values to as high as 16,000. A very high white blood cell count (>18,000/mm^3) indicates intestinal gangrene, perforation, peritonitis, or abscess formation, but this count may also be high in acute bacterial gastroenteritis, streptococcal diseases, pyelonephritis, pelvic inflammatory disease, hemolytic uremic syndrome, and pneumonia.

The differential cell count may also be helpful. In studies of children with acute appendicitis, 95% had neutrophilia, but only half had leukocytosis in the first 24 hours. If the child's history and physical examination findings are highly suggestive of appendicitis, a normal or mildly elevated white blood cell count should not dissuade the clinician from that diagnosis. However, a striking lymphocytosis may suggest gastroenteritis or a systemic illness. Overreliance on the complete blood count alone can cause delay in reaching the correct diagnosis.

Urinalysis

The urinalysis is an important and useful laboratory test in the evaluation of abdominal pain. The presence of ketones and a high specific gravity suggest poor food intake and dehydration. Large amounts of glucose and ketones in the urine indicate diabetic ketoacidosis. A pregnancy test should be performed on postpubertal girls, regardless of sexual activity history. The presence of both white cells and bacteria indicates a urinary tract infection; either finding alone may not be sufficient for that diagnosis. White blood cells may be present in the urine from irritation caused by an inflammatory mass adjacent to the bladder or ureter; hematuria may be seen with nephrolithiasis.

Other Laboratory Tests

Other laboratory tests, such as measurement of serum electrolytes, amylase, lipase; liver function studies including gamma-glutamyl transpeptidase (GGT); and inflammatory markers (C-reactive protein or sedimentation rate), should be ordered on the basis of the differential diagnosis after a thorough history and physical examination are completed.

◆ Imaging Evaluation

Multitudes of imaging studies are available; none should be obtained until the patient has been examined.

Plain Radiography

Plain radiographs, especially kidney-ureter-bladder (KUB) films, with or without upright lateral views of the chest and abdomen, are routinely obtained in most emergency departments as part of the evaluation of acute abdominal pain. The chest film helps assess the presence of a lower lobe pneumonia, which often causes severe abdominal pain, especially in small children. However, early in the disease, the physical examination may be more helpful. Often, if the KUB-abdominal radiographic study includes the lower lobes, the chest radiographic study can be deferred and performed only if the KUB demonstrates lung abnormalities.

Only approximately 10% of abdominal radiographic studies are positive when they are obtained as part of the routine work-up for abdominal pain. Of those that are limited to patients with serious illness, 46% of the results are positive. Plain abdominal radiographs may be helpful to confirm the presence of intestinal obstruction, pneumatosis intestinalis, renal or biliary tract calculi, calcified fecaliths, or intestinal perforation (pneumoperitoneum–free air). These studies detect bowel distention (air-fluid levels on upright views), calcification, free air, and large masses but are not helpful in detecting most other diseases. If free air or intestinal obstruction is suspected, the abdominal films must include a flat and upright or decubitus view of the abdomen to demonstrate the air-fluid interface.

In **acute appendicitis**, a calcified appendicolith (appendiceal fecalith) may be seen (Fig. 10.4). This finding automatically makes the diagnosis of appendiceal dysfunction and confirms the need for appendectomy. The absence of an appendicolith on KUB does not rule out appendicitis. More often, the noncalcified appendicolith may obstruct the appendix; ultrasonographic or computed tomographic (CT) imaging is necessary to visualize this lesion. If an inflammatory

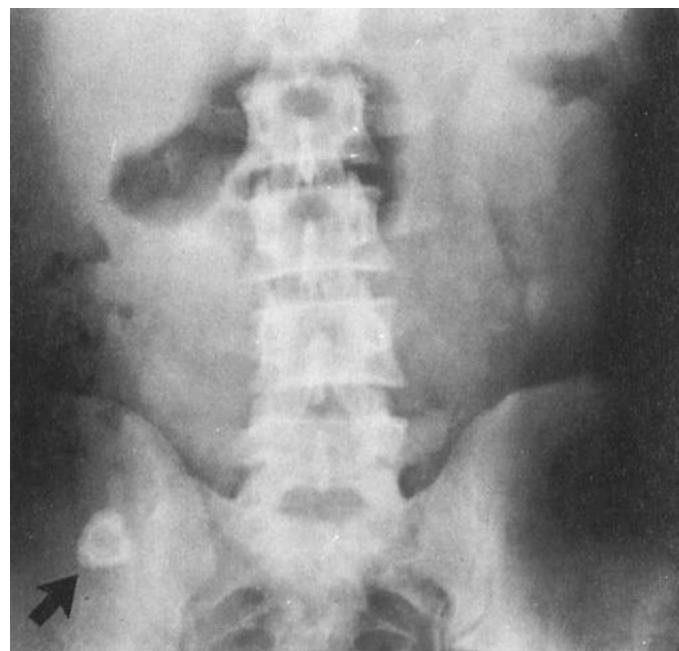

FIGURE 10.4 The patient described the gradual onset of anorexia, nausea, and vague periumbilical abdominal pain. Twenty-four hours later, the pain was much more severe in the right-lower quadrant, where localized peritoneal signs were apparent. The radiographic film of the abdomen reveals a huge calcified density in the right-lower quadrant; it proved to be an appendiceal fecalith at surgery. (From Reilly BM. Abdominal pain. In: *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia, WB Saunders, 1991:16.)

mass lies near the iliopsoas muscle, mild lumbar scoliosis may be present as a result of spasm of the muscle.

Radiographic studies are not always necessary. If the diagnosis is already obvious, specific therapy is indicated. In some situations, other types of imaging studies are more useful, and plain radiographs are not prerequisite.

Ultrasonography

Ultrasonographic examination is ideal for children. It is usually painless, readily available, emits no radiation, requires no intravenous contrast material, and can be performed without sedation. Unfortunately, it is operator dependent and can be difficult to perform in the setting of extreme pain or lack of cooperation. Lower-abdominal **gynecologic pain** in females, especially in adolescent females, can be confused with appendicitis. Pelvic ultrasonography demonstrates pathologic processes of the ovaries and fallopian tubes, the size of the uterus, and the presence of free fluid in the pelvis. An enlarged, inflamed appendix can also be visualized (Fig. 10.5). Any female with abdominal pain in whom the diagnosis is not obvious should undergo an ultrasonographic examination.

Gallstones, a dilated thick-walled gallbladder, or a dilated common bile duct can be visualized by ultrasonography; all 3 support the diagnosis of biliary disease. Edema and enlargement of the pancreas are seen in acute pancreatitis. Ultrasonography also details the character of abdominal masses, differentiating cystic from solid masses, and can be helpful in demonstrating free fluid or abscesses. The anatomy of the urinary tract is well defined by ultrasonography; nephromegaly may be seen with pyelonephritis. The choice of ultrasonography versus CT is dependent on the expertise of the regional imaging center. Abdominal ultrasonography is an excellent screening method for detecting intussusception and midgut volvulus. If an ileus or intestinal obstruction is present, interpretation of the ultrasonographic examination becomes difficult because of the multiple air-filled loops of intestine.

Contrast Studies

In some situations, certain bowel lesions are best delineated with a contrast medium placed in the bowel, either in an upper gastrointestinal series or by enema. If a colonic obstruction is suspected, such as in **Hirschsprung disease**, the appropriate contrast material is a barium enema. However, the sensitivity and specificity of contrast enema for detection of Hirschsprung disease is approximately 70% and 83%, respectively. If the suspicion is high for the disease, the patient should be referred for further evaluation with either suction rectal biopsy or anorectal manometry. If the presence of gastrointestinal perforation is possible, regardless of the etiology, a water-soluble agent should be used instead of barium.

Malrotation of the midgut with a volvulus in infants and older children is often seen on ultrasonography but can be diagnosed by an upper gastrointestinal study. In the infant who presents with an acute abdomen and bilious vomiting and in the older child who manifests chronic abdominal pain and intermittent vomiting, the oral barium contrast study is highly reliable to rule out causes of obstruction such as intestinal malrotation with midgut volvulus or other causes for anatomic obstruction (duodenal web, annular pancreas, superior mesenteric artery syndrome).

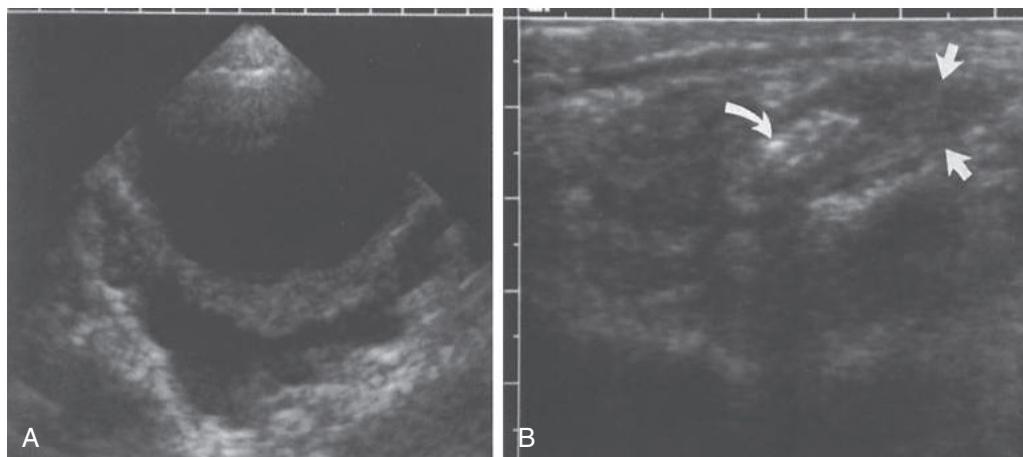
Intussusception is both diagnosed and treated by means of barium enema; however, initial diagnosis is possible with ultrasonography. The sudden onset of severe, diffuse pain, along with the suggestion of a soft, nontender mass in the right upper quadrant of the abdomen in a previously well young child constitute the classical picture of intussusception. Evidence of blood in the stool is usually a late finding and should not be expected early in the disease process. The plain films may be


FIGURE 10.5 A transverse scan of the pelvis shows free fluid pooling behind the bladder *(A)*. The longitudinal scan of the right lower quadrant *(B)* shows a shadowing appendicolith *(curved arrow)* in a thick-walled appendix, typical of appendicitis. *Straight arrows* outline the appendiceal tip, which looks ready to perforate. Free fluid in the pelvis always increases the suspicion of appendicitis. (From Teele R, Share J. Appendicitis and other causes of intraabdominal inflammation. In: *Ultrasonography of Infants and Children.* Philadelphia: WB Saunders; 1991:349.)

nonspecific, may show evidence of intestinal obstruction, or may show a mass in the right upper quadrant. A high index of suspicion is all that is needed to justify the barium enema study; some centers now use air rather than barium. Sedation with morphine is helpful for comforting the child and for performing a useful study. The weight of the barium column often completely reduces the intussusception, eliminating the need for surgical intervention. Brisk reflux of contrast into the terminal ileum signifies a complete reduction. This study should always be performed in consultation with a surgeon and with the child prepared to go to the operating room in case of failure of reduction or perforation of the colon. Successful hydrostatic reduction of the intussusception is accomplished in 50-75% of cases. Contraindications for reduction enemas include perforation and signs of peritonitis. It should be kept in mind that patients beyond the usual age range (3 months-6 years) for intussusception often have an anatomic lead point (polyp, Meckel diverticulum, lymphoma); successful hydrostatic reduction may not be possible in these situations. In the presence of pneumoperitoneum, peritonitis, or unsuccessful hydrostatic reduction, surgical intervention is indicated. Recurrences occur in 5% of patients treated with reduction enemas.

A mass from appendicitis that is pressing against the cecum or thickening of the cecal wall may be seen on the barium enema study, but ultrasonography and CT scanning with oral contrast media are much more reliable.

Computed Tomography

While ultrasound is an important diagnostic tool in the evaluation of acute abdominal pain in children, abdominal CT scan may also be valuable. Clinicians are reluctant to perform a CT scan due to the risk of radiation, especially in young children who are particularly sensitive to the adverse effects of radiation exposure. CT is very useful in the initial evaluation of abdominal trauma and in the determination of the extent of abdominal masses. Intravenous and gastrointestinal contrast must be used in CT of the abdomen to obtain the most information, especially if inflammatory bowel disease is suspected. CT is usually not helpful in the evaluation of chronic abdominal pain in children, and while it may be useful to evaluate a chronic, undefined inflammatory process, MRI has superior accuracy over CT with no radiation risk. Unfortunately, MRI is not always easily accessible on emergency basis and the examination can be time consuming.

◆ Management

The immediate concern in management is the differentiation of serious surgical and medical problems from the more common but less serious causes of acute abdominal pain. A guide to the treatment of the child with acute-onset abdominal pain is noted in Fig. 10.6. A mild, nonspecific illness may be treated on an outpatient basis, with follow-up by telephone or in the office. However, the child with abdominal pain who appears ill without a specific diagnosis may warrant evaluation by a pediatric surgeon. If the diagnosis is still not apparent, the child should be admitted for active observation, which includes no oral food or liquid, appropriate intravenous fluids, hourly vital signs, and frequent examinations. If the abdominal examination is difficult because of poor cooperation, or severe pain, analgesia is appropriate. In the case of appendicitis, morphine therapy does not reduce the diagnostic accuracy by an experienced clinician. Analgesics may permit an adequate abdominal examination but do not eliminate the tenderness caused by an inflammatory process. The examination should be repeated every 2-3 hours. About 10% of children admitted for observation go on to show obvious signs of a process warranting surgery in the first few hours. In approximately 50% of the observed children, a specific nonsurgical diagnosis becomes apparent.

SPECIFIC CAUSES OF ACUTE ABDOMINAL PAIN

Appendicitis

Appendicitis is an acute inflammation of the appendix that may be initiated by luminal obstruction by a fecalith, lymphoid hyperplasia (secondary to viral infections), inflammation, or, in rare cases, parasites (pinworm, *Ascaris* species). Obstruction with ongoing distal secretion of mucus causes distention of the appendix, increased luminal pressure, and subsequent arterial obstruction and ischemia. Mucosal ulceration, fibropurulent serosal exudates, and bacterial infection lead to gangrene from vascular obstruction with subsequent perforation. On occasion, the greater omentum may seal over a ruptured

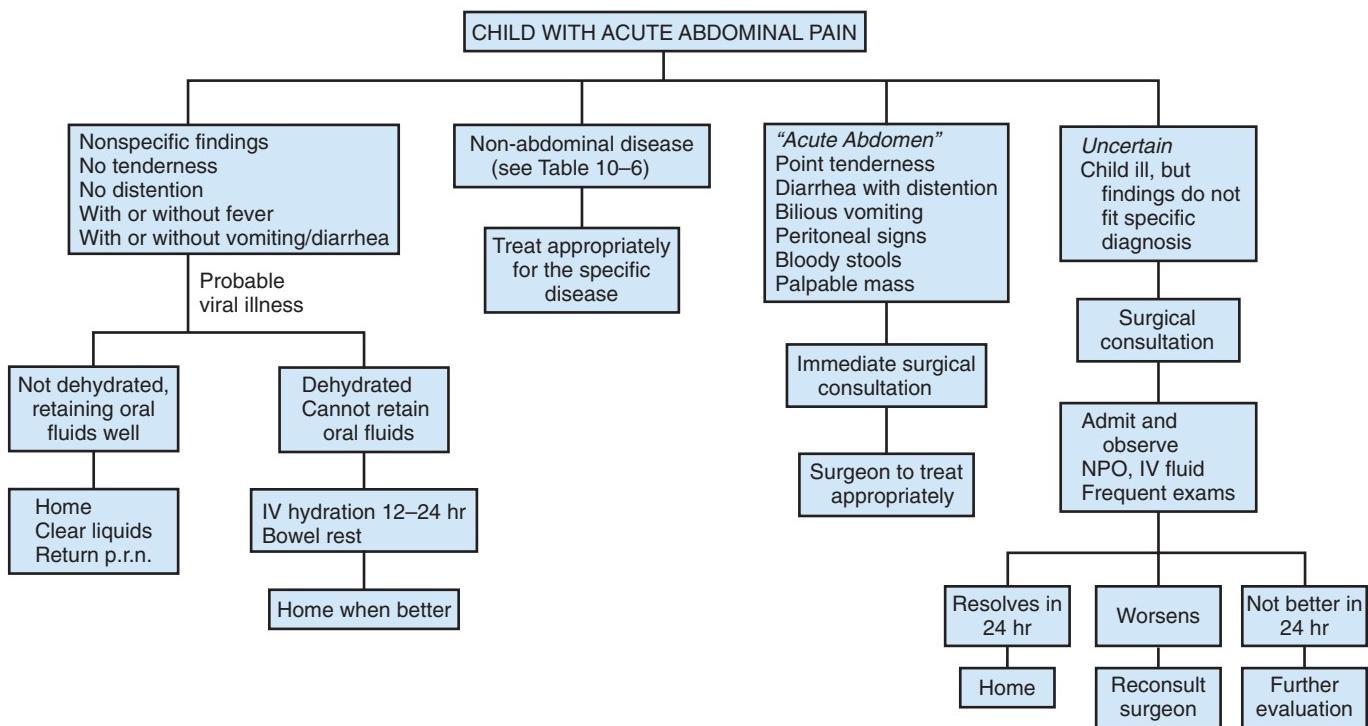
(See *Nelson Textbook of Pediatrics,* p. 1887.)


FIGURE 10.6 Algorithm for evaluating acute abdominal pain. IV, intravenous; NPO, nil per os (no oral intake); p.r.n., as needed.

appendix, producing a right lower quadrant mass and periappendiceal abscess.

Appendicitis may be simple (focal inflammation, no serosal exudate), suppurative (obstructed, inflamed, edematous, increased local peritoneal fluid with omental and mesenteric containment, or walled off), gangrenous (similar to suppurative, plus gray-green or red-black areas of gangrene, with or without microperforations, and purulent peritoneal fluid), ruptured (gross perforation, usually on antimesenteric side; peritonitis present), or abscessed (development of pus from rupture into right ileal fossa, lateral to cecum or retrocecal, subcecal, or pelvic). The bacteriologic components of appendicitis include normal intestinal flora, such as enterococci, *Escherichia coli*, *Pseudomonas* species, *Klebsiella* species, and anaerobic bacteria, such as *Clostridium* and *Bacteroides* species.

Appendicitis affects approximately 60,000 children each year in the United States; it primarily affects adolescents and young adults but may develop at any age, even in neonates. The disease is particularly severe in very young children, often because of a delay in diagnosis with subsequent perforation. Appendicitis in young children is difficult to diagnose because of atypical manifestations and the clinician's inability to obtain an accurate history. The thinness of the appendix and the paucity of the omentum in younger children may result in rapid, unimpeded spread of intraabdominal infection after rupture.

Diagnosis

An accurate and early diagnosis is critical for avoiding perforation and peritonitis and for excluding other causes of abdominal pain. Appendicitis usually manifests initially with a gradual onset of periumbilical (occasionally epigastric) pain, which may begin as a dull ache but becomes constant (or, less often, colicky) and of mild to moderate intensity. This is then followed by anorexia, nausea, and sometimes emesis. Emesis preceding the pain is more typical of gastroenteritis. On occasion, an inflamed appendix irritates the colon, producing

diarrhea. Furthermore, the appendix may irritate the bladder, causing urinary frequency and dysuria. Pain may transiently stop, but as local peritonitis develops, the pain will continue but shift to the right lower quadrant. The shifting of pain from the periumbilical area to the right lower quadrant area may take 12-36 hours but usually occurs in 2-8 hours and may not yet be evident in an acute onset of less than 4-6 hours. McBurney point corresponds to the location of the base of the appendix and is found by placing the little finger of one hand in the umbilicus and the thumb on the anterior superior ileal spine. The index finger, if extended perpendicularly to the abdominal wall, identifies McBurney point. Unfortunately, the appendix is not always in its classic position; thus, appendicitis may produce pain in the pelvis, in the retrocecal area (back or flank pain, psoas muscle spasm with limp), or elsewhere (Fig. 10.7). With these locations, the psoas or obturator sign may be positive (see Fig. 10.3).

Patients with unperforated appendicitis may present with a low-grade fever (<38.5°C) and display very characteristic behaviors. They can be anxious while watching where examiners place his/her hands, be motionless, walk slowly, get on the examining table with difficulty, or exhibit a nondistended but tender abdomen with voluntary guarding, reduced bowel sounds, and point tenderness in any area overlying the appendix. Rectal examination may reveal right-sided or diffuse tenderness and a mass.

Perforation or extensive gangrene should be suspected in the presence of progression for more than 36-48 hours; high fever; diffuse abdominal pain and tenderness; a rigid, board-like abdomen; leukocytosis; a right lower quadrant mass; and other signs of generalized peritonitis (see Table 10.9).

Laboratory and Radiographic Testing

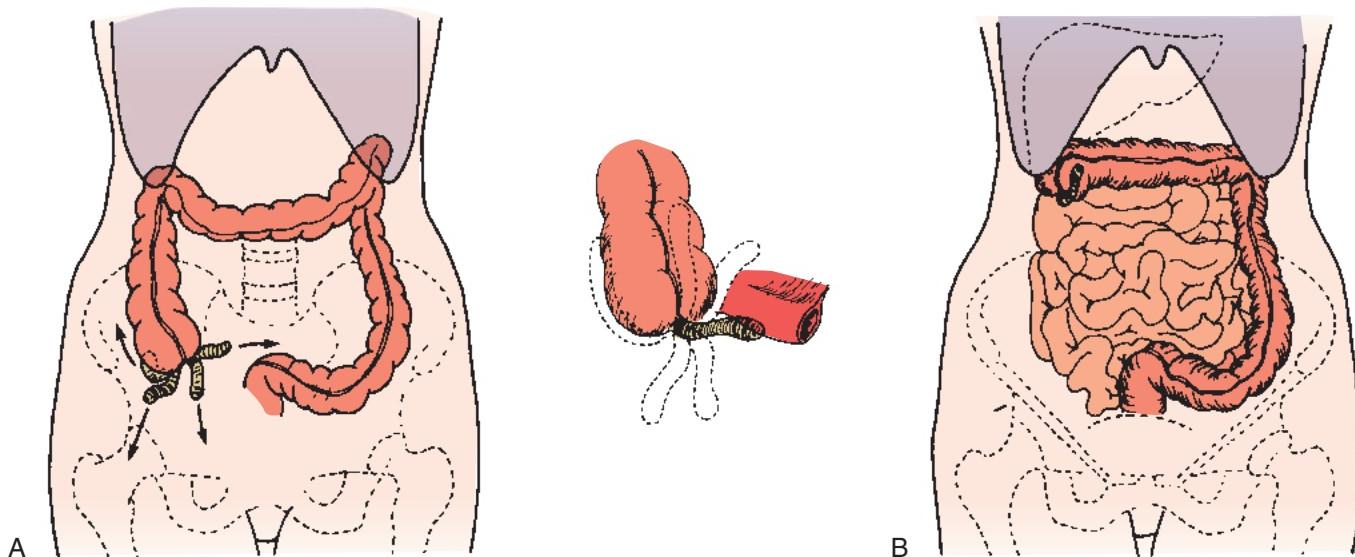
Ultrasonography has been of benefit in the diagnosis of appendicitis and in excluding other important disease processes (Table 10.10). Helpful ultrasonographic features suggestive of appendicitis include a


FIGURE 10.7 The appendix. *A,* The appendix may be located anteriorly, medially, or retrocecally or in the pelvis. *B,* The location of the appendix depends on the location of the cecum. Because the bowel may be quite mobile in some patients, the appendix may be located in many different sites in the abdomen. In this figure, the appendix is in the right upper quadrant. (From Reilly BM. Abdominal pain. In: *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:728.)

TABLE 10.10 Final Diagnoses in Cases of Clinically Suspected Appendicitis

Appendicitis	Perforated peptic ulcer
Gastroenteritis	Urinary tract infection
Pelvic inflammatory disease	Meckel diverticulitis
Ovarian cyst: torsion	Pancreatitis
Ectopic pregnancy	Primary peritonitis
Mesenteric adenitis	Cholecystitis

noncompressible appendix, an inability to visualize the appendix when ruptured, the presence of periappendiceal fluid, or the presence of an appendicolith (Figs. 10.8 and 10.9). Ultrasonography helps define other disease processes, such as mesenteric adenitis (Fig. 10.10) and gynecologic processes. These conditions must be considered in all female patients. Ectopic pregnancy is a particularly serious condition that must not be missed (Fig. 10.11). Gastroenteritis is one of the more common conditions to be considered in the differential diagnosis (Table 10.11).

Treatment

Appendicitis is treated by surgical appendectomy and ligation of the stump by open or laparoscopic methods. If an abscess is present in the right lower quadrant and the patient demonstrates few signs of toxicity, elective nonurgent appendectomy may be delayed to permit preoperative rehydration and broad-spectrum antibiotic therapy. If the appendix is not perforated, some centers treat with only broad-spectrum antibiotics. In operative appendicitis, parenteral antibiotics are given before surgery and are continued postoperatively only in the presence of frank contamination, such as gangrenous or perforated appendicitis. The duration of antibiotic therapy is determined by the presence of infectious complications. If the appendix appears normal, other intraabdominal sources of pain should be sought during the surgery.

Complications of appendicitis are uncommon but include sepsis, intraabdominal abscess formation, wound infections, hepatic abscesses, ileus, and peritoneal adhesion formation. There is subsequent risk for intestinal obstruction and tubal infertility in females.

Pancreatitis

Pancreatitis is an acute inflammatory condition of the pancreas and is often a result of obstruction of the pancreatic duct. Release and activation of pancreatic digestive enzymes subsequently result in extensive destruction (autodigestion) and necrosis of pancreatic and, if severe, adjacent tissue. Proteolysis, fat necrosis, and hemorrhage are noted in severe or fatal cases of pancreatitis, which is often complicated by multiorgan dysfunction syndrome (e.g., hypotension, acute respiratory distress syndrome, acute kidney injury, cardiogenic shock). Pancreatitis is less common in children than in adults, in whom the cause is often alcohol ingestion or gallstones. The etiologic factors in childhood encompass a broad differential diagnosis and often include passage of biliary stones, drugs (valproate), multisystem diseases (hemolytic uremic syndrome, cystic fibrosis), trauma (including child abuse), biliary or pancreatic anatomic anomalies, infections, and metabolic conditions (hypercalcemia, hypertriglyceridemia) (Table 10.12).

Manifestations

Manifestations of acute pancreatitis include intense epigastric abdominal pain that may be described as steady, boring, constant, achelike, knifelike, and exacerbated by recumbency, that radiates to the back, upper abdominal quadrants, or the scapula. Emesis is common, often protracted, and occasionally bilious. Fever is usually low to moderate grade; high fever (>39°C) suggests the presence of a primary infectious process with or without secondary pancreatitis or bacterial superinfection and pancreatic abscess formation. The patient often assumes a hunched-over or knee-chest lateral fetal posture and may manifest epigastric tenderness; bowel sounds may be reduced or absent. Signs of peritonitis suggest more extensive necrosis, as do signs of spreading hemorrhage, such as blue-green discoloration of the flanks (Grey Turner sign) or of the periumbilical region (Cullen sign). Intravascular

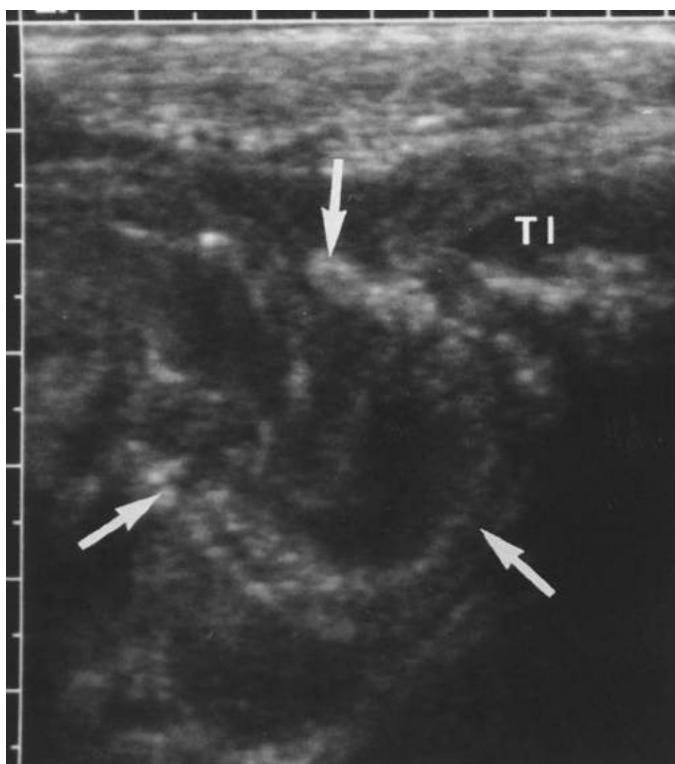
(See *Nelson Textbook of Pediatrics,* p. 1913.)


FIGURE 10.8 An ultrasound scan of the right lower quadrant in a 6-year-old girl, demonstrating a thick-walled cecum *(arrows)* outlined by echogenic fluid. No appendix was found in spite of careful ultrasonographic searching. During surgery, the patient was found to have a perforated appendix and early periappendiceal abscess. TI, terminal ileum. (From Teele R, Share J. Appendicitis and other causes of intraabdominal inflammation. In: *Ultrasonography of Infants and Children*. Philadelphia: WB Saunders; 1991.)

fluid depletion, cardiogenic shock, hemorrhagic shock, hypocalcemic tetany, or systemic inflammatory response syndrome with multiorgan system failure may ensue. Pain may last for 3-10 days.

The diagnosis is confirmed by an elevated serum amylase and/or lipase level (lipase levels may be elevated initially with normal amylase values). The differential diagnosis of hyperamylasemia is seen in Table 10.13. Ultrasonography and CT scan are helpful in identifying the acutely inflamed pancreas (Fig. 10.12), the degree of necrosis, and the later development of a pancreatic pseudocyst (Fig. 10.13).

Adverse prognostic factors in severe acute pancreatitis include the presence of leukocytosis (white blood count >16,000/mm^3), hyperglycemia (glucose level >200 mg/dL), a high lactic dehydrogenase level (>350 U/L), and a high aspartate aminotransferase level (>250 U/L) on admission and a decrease in hematocrit value (>10%), an increase in blood urea nitrogen level (>5 mg/dL), a low calcium level (<8 mg/dL), hypoxia (Pao$_2$ <60 mm Hg), acidosis (base deficit >4 mmol/L), or severe dehydration by 48 hours of hospitalization. The degree of pancreatic necrosis may be determined from the failure of CT scans to depict intravenous contrast parenchymal enhancement; severe pancreatitis is associated with more than 50% necrosis of the gland.

Complications

Complications of pancreatitis include local tissue necrosis with or without superinfection (pancreatic abscess), fistulization (to colon), left-sided pleural effusion, gastrointestinal hemorrhage (ulceration, vascular rupture, splenic rupture), shock, coagulopathy, acute kidney injury, myocardial depression, acute respiratory distress syndrome, hyperglycemia, hypocalcemia, subcutaneous nodules (fat necrosis), hypoalbuminemia, mental changes, and retinopathy.

Management

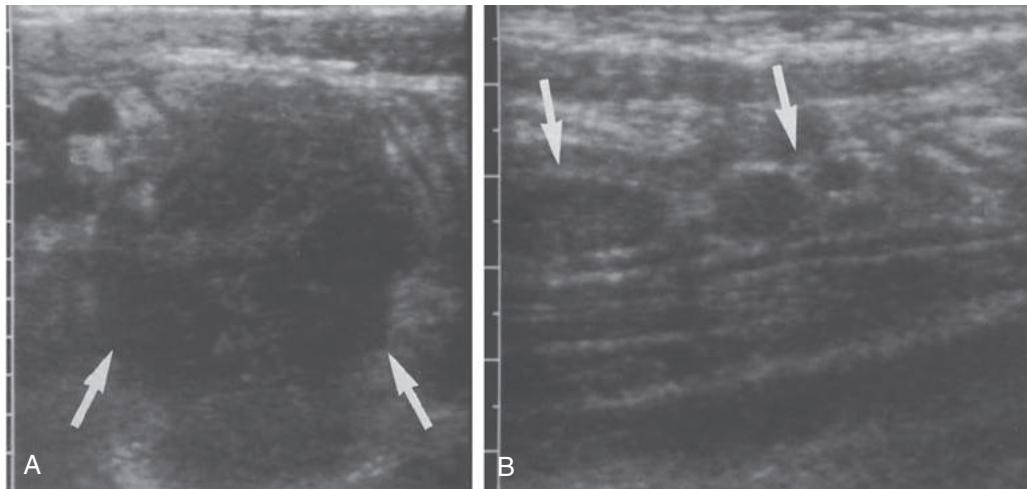
The management of acute pancreatitis consists of supportive care, such as nasogastric tube decompression for patients with an ileus or severe emesis, administration of intravenous fluids, administration of


FIGURE 10.9 An 11-year-old girl presented with fever, diarrhea, and vomiting. Ten days before admission to the hospital, she was seen by a physician because of abdominal pain. She had been partially treated with antibiotics for a presumed "strep throat" in the interim. When she presented to the hospital, she again had pain in the right lower quadrant, especially when the ultrasound transducer was pressed over the area. *A,* The right-lower quadrant abscess *(arrows)* was quickly identified. The appendix could not be visualized. *B,* In scans along the psoas, multiple lymph nodes *(arrows)* were apparent. The child's appendix had ruptured 1 week before admission, but her symptoms had been masked by the antibiotics that she had been given. (From Teele R, Share J. Appendicitis and other causes of intraabdominal inflammation. In: *Ultrasonography of Infants and Children*. Philadelphia: WB Saunders; 1991:348.)

narcotics for pain, and therapy for accompanying complications (e.g., shock, adult respiratory distress syndrome, and acute kidney injury). Endoscopic sphincterotomy by endoscopic retrograde cholangiopancreatography (ERCP) is of benefit if gallstones are present, although ERCP has risks that include the induction of pancreatitis.

Enteral alimentation should be initiated as soon as possible, even with a partial ileus, as early feeds are *not associated* with increased pain, longer hospital course, or elevation in serum lipase. Alimentation may be by oral, nasogastric, or nasojejunal routes.

Additional therapies include prophylactic antibiotics in acute necrotizing pancreatitis. Infected necrotic tissue must be removed surgically; large persistent pseudocysts are managed by CT-guided drainage or surgical drainage.

Cholelithiasis

Gallstones are uncommon in children, but they complicate chronic diseases, such as hemolytic anemia (sickle cell anemia, spherocytosis), cholestatic jaundice in which total parenteral nutrition is given, and other cholestatic diseases. Gallstones may result from prematurity or drug intake (furosemide, ceftriaxone), or they may be idiopathic. Biliary obstruction (stone in cystic or common bile duct) often results in jaundice; sudden onset of severe, sharp right upper quadrant pain; localized deep tenderness in the right upper quadrant (superficial tenderness suggests an associated cholecystitis); and emesis. The pain is episodic and colicky, but often constant, superimposed with waves of more intense pain, and may radiate to the angle of the ipsilateral scapula, back, or other areas of the abdomen or chest. Patients frequently move about to find a comfortable position. There may be associated diaphoresis, pallor, tachycardia, weakness, nausea, and lightheadedness. A round or pear-shaped, tender mass may be palpated in the right upper quadrant of the abdomen if the gallbladder is distended. The pain may be diurnal, with increased intensity at night. Many patients with single or multiple gallstones without obstruction are asymptomatic.

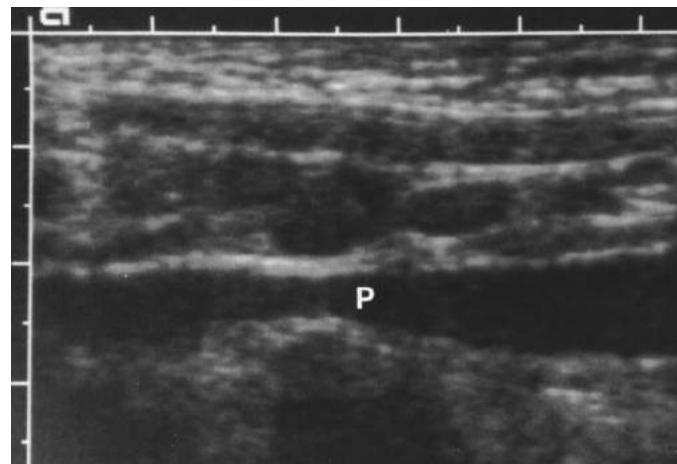
Acute cholecystitis is caused by inflammation of the gallbladder wall as a result of duct obstruction (i.e., calculus) or nonobstructing (i.e., acalculous) conditions and is manifested by fever, mild jaundice, severe abdominal pain, emesis, nausea, and leukocytosis. Pain may be similar to that in cholelithiasis and radiates to the right scapula,


FIGURE 10.10 This longitudinal scan of the right lower quadrant shows lymph nodes arranged in a line along the psoas muscle *(P)*. These are nodes enlarged from mesenteric adenitis. The patient did not have appendicitis. (From Teele R, Share J. Appendicitis and other causes of intraabdominal inflammation. In: *Ultrasonography of Infants and Children.* Philadelphia: WB Saunders; 1991.)
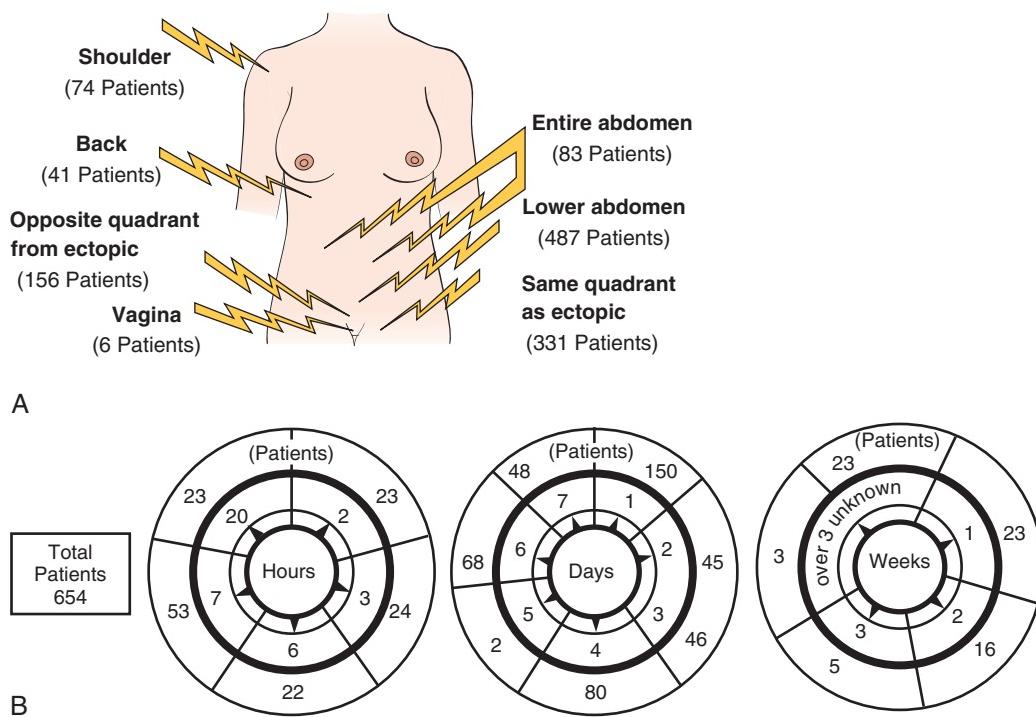

FIGURE 10.11 Ectopic pregnancy. *A,* Anatomic location of pain in 654 patients with ectopic pregnancy. *B,* Duration of abdominal pain before the diagnosis of ectopic pregnancy was confirmed among 654 patients. TABLE 10.11	Comparison of Gastroenteritis and Appendicitis	
	Gastroenteritis	**Appendicitis**
Pain	Diffuse, cramps, intermittent	Periumbilical shifting to RLQ; constant Exacerbated by movement, coughing
Vomiting	With or before pain	Follows pain
Diarrhea	Frequent, large volume	Can occur; small volume (from irritation of bowel); may be watery, too
Fever	Variable	Low grade, goes up with gangrene or perforation
Course	Intermittently improves	Worsens with time
Systemic symptoms	Variable: headache, malaise, myalgia, arthralgia, sore throat	Rare
Physical examination	General: fussy, restless, frequent motion Abdomen: soft, mild, diffuse tenderness, hyperactive bowel sounds	Quiet, discomfort with movement Abdomen: RLQ tenderness, guarding peritoneal signs, with/without rectal tenderness/mass, absent bowel sounds
Laboratory values	WBC count: variable, may be quite high Urine: nonspecific	WBC count: mild elevation, early left shift; becomes high only with gangrene or perforation Urine: may have WBCs and/or RBCs if bladder irritated, ketosis if vomiting is prolonged
Imaging studies	Abdominal films: nonspecific ileus Ultrasonography: not indicated	Abdominal films: often nonspecific, with/without fecalith, with/without loss of psoas definition, with/without scoliosis caused by inflammation in RLQ Ultrasonography: enlarged appendix, peritoneal fluid, RLQ abscess, absent appendix, fecalith

RBC, red blood cell; RLQ, right lower quadrant; WBC, white blood cell.

shoulder, or chest. The Murphy sign is demonstrated by palpating an acutely inflamed gallbladder, which causes the patient to halt respiration and feel the pain. Fever of greater than 39.5°C suggests perforation or gallbladder gangrene, whereas a high direct bilirubin level (>4 mg/dL) suggests a common duct stone. Pain may last for 5-10 days. Passage of stones or microlithiasis (sludge) may also produce acute pancreatitis. Intolerance to fatty foods is, unfortunately, a nonspecific observation.

Diagnosis

The diagnosis is confirmed by ultrasonography that demonstrates acalculous or calculus-induced cholecystitis or acute duct obstruction by a stone (Fig. 10.14).

Treatment

Some treatment of obstructing stones may include endoscopic, open, or laparoscopic cholecystectomy. Some patients may go directly to surgery. However, medical management may include ursodeoxycholic acid for stone dissolution. Meperidine is used for pain relief, and broad-spectrum antibiotics are indicated for cholecystitis or cholangitis.

Peptic Ulcer Disease

Peptic ulceration is becoming recognized in children with increasing frequency. Risk factors for peptic ulcer disease include gastritis, a positive family history of ulcer disease, presence of *Helicobacter pylori*, treatment with nonsteroidal antiinflammatory agents and corticosteroids, cigarette smoking, and severe injury (burns, head injury, shock). Manifestations include pain, gastrointestinal bleeding (melena, hematemesis, anemia), emesis, and, in rare cases, perforation. Nocturnal pain, pain relieved by food, and a family history of peptic ulcer disease are often present in older affected children. The pain is often chronic, recurrent, and located in the epigastrium; tenderness may be localized to the epigastric region, but this is an inconsistent finding.

Acute perforation is uncommon in children but is characterized by sudden worsening of pain or a new abrupt onset of excruciating epigastric pain. There is associated pallor, faintness, weakness, syncope, diaphoresis, and a rigid abdomen. Corticosteroids may mask some of the signs of perforation.

CHRONIC ABDOMINAL PAIN

Recurrent abdominal pain (RAP) in children remains one of the most challenging common conditions treated by pediatricians. Intermittent severe, episodic pain can be frightening to both families and care providers because it may be an indication of serious disease. It has been reported to occur in 10-15% of children between the ages of 4 and 16 years. In only a small minority of patients with RAP, the symptoms can be explained by discernable organic disease. However, the term *RAP* is a descriptive term and should not be used as a diagnosis. RAP may be caused by several different conditions that include, but are not limited to, celiac disease, inflammatory bowel disease, peptic ulcer, biliary tract disease, pancreatitis, or functional pain. Pain pathways can initially be influenced by the presence of pathology such as inflammation or tissue damage that often persists despite the absence of identifiable pathology.

The term **functional abdominal pain** refers to pain that has no anatomic, histologic, or "organic" etiology. This type of pain is the hallmark of functional gastrointestinal disorders (FGIDs) that include irritable bowel syndrome (IBS), functional dyspepsia (FD), functional abdominal pain (FAP), and abdominal migraine (AM). A common feature among patients with functional gastrointestinal disorders is the heightened sensitivity to experimental pain, also known as visceral hyperalgesia. A unifying theory of all functional gastrointestinal disorders is the alteration of the brain-gut axis that can present with clusters of symptoms related to abnormal signals arising from the gastrointestinal tract or abnormal processing of signals in the central nervous

system. Without proper explanation of the term *functional,* most families would not understand the condition since the term is very vague and nondescriptive. Symptoms are physiologic and modifiable by sociocultural and psychologic influences. Functional pain can be triggered or influenced by gastrointestinal infections, food, allergies, as well as stress or physical and sexual abuse. These experiences may have a long-lasting impact on a child and make him or her more susceptible to the development of FGIDs by affecting motility, altered intestinal permeability, or visceral hyperalgesia, which conversely impact the development of altered or maladaptive coping skills later in life. The *functional* nature of this pain does not mean that the pain is imaginary or that it may not interfere with the child's daily activities. Patients with functional abdominal pain experience real pain and should not be considered to be faking it or not experiencing it at all. Psychosocial factors, along with altered gut physiology, ultimately play an important role in the development of several pain-associated FGIDs, including

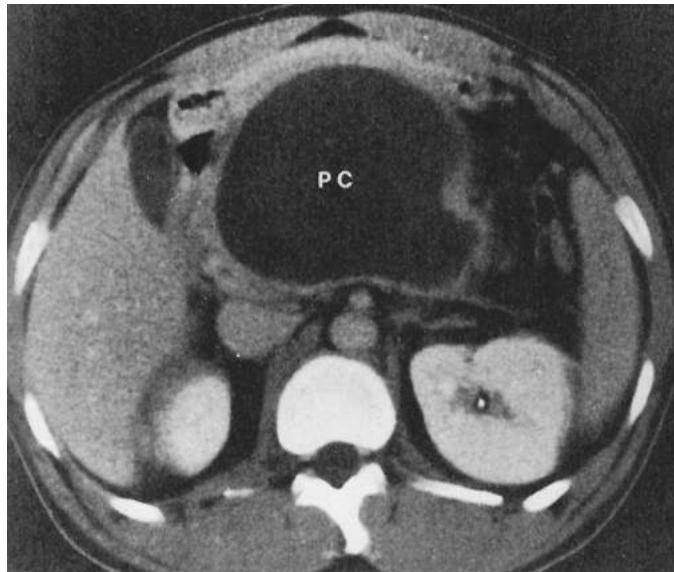
FIGURE 10.12 Acute pancreatitis. Computed tomographic (CT) scan through the body of the pancreas demonstrates a halo of decreased attenuation around the pancreas that represents a peripancreatic zone of edema and fluid *(curved arrows)*. Note the pancreatic ascites, most obvious lateral to the liver *(small arrows)*. If intravenous contrast were administered before the CT scan, the inflamed pancreas would appear more dense (whiter). A, aorta; IVC, inferior vena cava; K, kidney; L, liver; PV, portal vein; S, spleen; ST, stomach. (From Freeny P, Lawson T. In: Putman CE, Ravin CE, eds. *Textbook of Diagnostic Imaging*. Philadelphia: WB Saunders; 1988.)


FIGURE 10.13 Pseudocyst. Follow-up computed tomographic scan (same patient as in Fig. 10.12) 5 months after the episode of acute pancreatitis demonstrates a large pseudocyst (PC). This large pseudocyst will probably not resolve spontaneously and may need drainage. (From Freeny P, Lawson T. In: Putman CE, Ravin CE, eds. *Textbook of Diagnostic Imaging*. Philadelphia: WB Saunders; 1988.)

functional abdominal pain, irritable bowel syndrome, functional dyspepsia, and abdominal migraine. The diagnostic Rome criteria for each of these disorders permit clinicians to make a clinical diagnosis with limited diagnostic testing. Applying the criteria in the clinical setting allows the care provider to validate the reality of the symptoms and develop an appropriate physician-patient relationship aimed at improving symptoms and functioning. All too often, the clinician repeatedly performs unnecessary diagnostic tests to rule out pathology. This often leads to dismissal of the patient's concerns or prevents an effective collaboration in the patient's care that promotes a vicious cycle of symptom anxiety and health-seeking behavior. Applying the Rome criteria along with a proper history and physical examination that includes "red flags" is most of the time sufficient to make a clinical diagnosis of a FGID and to initiate proper treatment.

MAKING A DIAGNOSIS OF FUNCTIONAL ABDOMINAL PAIN

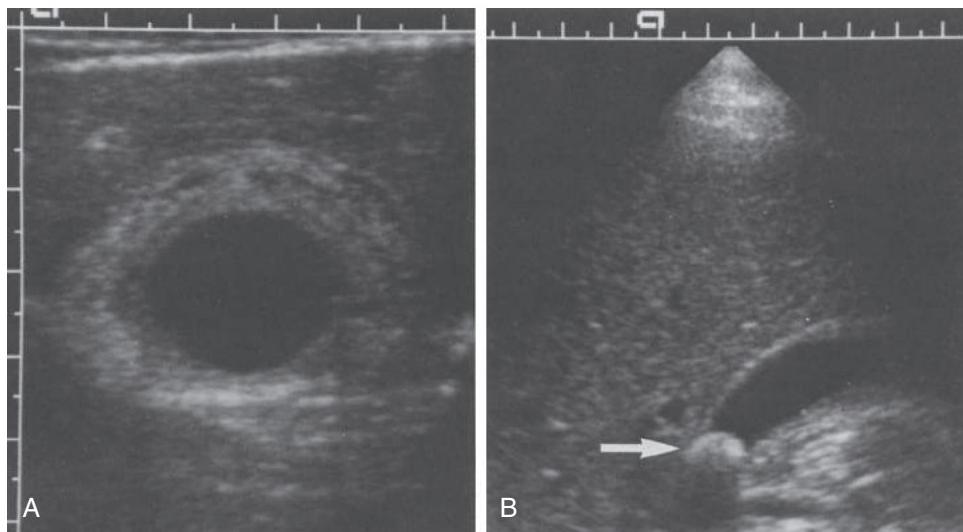
The history should be detailed and, in most instances, obtained separately from the parents and the child. A private conversation with each often provides better insight into all factors affecting the child. In addition to covering the historical information already detailed, the clinician should pay attention to factors in the child's environment, family, school, and social interactions that may be sources of undue stress. Care providers often have difficulty making a positive diagnosis of a functional gastrointestinal disorder, particularly since there are no biologic markers. The diagnostic evaluation of a child with abdominal pain begins with a history to distinguish chronic from acute pain and addressing red flags. The revised **Rome III criteria** for childhood functional abdominal pain are met if the duration of pain exceeds 2 months


FIGURE 10.14 Transverse scan with linear array transducer shows pericholic edema in a teenaged boy, who presented with severe pain in the right upper quadrant from acute cholecystitis *(A)*. A longitudinal scan of the right upper quadrant *(B)* shows a stone *(arrow)* that was thought to be impacted in the neck of the gallbladder because it did not change at all with position. The patient had severe pain with palpation over the gallbladder. (From Teele R, Share J. The liver. In: *Ultrasonography of Infants and Children.* Philadelphia: WB Saunders; 1991.)

(episodic or continuous). Children with pain-associated FGIDs may be subclassified into one of four clinical diagnostic categories that include (1) **functional dyspepsia** (abdominal pain associated with symptoms centered in the upper abdomen), (2) **irritable bowel syndrome** (abdominal pain associated with altered bowel pattern), (3) **functional abdominal pain** (isolated paroxysmal abdominal pain), or (4) **abdominal migraine** (paroxysmal intense pain that can be associated with either pallor, headache, photophobia, nausea, or vomiting). The diagnosis of abdominal migraine is sometimes easier to make since symptoms are episodic and occur abruptly after periods of normal well-being. It is not uncommon to get a history of the child waking up in the middle of the night with pain and vomiting and then having complete resolution of symptoms after 1-2 days. The frequent occurrence or change in location of pain or alternating bowel habits in the same patient, however, is not uncommon. Clinicians do not always feel comfortable simply relying on Rome criteria or are unaware that they exist. Functional pain should be considered when abdominal pain persists a month beyond the usual course of an acute illness (i.e., gastroenteritis). Children often present with intermittent, periumbilical pain that usually waxes and wanes and can often experience other comorbid symptoms, including headaches, joint pain, dizziness, pallor, and diaphoresis. Nausea occurs in as many as 50% of children with pain-associated FGIDs and is a major factor contributing to significant disability.

Severity and Location of Pain

Functional pain can vary in intensity ranging from mild intermittent pain to severe intense pain that disrupts a child's life, family, and school attendance. Excluding organic causes of chronic abdominal pain remains a challenge for pediatricians, particularly given the heterogeneity of FGID symptoms. Although the location of pain does not always help differentiate between functional and organic causes, periumbilical pain has been shown to be most likely associated with functional pain. Substernal pain should raise the suspicion for an esophageal cause, such as erosive esophagitis from gastroesophageal reflux.

Chronic abdominal pain in the presence of dysphagia or history of food impaction should prompt a referral to the specialist to rule out **eosinophilic esophagitis**. Epigastric pain can be caused from pathology in the esophagus, stomach, duodenum, and pancreas or from functional dyspepsia. Pain originating from hepatobiliary structures, including the gallbladder, liver, and head of the pancreas usually is primarily in the right upper quadrant. Certain conditions must be considered in patients who present with chronic pain in the right lower quadrant and these include chronic appendicitis, abdominal wall pain, or Crohn disease. Identifying certain characteristics or "red flags" that can assist the clinician in detecting organic disease in patients with chronic abdominal pain would be important, since it could limit unnecessary diagnostic testing in those with FGID and potentially prevent a delay in the diagnosis a specific organic disease.

◆ Approach to Treatment

Although clinically challenging, with the correct approach, managing the child with functional pain can be very rewarding for both the patient and physician. The first goal is to identify physical and psychologic stress factors that may have an important role in onset, severity, exacerbations, or maintenance of pain. Equally important is to reverse environmental factors that serve as reinforcers of the pain behavior. Parents and the school must work together to support the child. Regular school attendance is extremely important and should be encouraged even in the presence of pain. It is oftentimes helpful for the care provider to communicate directly to school officials to explain the nature of the problem. At home, less attention should be directed toward the symptoms. In the clinic, defining the problem and establishing an effective physician-patient relationship is an important part of therapy. Attention should focus on improvement of daily symptoms and quality of life, as well as the child's return to normal activities. Once the evaluation, including the history, physical examination, and appropriate screening laboratory tests, has been completed, and findings are normal, a search for nonorganic sources of pain should not be continued. Instead, the appropriate treatment should be initiated.

The child with functional pain may improve once the child and the family understand the nature of the pain and a proper explanation is given by the provider. Knowing that there is no serious organic disease and that the sensations are not imaginary is usually welcome information to the family. However, the conversation about functional abdominal pain should be brought up during the first visit and should not be discussed only after doing extensive testing. The family should understand that testing is only to confirm the absence of other disorders and confirm the possibility of functional pain.

There is a spectrum of functional pain in terms of severity. Some patients have minimal severity and frequency of pain while others have daily, unremitting pain that results in school absences, functional disability, and diminished quality of life. The total number of days missed from school is a good indicator of disability and should always be asked during the visit. For those with mild symptoms not interfering with daily activities, simple treatment strategies such as stool softeners for constipation often provide sufficient relief, such that the child can resume a more normal life. Similarly, dietary manipulation with lactose or fructose avoidance is often an important first step in the child with mild, chronic abdominal pain. **Carbohydrate malabsorption** or intolerance from lactose, sorbitol, or high-fructose corn syrup (fruit juices and sodas) may produce pain that responds to dietary elimination of the offending sugar. These simple strategies should not be tried on the child with significant disability and school absences, mainly because they are unlikely to work and time would be lost in trying to get the child back to functioning. The clinician should refrain from talking to patients and family using negative comments such as "you will have to learn to live with this pain." This leads to considerable gloom and hopelessness and will make the condition much more difficult to treat. Sometimes, despite diligent evaluation by the most skilled and patient clinician, symptoms can persist. There are no U.S. Food and Drug Administration–approved drugs for the treatment of chronic abdominal pain in children and little evidence of efficacy for most commonly used medications. It is important to consider that the clinician must spend time educating the family regarding the suspected mechanisms and how and why pharmacotherapy may or may not work. In the more severe, disabled patients, patient education should be considered part of a therapeutic program that includes physical reconditioning, exercise, sleep restoration and in many cases, thought reprocessing. Psychologic therapies such as cognitive behavioral therapy, hypnosis, relaxation, meditation, or biofeedback have been shown to be as effective, and sometimes better than pharmacologic therapy. Families should always be educated on the potential modification, of the "pain behavior" and potential benefits of lifestyle modifications.

A therapeutic trial with medications should be discussed with the family and should have a well-defined duration and goals. Also, the dose should be adequate to achieve the desired effect. If history and physical examination suggest dyspepsia or epigastric pain without red flags, a trial of acid suppression is very appropriate as an initial step. Similarly, if the history and physical examination suggest constipation as the cause for pain, then the proper therapy with osmotic laxatives or cathartics should be initiated. Pharmacologic therapy, including anticonvulsant or antidepressant agents, has not consistently proven to be effective in children with functional abdominal pain. Such therapy has sometimes been effective in young adults but is not recommended for younger children under 8 years of age. Amitriptyline has been used in small doses and anecdotally has been successful in alleviating functional abdominal pain. It is widely used for chronic pain conditions including migraine headaches, fibromyalgia, neuropathic pain and is considered to be effective at much lower doses than those used for depression.

Cyproheptadine is an antagonist of serotonin, histamine H_1, and muscarinic receptors. It has been used to treat allergic rhinitis, migraine headaches, and anecdotally as an appetite stimulant in children. Antispasmodics such as hyoscyamine or dicyclomine can produce significant anticholinergic side effects including dry mouth, dizziness, and blurred vision. Most antispasmodics should be used as adjuvant therapy for the treatment of chronic abdominal pain and only for episodic pain and not as daily treatment.

Small intestinal bacterial overgrowth may be a cause of chronic abdominal pain. Rifaximin has low systemic absorbance and localized effect on intestinal flora and is approved for diarrhea-predominant IBS in adults. In adolescents with functional pain, bloating, and/or diarrhea, empirical treatment with this antibiotic may be considered. Although short-term treatment appears to be well tolerated in adults, multiple treatments with rifaximin may be needed, which increases the concern for antimicrobial resistance.

The dearth of successful treatment options for chronic abdominal pain often results in patients opting for alternative methods. There appears to be a growing desire among patients and families for a more "natural" approach to therapy. It has been suggested that approximately 35% of adult patients with functional bowel disorders use complementary or alternative medicine despite the perceived lack of efficacy by some clinicians.

If the symptoms are mild and not severe enough to interfere with a child's school or daily activities, using alternative therapies for which there are some scientific evidence of benefit may be a good starting point. These include peppermint oil, melatonin, and STW5 (Iberogast). Concentrated peppermint oil is increasingly being used in the treatment of abdominal pain in children. The menthol component of peppermint oil acts as a calcium channel blocker that causes relaxation of intestinal smooth muscle. Peppermint oil, administered in pH-dependent, enteric-coated capsules has been shown to reduce abdominal pain severity over placebo in both adults and children. Melatonin is likely to be effective in less severe patients with functional pain with minimal co-morbidities and has the added benefit of having a low side effect profile. Iberogast is a mixture of nine herbal plant extracts that is being used as an alternative approach for the treatment of functional dyspepsia and IBS. The exact mechanism of this herbal preparation is not known but several trials have suggested that it is effective in alleviating symptoms of FD and IBS. The combination consists of liquid extracts from chamomile flowers, bitter candytuft, angelica root, caraway fruits, milk thistle, lemon balm leaves, greater celandine, licorice root, and peppermint leaves.

RED FLAGS

Red flags or "alarm signals" are critical to investigate in the history and physical exam of abdominal pain. The presence of red flags raises the suspicion of an underlying organic disorder and includes pain localized away from the umbilicus, pain related to menstrual cycle, back pain, multisystem complaints, anorexia, weight loss, evidence of GI bleeding (anemia, hematemesis, melena, hematochezia, rectal bleeding, occult bleeding), profuse diarrhea, extraintestinal symptoms (fever, rash, recurrent aphthous ulcers), and a positive family history of inflammatory bowel disease, celiac disease, or peptic ulcers. Anemia, hematochezia, and weight loss in children with chronic abdominal

pain are predictive of inflammatory bowel disease. Physical findings of linear growth deceleration, localized fullness or mass effect, hepatomegaly, splenomegaly, back or costovertebral angle tenderness, perianal skin tags or fistulas, soiling, or occult blood in stools should be taken seriously and should prevent the diagnosis of a FGID until further work-up is completed. Biochemical analysis that raises suspicion for organic disorders include iron deficiency anemia, high sedimentation rate or C-reactive protein, hypoalbuminemia, and abnormal liver or kidney function tests, or elevated amylase and lipase. A high stool calprotectin level suggests an inflammatory process and should be obtained in the presence of diarrhea. In cases in which recurrent vomiting is a significant part of the history, an upper GI series should be obtained to rule out gastric outlet disorder, malrotation, or partial small bowel obstruction. An abdominal ultrasound should also be considered in order to investigate the possibility of gallstones, pseudocyst, ureteropelvic junction obstruction, or a retroperitoneal mass. Contrast CT scans in the evaluation of chronic functional pain is seldom helpful and should not be ordered unless a specific cause is being investigated.

Diarrhea

Bhaskar Gurram

Diarrhea is defined as a stool volume of greater than 10 g/kg/day in infants and toddlers and greater than 200 g/day in older children. Functionally, diarrhea should be considered if a patient is passing 3 or more unusually loose stools in a 24-hour period or is passing stools more frequently than usual, with a consistency looser than what is considered normal for that individual. Diarrhea is classified broadly by the duration of symptoms. **Acute diarrhea** is usually a self-limited illness that lasts for 2 weeks or less. **Chronic diarrhea** persists for more than 2 weeks. The etiologies of acute and chronic diarrhea differ by age (Table 11.1).

Diarrhea is further classified by pathophysiology, which typically involves 1 or more of the following mechanisms: (1) **osmotic diarrhea**, characterized by the presence of an increased intraluminal osmotic load leading to passive diffusion of fluid into the gastrointestinal lumen; (2) **secretory diarrhea**, characterized by increased secretion of fluid into the gastrointestinal lumen beyond the capacity to be reabsorbed; and (3) altered gastrointestinal tract motility. Differentiating osmotic from secretory diarrhea allows for a more directed diagnostic evaluation (Table 11.2). **Osmotic diarrhea** may be related to the malabsorption of carbohydrate, fat, or protein or to the presence of nonabsorbable substances in the gastrointestinal lumen. The characteristics of the stool may provide information that allows for the identification of the malabsorbed substance, particularly for isolated carbohydrate and fat malabsorption (Table 11.3). **Secretory diarrhea** is characterized by an excess of crypt cell fluid and electrolyte secretion that exceeds the absorptive capabilities of the villi and is classified by the presence or absence of normal villi. **Inflammatory diarrhea** of both infectious and noninfectious etiologies usually involves both osmotic and secretory components. Finally, surgical bowel resection may decrease the surface area available for the resorption of both fluid and solutes, leading to both a secretory and osmotic diarrhea. The causes of diarrhea based on pathophysiology are presented in Table 11.4.

ACUTE DIARRHEA

◆ History

Acute diarrhea in children is most often infectious (Table 11.5), although it may be secondary to noninfectious inflammatory processes, toxins, or medications. The etiology of acute diarrhea is suggested by both the history and characteristics of the stool. Fever or blood in the stool suggests an infectious cause. Watery diarrhea is typical of viral gastroenteritis, as well as some bacterial and parasitic infections. **Dysentery**, characterized by severe diarrhea and the presence of blood and mucus in the stool, suggests bacterial colitis. Vomiting and diarrhea developing within hours of ingesting food suggests exposure to preformed toxins in the food, rather than the acquisition of an enteric pathogen from the food, which is characterized by a predominantly diarrheal illness developing within days of exposure (Fig. 11.1). A recent history of travel suggests **traveler's diarrhea**, more than 80% of which is caused by bacterial species that are endemic to the area of travel, to which the patient has not been previously exposed. Recent travel may also suggest parasitic or helminthic infection. Exposure to health care settings suggests **nosocomial diarrhea**. Patients with a history of immunodeficiency or malnourishment may be more likely to have an infection with atypical or opportunistic organisms or to have a more protracted and severe course. Hematuria or oliguria may suggest **hemolytic uremic syndrome** as a complication of infection with *Escherichia coli* 0157 : H7 or *Shigella.*

◆ Physical Examination

Physical examination should focus on assessing the level of hydration and the need for fluid resuscitation (Table 11.6). The general examination may reveal nonenteric infections that could present with diarrhea, such as otitis media, pneumonia, or sepsis. Abdominal tenderness or masses suggest appendicitis, intussusception, or less commonly, toxic megacolon. Generalized toxicity or shock may occur with hemolytic uremic syndrome or with sepsis, such as from invasive *Salmonella* or staphylococcal toxic shock syndrome.

Viral Diarrhea

Rotavirus infection. Rotavirus is the leading cause of severe diarrhea in infants and young children. The introduction of an effective vaccine has decreased the incidence, with most infections occurring in unvaccinated children under 3 years of age. Transmission is by the fecal-oral route and the incubation period ranges from 1 to 3 days. Patients typically present with the acute onset of fever and vomiting followed 1-2 days later by watery diarrhea. Symptoms generally persist for 3-8 days. In moderate to severe cases, dehydration, electrolyte abnormalities, and acidosis may occur. In immunocompromised children, persistent infection and chronic diarrhea can develop, with persistently positive diagnostic assays. Chronic infection is to be differentiated from postinfectious malabsorption seen in some immunocompetent children, in whom the small intestinal mucosa may require 3-8 weeks to recover its absorptive ability. Diagnosis is confirmed by nucleic acid amplification assays, enzyme immunoassay (EIA), immunochromatography, or latex agglutination assay for group A rotavirus antigen detection in the stool.

Norovirus infection. Norovirus is a single-stranded RNA virus of the *Calciviridae* family and is the leading cause of epidemic outbreaks of acute gastroenteritis, as well as the most common cause of foodborne illness and foodborne disease outbreaks in the United States. Young children have the highest incidence of infection. Transmission is via the fecal-oral route or through contaminated food or water. Norovirus gastroenteritis typically presents with the abrupt onset of vomiting accompanied by watery diarrhea, abdominal cramps, nausea,

TABLE 11.1 Differential Diagnosis of Acute and Chronic Diarrhea by Age

Infants	Children	Adolescents
Acute		
Common

and vomiting. Systemic manifestations, including myalgia, fatigue, and headache may accompany gastrointestinal symptoms. Diagnosis is confirmed by nucleic acid amplification assays that detect viral RNA from the stool.

Bacterial Diarrhea

Most bacterial diarrheal illnesses are foodborne and affect infants and young children more frequently than adults. Bacterial infections of the intestine cause diarrhea via direct invasion of the intestinal mucosa, followed by intraepithelial cell multiplication or invasion of the lamina propria. Cellular invasion may be followed by the production of cytotoxin, which disrupts cell function, and/or the production of enterotoxin, which alters cellular electrolyte and water balance. Bacterial adherence to the mucosal surface may result in flattening of the microvilli and disruption of normal cell functioning. Symptomatic differentiation from viral causes of diarrhea may be difficult, and sequelae of infections are varied (Table 11.7).

Salmonella infection. Nontyphoidal *Salmonella* organisms are estimated to cause 1 million annual gastrointestinal infections in the United States. The attack rate is highest in infancy; the incidence of symptomatic infections is lower in patients older than 6 years. *Salmonella* infection may cause an asymptomatic intestinal carrier state (rare in children), enterocolitis with diarrhea, or bacteremia without gastrointestinal manifestations but with subsequent local infections, such as meningitis or osteomyelitis. *Salmonella* infection is usually spread through contaminated water supplies or food (e.g., meat, chicken, eggs, raw milk, and fresh produce). Most infections in the United States are sporadic rather than epidemic. Although an infected food handler may contaminate food sources, farm animals or pets are often the vector. Cats, turtles, lizards, snakes, and iguanas may also harbor *Salmonella* organisms. Outbreaks may occur among institutionalized children; outbreaks in daycare centers are rare.

After a 12- to 72-hour incubation period, gastroenteritis develops and is characterized by the sudden onset of diarrhea, abdominal cramps and tenderness, and fever. The diarrhea is watery, with stools containing polymorphonuclear leukocytes and, on occasion, blood. The peripheral blood white blood cell count is usually normal.

Symptoms slowly resolve within 3-5 days, although excretion of the organism may persist for several weeks. The organism is readily isolated from culture of the stool or a rectal swab, or may be identified via multiplex polymerase chain reaction (PCR) assays that detect multiple bacterial, viral, and parasitic enteric pathogens.

Shigella infection. Most *Shigella* infections in the United States occur in young children 1-4 years of age, with a peak seasonal incidence in late summer and early autumn. It may also be the most common bacterial cause of diarrhea outbreaks in daycare settings. The organism is transmitted via the fecal-oral route, most often by the hands. During a 12- to 72-hour incubation period, patients may develop a nonspecific prodrome characterized by fever, chills, nausea, and vomiting. A predominantly rectosigmoid colitis develops and results in abdominal cramps and watery diarrhea. In more severe infections (**bacillary dysentery**), blood and mucus are passed in small, very frequent stools. High fever in young infants may induce febrile seizures, and some patients may develop hemolytic uremic syndrome. Bacterial culture of the stool or a rectal swab, or the use of multiplex PCR assays, allows for differentiating this organism from other pathogens. If positive, antibiotic treatment is usually indicated.

Campylobacter infection. Many animal species, including poultry, farm animals, and household pets, serve as reservoirs for *Campylobacter jejuni*. Transmission occurs through ingestion of contaminated food, especially undercooked food, and through person-to-person spread via the fecal-oral route. The disease is common in infants and adolescents, and both daycare and college outbreaks have been reported. Asymptomatic carriage is uncommon. *Campylobacter* infection causes disease that may range from mild diarrhea to frank dysentery. The organism causes diffuse, invasive enteritis that involves the ileum and colon. Fever, cramping, abdominal pain, and bloody diarrhea are characteristic and may mimic symptoms of acute appendicitis or inflammatory bowel disease. Fever and diarrhea usually resolve after 5-7 days; prolonged illness or relapse occasionally occurs. *Campylobacter* infection is also known to cause meningitis, abscesses, pancreatitis, and pneumonia. Guillain-Barré syndrome has been reported after *Campylobacter* infection. Identification is via stool or rectal swab bacterial culture, or via multiplex PCR assay. If positive, antibiotic treatment is indicated.

Yersinia infection. Infection with either *Yersinia enterocolitica* or *Y. pseudotuberculosis* may cause various clinical syndromes, including gastroenteritis, mesenteric adenitis, pseudoappendicitis, and postinfectious reactive arthritis. The organism is present in animals and may be spread to humans by consumption of undercooked meat (especially pork), unpasteurized milk, and other contaminated foods. Person-to-person spread also occurs. Young children are particularly susceptible to disease, and the frequency of infections increases during the summer months.

The organisms may be identified via multiplex PCR assay or may be cultured from rectal swab or stool specimens, but selective media are required, and the organism may not be identified via culture for several weeks. The microbiology laboratory should be notified if

TABLE 11.2 Differentiating Osmotic from Secretory Diarrhea		
	Osmotic	**Secretory**
Stool volume	Small (<200 mL/24 hr)	Large (>200 mL/24 hr)
Response to fasting	Diarrhea improves	Diarrhea continues
Stool sodium	<70	>70
Stool osmotic gap*	>50	<50

TABLE 11.4 Differential Diagnosis of Diarrhea by Pathophysiology

Osmotic Diarrhea

1. Carbohydrate malabsorption
   - Lactose intolerance
   - Osmotic laxatives (lactulose, polyethylene glycol 3350)
   - Antacids (magnesium hydroxide)
   - Ingestion of excessive amounts of non-absorbable sugar or sugar alcohols (sorbitol in chewing gum, diet candy, sucralose)
   - Dietary ingestion of excessive fructose (high-fructose corn syrup, ingestion of high-fructose–containing fruits in excessive amounts)
   - Disaccharidase deficiency (sucrose-isomaltase deficiency, glucose-galactose malabsorption, maltase-glucoamylase deficiency, congenital lactase deficiency)
   - Gastrocolic fistula, jejuno-ileal bypass, short-bowel syndrome
2. Fat malabsorption
   - Pancreatic insufficiency
   - Defective handling of bile acids (e.g., primary bile acid malabsorption, cholestasis)
   - Defective mucosal lipid handling (e.g., intestinal lymphangiectasia, abetalipoproteinemia, chylomicron retention disease)
3. Protein malabsorption
   - Primary enterokinase deficiency
   - Hartnup disease

Secretory Diarrhea

- Normal villous architecture
  - Chloride-losing diarrhea ($Cl^- - HCO_3^-$ exchanger defect)
  - Sodium-losing diarrhea ($Na^+ - H^+$ exchanger defect)
  - Familial diarrhea syndrome (gain-of-function mutation of guanylate cyclase 2C)
  - Neurogenin-3 mutation
- Villous atrophy
  - Microvillous inclusion disease
  - Tufting enteropathy
  - Acrodermatitis enteropathica
  - Trichohepatoenteric syndrome (phenotypic or syndromic diarrhea)
  - Congenital disorders of glycosylation defects

Autoimmune polyglandular syndrome type 1

Neuroendocrine tumors

Inflammatory (Combination of Secretory and Osmotic)

1. Infectious
2. Celiac disease
3. Inflammatory bowel disease
4. Autoimmune enteropathy and infantile-onset inflammatory bowel disease
   - Interleukin-10 and interleukin-10 receptor defects
   - Hyperimmunoglobulin D from mevalonate kinase deficiency presenting as severe neonatal colitis
   - IPEX/IPEX-like syndrome
5. Postinfectious enteropathies
6. Eosinophilic gastroenteritis
7. Idiopathic

Decreased Surface Area for Absorption

1. Short-bowel syndrome

IPEX, Immune dysregulation, polyendocrinopathy, enteropathy, X-linked.

TABLE 11.5 Causes of Acute Gastroenteritis in Children

Viruses
- Noroviruses and other *Calciviridae*

- *Salmonella typhi* and *Salmonella paratyphi*
- *Vibrio cholarae*
- *Aeromonas* species

Protozoa
- *Cryptosporidium*
- *Giardia lamblia*
- *Entamoeba histolytica*

Helminths
- *Strongyloides stercoralis*

Yersinia infection is suspected. Antibiotics are not effective in alleviating symptoms of *Yersinia* enteritis or in shortening the period of bacterial excretion. Patients with extraintestinal infection should receive therapy.

Escherichia coli *infection.* Although *E. coli* comprise the predominant normal flora in the colon, some strains are pathogenic. Diarrhea caused by *E. coli* can be watery, inflammatory, or bloody, depending on the strain involved. These diarrheogenic *E. coli* strains are classified into 5 major groups on the basis of serogrouping or pathogenic mechanisms: (1) enteropathogenic *E. coli* (EPEC), an important cause of diarrhea in infants; (2) enterotoxigenic *E. coli* (ETEC), a cause of diarrhea in infants and a cause of traveler's diarrhea; (3) enteroinvasive *E. coli*, a cause of watery ETEC-like illness or, less commonly, a dysentery-like illness; (4) enterohemorrhagic *E. coli*, a cause of hemorrhagic colitis and hemolytic uremic syndrome (HUS); and (5) enteroaggregative *E. coli*, a cause of persistent diarrhea.

Enteric infections with *E. coli* are acquired via the fecal-oral route. Enterohemorrhagic strains are the only diarrhea-producing *E. coli* strains common in the United States and have been associated with foodborne epidemic outbreaks transmitted in some cases by undercooked meat.

EPEC is a well-established cause of infantile diarrhea, especially in developing countries. Asymptomatic carriage is common. At least 2 separate mechanisms are responsible for diarrhea: adherence to intestinal epithelial cells leading to villous injury and mucosal inflammation, and production of a toxin similar to that of *Shigella* organisms. Chronic infection resulting in failure to thrive may also occur.

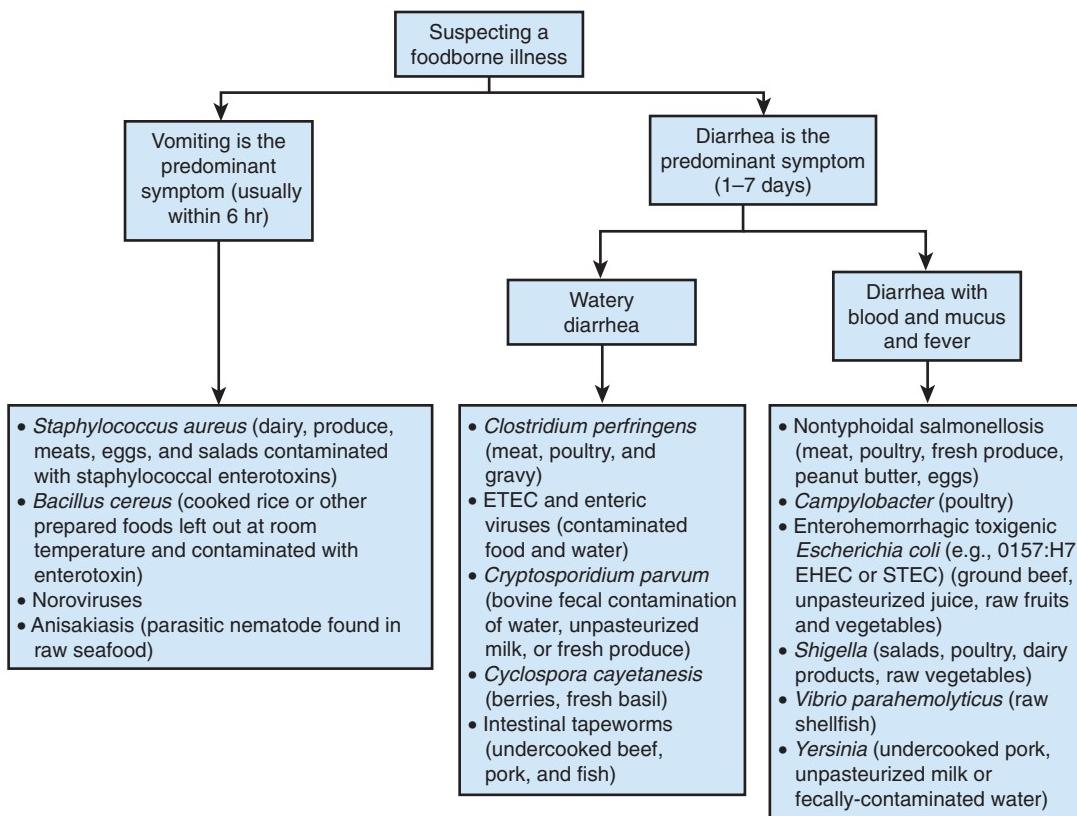
ETEC is the major cause of traveler's diarrhea; occasional nosocomial outbreaks have also occurred in hospitalized infants. At least 3 different types of *E. coli* enterotoxins (heat-labile, heat-stable toxin A, and heat-stable toxin B) have been identified. Definitive diagnosis requires enterotoxin identification, and this method is not widely available.


FIGURE 11.1 Differentiating causes of foodborne illness. EHEC, enterohemorrhagic *E. coli*; ETEC, enterotoxigenic *E. coli*; STEC, Shiga toxin–producing *E. coli*.

TABLE 11.6	**Assessment of Degree of Dehydration**		
Signs and Symptoms **General Appearance**	**Mild**	**Moderate**	**Severe**
Infants/young children	Thirsty; alert; restless	Thirsty; restless or listless	Drowsy or lethargic; limp, cold, sweaty, cyanotic
Older children	Thirsty; alert; restless	Thirsty; alert (usually)	Usually conscious (but at reduced level), apprehensive; cold, sweaty, cyanotic extremities; wrinkled skin on fingers/toes; muscle cramps
Tachycardia	Absent	Present	Present
Palpable pulses	Present	Present (weak)	Decreased
Blood pressure	Normal	Orthostatic hypotension	Hypotension
Cutaneous perfusion	Normal	Normal	Reduced/mottled
Skin turgor	Normal	Slight reduction	Reduced
Fontanel	Normal	Slightly depressed	Sunken
Mucous membranes	Moist	Dry	Very dry
Tears	Present	Present/absent	Absent
Respirations	Normal	Deep, may be rapid	Deep and rapid
Urine output	Normal	Oliguria	Anuria/severe oliguria

From Lewy JE. Nephrology: Fluids and electrolytes. (Modified from World Health Organization Guide.) In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics*. 2nd ed. Philadelphia: WB Saunders; 1994:582.

TABLE 11.7 Complications of Bacterial Enteric Infections

Complication	Important Bacterial Agents	Clinical Considerations
Dehydration	*Vibrio cholerae*, any bacterial enteropathogen	Complication of all forms of acute watery diarrhea; should prompt aggressive fluid and electrolyte replacement
Bacteremia	*Salmonella*, *Campylobacter fetus*	Organisms that deeply penetrate the intestinal mucosa are prone to cause bacteremia; certain high-risk conditions predispose to systemic *Salmonella* infection
Hemolytic uremic syndrome	Shiga toxin–producing *Escherichia coli*, *Campylobacter jejuni*	Shiga toxin is absorbed, causing injury to endothelial cells of the glomerular capillaries with intravascular coagulation
Guillain-Barré syndrome	*Campylobacter*, *Salmonella*, *Shigella flexneri*, *Yersinia*	Most cases occur as a result of molecular mimicry, with antibodies directed to *Campylobacter* lipooligosaccharides and peripheral nerve gangliosides; probability of development of Guillain-Barré syndrome within 2 mo after *Campylobacter* infection estimated at <2/10,000 cases
Reactive arthritis and iritis	Inflammatory bacterial pathogens (e.g., *Campylobacter*) are most important, but most bacterial pathogens can produce the syndrome	Occurs in 2.1/100,000 cases of *Campylobacter* infection and 1.4/100,000 cases of *Salmonella* infection; affected persons may be HLA-B27–positive or HLA-B27–negative
Postinfectious irritable bowel syndrome	*Vibrio cholerae*, any bacterial enteropathogen	Enteric bacterial infection with intestinal inflammation in a susceptible host leads to altered intestinal findings and postinfectious irritable bowel syndrome; duration is ≥5 yr

Enterohemorrhagic *E. coli* produces a **Shiga-like cytotoxin** and causes diarrhea, hemorrhagic colitis, and, in about 20% of infected persons, **hemolytic uremic syndrome (HUS)**. Both epidemic and sporadic cases have been recognized. Infection is more common in the summer and fall. A particular serotype, *E. coli* 0157:H7, has been linked to the development of HUS in young children. The most common manifestations of enterohemorrhagic *E. coli* infection begin with severe abdominal cramps and watery diarrhea, followed by grossly bloody stools and emesis. Fever is uncommon. Fecal leukocytes are absent or few. Other manifestations include asymptomatic infection and watery diarrhea without progression to hemorrhagic colitis. *E. coli* 0157:H7 is cleared from the stool in 5-12 days. If HUS develops, symptoms become noticeable in the week after the onset of diarrhea and consist of renal failure, microangiopathic hemolytic anemia, thrombocytopenia, and diarrhea. There is no role for antimicrobial therapy in enterohemorrhagic *E. coli* disease. Antibiotics neither shorten the duration of disease nor prevent progression to HUS; they may predispose to HUS.

Clostridium difficile *infection.* *Clostridium difficile* causes acute and chronic diarrhea in children when the normal colonic flora is disrupted. **Pseudomembranous colitis** is the most severe form of this infection, occurring as a result of a severe inflammatory response to the *C. difficile* toxins. Transmission occurs through person-to-person contact and through environmental contamination via the spores formed by *C. difficile*, which retain viability for up to 1 week on dry surfaces.

The prevalence of carrier status for *C. difficile* in healthy, asymptomatic outpatients is as high as 50% in healthy infants, but is usually less than 5% in patients over 5 years of age. *C. difficile* and its toxin have been identified in the feces of healthy infants in concentrations similar to those found in adults with pseudomembranous colitis. The apparent resistance of infants to *C. difficile* and its toxin is related to the developmental absence of the toxin-binding site in the immature intestine. Asymptomatic carriage rates in hospitalized patients may be as high as 20%. Infection is highly associated with recent antibiotic exposure, particularly to broad-spectrum antibiotics, which disrupt the endogenous colonic flora that inhibits the growth of *C. difficile*. Other risk factors for *C. difficile* diarrhea include inflammatory bowel

disease, gastrointestinal surgery or procedures, and immunocompromised status.

C. difficile infection should be considered in patients in whom diarrhea develops during or within several weeks of antibiotic therapy. Illness associated with this organism varies from a mild, self-limited, nonbloody diarrhea to severe hemorrhagic colitis, protein-losing enteropathy, toxic megacolon, colonic or cecal perforation, peritonitis, sepsis, shock, and death. In rare cases, manifestations of *C. difficile* infection include fever or abdominal pain without diarrhea.

The colitis is caused by potent toxins produced by the organism: **toxin A**, a lethal enterotoxin that causes hemorrhage and fluid secretion in the intestines; and **toxin B**, a cytotoxin detectable by its cytopathic effects in tissue culture. Both toxins play a role in disease production, although toxin A may be more important.

C. difficile infection is currently diagnosed either by enzyme immunoassay for *toxins* in stool or by nucleic acid amplification tests that identify the microbial *toxin* genes in unformed stool. Sigmoidoscopy or colonoscopy reveals pseudomembranes in 30-50% of cases, typically in association with more severe disease. Treatment is indicated for severe disease.

Aeromonas *infection.* *Aeromonas* species are gram-negative bacilli that are found in a variety of freshwater sources and that are capable of causing a wide array of disease, including a mild, self-limited diarrheal illness in children. Occasionally, *Aeromonas* may cause dysentery or a protracted diarrheal illness. The most common manifestation is a watery, nonbloody, nonmucoid diarrhea seen during the late spring, summer, and early fall. More severe infections may resemble ulcerative colitis, with chronic bloody diarrhea and abdominal pain.

Plesiomonas *infection.* *Plesiomonas shigelloides* is a *Vibrio*-like organism found in soil and water that is sometimes implicated in childhood diarrhea. It has been linked to consumption of raw shellfish or contaminated water, exposure to reptiles and tropical fish, and travel to Mexico and Asia. After an incubation period of 1-2 days, patients typically develop watery diarrhea and vomiting, although some may develop dysentery. Diagnosis is via stool culture. Symptoms may last up to 2 weeks, although the disease is typically self-limited in immunocompetent individuals.

Parasitic Diarrhea

Giardiasis. *Giardia intestinalis* is a flagellated protozoan that can cause diarrhea, malabsorption, abdominal pain, and weight loss. It spreads through contaminated food and water, as well as through person-to-person contact via the fecal-oral route. The latter mode of transmission is responsible for outbreaks of diarrhea in daycare centers and residential facilities. Infection is often asymptomatic. Symptomatic illness usually develops 1-3 weeks after exposure and may mimic acute gastroenteritis with low grade or no fever, nausea, vomiting, and watery diarrhea. In some patients, a chronic illness develops, characterized by intermittent, foul-smelling diarrhea, abdominal bloating, nausea, abdominal pain, and weight loss. Up to 40% of patients may develop secondary lactase deficiency following infection. Diagnosis is via EIA or direct fluorescent antibody (DFA) tests, which offer superior sensitivity and specificity compared to microscopy. If microscopy is performed, three separate samples of fresh stool should be examined for cysts or trophozoites, because excretion of the organism is only intermittent. Treatment is typically indicated in the presence of symptoms, to prevent institutional outbreaks, or to prevent spread to immunocompromised individuals.

Entamoeba histolytica infection. *Entamoeba histolytica* is acquired in warm climates via the ingestion of cysts in fecally contaminated food or water. Infected individuals are often asymptomatic. Amebic dysentery may occur, but hepatic abscess and other remote infections are uncommon. Because cysts are shed in the stool on an intermittent basis, examination of several fecal specimens may be required for identification. Stool antigen detection assays allow for differentiation between *E. histolytica* and the more prevalent though less pathogenic *E. dispar*, which may also be detected on microscopy. Treatment is indicated to prevent the development of extraintestinal manifestations or spread to other individuals.

Cryptosporidium infection. This intracellular protozoan causes watery diarrhea in both immunocompetent and immunocompromised hosts and is an important cause of severe diarrhea in individuals infected with the human immunodeficiency virus. *Cryptosporidium* has also been recognized as an occasional cause of self-limited diarrhea in travelers, as well as in children in daycare centers and persons in residential institutions. The mechanisms by which these organisms cause diarrhea are unknown. Nucleic acid amplification assays and EIA tests are available for diagnosis. Identification via microscopy requires specialized staining techniques that should be requested if *Cryptosporidium* infestation is suspected.

Other Causes of Acute Diarrhea

Parenteral secondary diarrhea. Acute diarrhea that accompanies infections outside of the gastrointestinal tract is termed **parenteral diarrhea**. Upper respiratory tract and urinary tract infections may be associated with increased bowel movement frequency or stool water. The mechanism is unclear but may involve alterations in bowel motility, changes in diet, or the effects of antibiotic treatment.

Medications. Various nonlaxative prescription and over-the-counter medications may cause acute diarrhea (Table 11.8). The most commonly implicated agents are antibiotics, acting through mechanisms other than *C. difficile*.

Food poisoning (Table 11.9; see Fig. 11.1). **Staphylococcal food poisoning** results from ingestion of preformed enterotoxin, produced in contaminated food that has incubated at or above room temperature for a suitable period. Staphylococcal food poisoning is suggested by the sudden onset of vomiting that is followed by explosive diarrhea, usually within 4-6 hours after ingestion of the contaminated food. The illness is self-limited and usually resolves within 12-24 hours. The

TABLE 11.8 Medications and Substances Associated with Diarrhea in Children

Agent	Mechanism
Stimulant laxatives (e.g., senna, bisacodyl)	Increased intestinal secretion (phenolphthalein, bisacodyl)
Antacids	Osmotic effect (Mg^{2+})
Prokinetic agents	Increased peristalsis (metoclopramide, bethanechol, cisapride)
Measles-mumps-rubella vaccine	Unknown
Thyroid hormone	Increased peristalsis
Chemotherapeutics	Intestinal mucosal injury
Heavy metals	Toxic effect
Organophosphates	Cholinergic effects
Diuretics	Unknown
Digitalis	Unknown
Colchicine	Unknown
Indomethacin	Prostaglandin synthesis inhibition
Theophylline	Increased peristalsis

diagnosis is based on the typical historical presentation. Treatment is supportive; antibiotics are not indicated.

Bacillus cereus, a gram-positive sporulating organism found in soil, is usually associated with contamination of refried rice or vegetables. Two food poisoning syndromes can occur. A short incubation period disease (1-6 hours) results from ingestion of preformed toxin and is characterized by nausea, vomiting, and diarrhea, similar to staphylococcal food poisoning. A long incubation period disease (8-16 hours) is caused by in vivo production of an enterotoxin and is characterized by abdominal pain, tenesmus, and profuse watery diarrhea. Vomiting is usually absent. Both syndromes resolve spontaneously within 24 hours and are managed with supportive care.

Clostridium perfringens food poisoning has been associated with ingestion of contaminated beef and poultry. The disease results from the production and release of an enterotoxin into the lower bowel 8-24 hours after ingestion of the vegetative form of the organism. Onset is sudden, with abdominal pain and watery diarrhea. Fever and vomiting are absent. Treatment is supportive.

CHRONIC DIARRHEA

The etiology of chronic diarrhea is dependent on the age of the patient (see Table 11.1) and is additionally influenced by socioeconomic factors and the clinical setting. In developing countries, chronic diarrhea is frequently caused by acute infections, as malnutrition tends to prolong the course of infectious enterocolitis. The most common etiologies of chronic diarrhea in developed countries are functional intestinal disorders, nutrient malabsorption (cystic fibrosis), celiac disease, and inflammatory bowel diseases, but persistent infections of the intestinal tract may also occur.

◆ History

The history should establish the age of onset, as well as the frequency and nature of the stools, including the presence of blood, nighttime stooling, urgency, weight loss, and any associated systemic symptoms. History should also ascertain any recent travel, other sick contacts, or swimming in freshwater sources. A history of recurrent infections, use of intravenous drugs, or other signs, symptoms, or risk factors for

TABLE 11.9 Foodborne Gastrointestinal Illnesses

Cause	Incubation Period	Clinical Clues	Common Vehicle	Diagnosis
Monosodium glutamate	Minutes to 2 hr	Burning in abdomen, chest, extremities, and neck; lightheadedness; chest pain	Found in some Asian cuisines	Large amount of monosodium glutamate in implicated food
Heavy metals (copper, zinc, cadmium, tin)	Minutes to 2 hr	Metallic taste, diarrhea, prominent vomiting, no fever	Carbonated or acidic beverages in metal containers	Chemical study of implicated beverage
Mushroom poisoning*	Minutes to 2 hr	Altered mental status with visual disturbance (encephalopathy)	Noncommercially obtained mushrooms	Identify mushroom and/or toxic chemical (e.g., muscarine, psilocybin)
*Fish/Shellfish-Related Toxins**				
Scombrotoxin poisoning	Minutes to 2 hr	Histamine reaction: flushing, headache, dizziness, burning of throat and mouth	*Scombridae* fish (includes tuna, mackerel, and bonito species), mahi-mahi	Identify fish and/or chemical toxin (ciguatoxin, tetrodotoxin, histamine, etc.)
Paralytic shellfish poisoning	Minutes to 2 hr	Paresthesia, dizziness, sometimes paralysis	Mussels, clams, oysters, scallops contaminated with toxins, typically from dinoflagellate algae species	
Tetrodotoxin poisoning	Minutes to 2 hr	Paresthesia	Various pufferfish and angelfish species. The toxin is produced by symbiotic or infecting bacteria in the fish species	
Ciguatoxin poisoning	2-24 hr	Itching, arthralgias, metallic taste, Paresthesias, cramps, visual disturbances, "Loose" painful teeth	Barracuda, red snapper, grouper, amberjack	
Norovirus	24-48 hr	Epidemic watery diarrhea	Contaminated ice machines, shellfish, ready-to-eat foods	Nucleic acid amplification assays
Staphylococcal enterotoxins	2-8 hr	Prominent vomiting, no fever, duration less than 24 hr	Ham, poultry, pastries (cream-filled), mixed salads, egg salad	Identification of preformed toxin or isolation of 10^5 colony-forming-units of organism from food
Bacillus cereus				
Emetic form: short incubation	2-8 hr	Prominent vomiting, no fever, duration less than 48 hr	Fried rice, macaroni-and-cheese, vegetables, other ready-to-eat foods left at room temperature. Symptoms and rapidity of onset are due to presence of preformed toxin	Identification of preformed toxin or isolation of 10^5 colony-forming-units of organism from food
Diarrheal form: longer incubation	8-14 hr	Abdominal cramps, severe diarrhea, no fever, duration less than 48 hr	Fried rice, macaroni-and-cheese, vegetables, other ready-to-eat foods left at room temperature. Symptoms are due to in vivo toxin production	Identification of preformed toxin or isolation of 10^5 colony-forming-units of organism from food or stool
Clostridium perfringens	8-14 hr	Abdominal cramps, severe diarrhea, no fever, duration less than 48 hr	Meat, poultry, gravy	Identification of preformed toxin or isolation of 10^5 colony-forming-units of organism from food or stool
Enterotoxigenic *Escherichia coli* (ETEC)	12 hr to several days	Abdominal cramps, watery diarrhea may be prolonged up to 7 days	Incomplete data (rarely reported)	Identification of enterotoxin or isolation of organism from stool
Invasive *Escherichia coli*	12 hr to days	Prolonged febrile diarrhea and/or dysentery	Incomplete data (rarely reported)	Isolation of organism from stool
Vibrio cholerae	12 hr to days	Abdominal cramps, watery diarrhea (rice-water stools). May be prolonged up to 1 wk	Contaminated food and water (very rare in United states)	Isolation of organism from food or stool
Vibrio parahemolyticus	12 hr to days	Prolonged febrile diarrhea and/or dysentery	Seafood	Stool culture (or food culture)

TABLE 11.9	Foodborne Gastrointestinal Illnesses—cont'd			
Cause	**Incubation Period**	**Clinical Clues**	**Common Vehicle**	**Diagnosis**
Shigella species	12 hr to days	Prolonged febrile diarrhea and/or dysentery	Fish, mixed salads	Stool culture (or food culture)
Campylobacter species	12 hr to days	Prolonged febrile diarrhea and/or dysentery	Unpasteurized milk, poultry or meat	Stool culture (or food culture)
Clostridium botulinum	12 hr to days	Diarrhea, constipation Guillain-Barré syndrome	Home-canned foods, fish, honey	Botulinum toxin in food, stool, and serum
Yersinia enterocolitica	Uncertain	Prolonged diarrhea and/or dysentery	Milk, pig intestine	Stool culture

*Potentially dangerous; observation in hospital often required.
Modified from Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:888.

immunodeficiency should be documented. Family history should be probed for the presence of gastrointestinal disorders or immunodeficiency.

◆ Physical Examination

Hydration status should be assessed. Growth parameters should be obtained and charted on appropriate age-matched growth charts. The physical examination should assess for signs of malnutrition, vitamin and micronutrient deficiency, and dermatologic manifestations of systemic diseases. Jaundice may suggest hemolysis or hepatic dysfunction. Signs of fat-soluble vitamin deficiency include bone deformities in vitamin D deficiency, dry scaly skin and Bitot spots in vitamin A deficiency, hyporeflexia or gait abnormalities in vitamin E deficiency, and bruises or bleeding in vitamin K deficiency. Joint examination may reveal arthritis associated with inflammatory bowel disease. Abdominal examination may reveal evidence suggestive of neuroendocrine tumors, and perianal examination may reveal evidence of inflammatory bowel disease (fistula, skin tags).

◆ Diagnostic Evaluation

The clinician should attempt to focus the diagnostic evaluation on only those conditions suggested by the history and physical examination. Invasive diagnostic procedures should be limited to those patients whose presentation contains red flags for serious disease (Table 11.10). Laboratory investigation should begin with microbiologic studies for bacteria and parasites in the stool. Acute infection with bacteria, such as *Yersinia*, *E. coli*, and *Salmonella* may develop into a chronic illness and can be detected by routine stool cultures and multiplex PCR assays. *C. difficile* testing should be performed, especially in the presence of risk factors. Antigen detection and PCR-based assays for *Giardia* and *Cryptosporidium* are more sensitive and specific than routine microscopy-based examinations and are indicated if these infections are suspected.

Except in the setting of neonatal-onset diarrhea, stool electrolytes and osmolality are of limited use. The differentiation of osmotic and secretory diarrhea is typically made by a trial of fasting and determining if there is improvement in the stool output: osmotic diarrhea improves or resolves upon fasting, whereas secretory diarrhea does not. **Stool-reducing substances** are positive in the setting of osmotic diarrhea secondary to carbohydrate malabsorption. In patients with osmotic diarrhea and negative reducing substances, it is essential to determine whether steatorrhea is present. If qualitative assays for fecal fat are negative, a more precise indication of steatorrhea may be obtained by quantifying fecal fat and calculating the coefficient of fat absorption, which requires a 72-hour collection of stool. Low fecal

TABLE 11.10 Red Flags in the Evaluation of Diarrhea
Presence of blood in stools
Persistent right upper or right lower quadrant abdominal pain
Involuntary weight loss or growth failure
Delayed puberty
Presence of associated symptoms, such as unexplained fever, suggesting inflammatory arthritides or other systemic diseases
Nocturnal fecal urgency or diarrhea
Perirectal/perianal disease
Persistent dysphagia

elastase suggests pancreatic insufficiency. Elevated levels of **stool alpha-1-antitrypsin (A1AT)** are suggestive of protein-losing enteropathy (PLE). Elevated **fecal calprotectin** or **fecal lactoferrin** are indicative of intestinal inflammation. The presence of fecal leukocytes or occult blood may indicate mucosal inflammation as well, though neither is sufficiently sensitive nor specific.

Blood tests should include a complete blood count to evaluate for anemia and thrombocytosis, which may suggest blood loss and inflammation, respectively. In the presence of anemia, red blood cell indices may reveal a microcytosis potentially indicative of iron deficiency or a macrocytosis suggestive of vitamin B_{12} or folate deficiency. A normocytic anemia may be seen in chronic inflammatory diseases. White blood cell count and differential and quantification of immunoglobulins A, G, and M screen for immune disorders. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) support inflammation but are nonspecific. Low albumin could be indicative of a chronic inflammatory process or PLE. Elevated anti-tissue transglutaminase immunoglobulin A (IgA) antibody is sensitive and specific for celiac disease, but a low total serum IgA level may result in a false-negative test. Levels of the fat-soluble vitamins A, 25-OH vitamin D, vitamin E, and vitamin K (reflected by prothrombin time) may be measured if fat malabsorption is suspected.

The algorithmic approach to evaluating chronic diarrhea is depicted in Fig. 11.2*A* and *B* and is enumerated in Table 11.11.

Disorders of Carbohydrate Malabsorption

The brush border epithelium of the small bowel contains enzymes necessary for carbohydrate digestion. These enzymes hydrolyze disaccharides and oligosaccharides into monosaccharides that are then absorbed by transporters on the luminal surface of enterocytes.

Carbohydrate malabsorption is secondary to either deficiency of a particular enzyme (e.g., congenital sucrase-isomaltase deficiency) or an abnormality in a transport protein involved with the absorption of monosaccharides (e.g., glucose-galactose malabsorption). The onset of various carbohydrate malabsorption syndromes can vary based on the timing of the introduction of particular carbohydrates (Table 11.12).

Patients with carbohydrate malabsorption disorders present with severe watery diarrhea, which results from osmotic action exerted by the malabsorbed carbohydrate in the intestinal lumen. Colonic bacteria ferment the malabsorbed sugars, which generates a mixture of gases (e.g., hydrogen, methane, and carbon dioxide) and short-chain fatty acids. These gases form the basis of carbohydrate-specific breath hydrogen testing, which is often used in diagnosis. The stools become acidified to a pH of less than 7, which can lead to diaper dermatitis.

Disaccharidase Deficiency

Congenital sucrase-isomaltase deficiency (CSID). CSID is an inherited deficiency of the ability to hydrolyze sucrose, maltose,

and starch. Exposure to these products leads to osmotic diarrhea, pain, bloating, abdominal distention, and at times, chronic malnutrition and failure to thrive. The sucrase-isomaltase gene is located on chromosome 3 (3q25.2-q26.2) and more than 25 mutations in the gene have been identified. These mutations result in a variety of defects in the structure and function of the enzyme, including isolated deficiencies in sucrase activity or isomaltase activity. This genetic heterogeneity results in phenotypic variability ranging from completely absent to low-residual sucrase activity, and from completely absent to normal isomaltase activity. Because sucrase-isomaltase is responsible for up to 80% of the maltase activity in the brush border, maltase activity is significantly reduced in almost all cases.

The exact prevalence of CSID is unclear, although rates are as high as 10% in the Greenland Inuit population, 7% in Canadians of native ancestry, and about 3% in Alaskans of native ancestry. Estimates of the prevalence of CSID in other North American and European populations generally range from 1 in 500 to 1 in 2000 among non-Hispanic

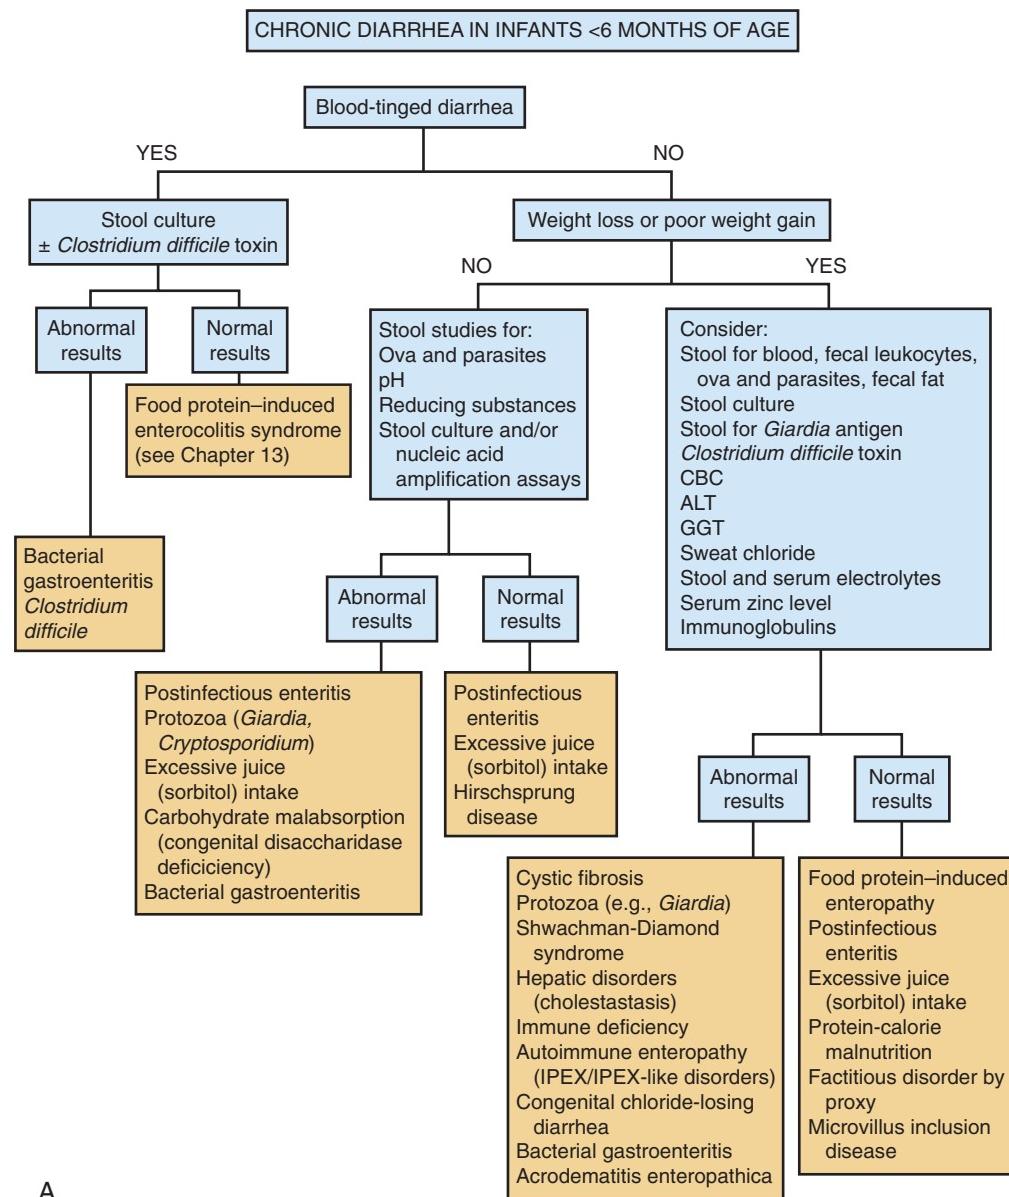

FIGURE 11.2 *A,* The algorithmic approach to chronic diarrhea in infants <6 months of age. ALT, alanine aminotransferase; CBC, complete blood count; GGT, gamma-glutamyl transferase; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked.

CHRONIC DIARRHEA IN INFANTS >6 MONTHS OF AGE (>2 WEEKS' DURATION)

Consider:
Stool for blood, pH, reducing substances, ova and parasites
Giardia antigen
Cryptosporidium antigen
Stool culture
Clostridium difficile toxin

Abnormal results

YES

NO

Weight loss or poor weight gain

YES

NO

Bacterial gastroenteritis
Protozoa (*Giardia*)
Clostridium difficile
Postinfectious enteritis
Disaccharidase deficiencies
Inflammatory bowel disease

Consider:
Stool studies for fecal leukocytes, fat, alpha-1-antitrypsin, and elastase
CBC with differential
ALT
GGT
ESR
CRP
HIV testing
Sweat chloride
Anti-tissue transglutaminase immunoglobulin A
Serum immunoglobulins
Serum zinc level (if rash present)

Excessive juice (sorbitol) intake
Chronic nonspecific diarrhea (toddler's diarrhea)
Postinfectious enteritis
Lactose intolerance
Irritable bowel syndrome
Constipation with overflow incontinence
Laxative abuse
Factitious disorder or factitious disorder by proxy

Postinfectious enteritis
Congenital disaccharidase deficiencies
HIV
Cystic fibrosis
Shwachman-Diamond syndrome
Celiac disease
Immune deficiency
Autoimmune enteropathy (IPEX/IPEX-like disorders)
Food protein–induced enteropathy
Hepatic disorders (cholestastasis)
Inflammatory bowel disease
Acrodematitis enteropathica
Protein-calorie malnutrition
Intestinal telangectasias

B

FIGURE 11.2, cont'd *B,* The algorithmic approach to chronic diarrhea in children >6 months of age. ALT, alanine aminotransferase; CBC, complete blood count; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GGT, gamma-glutamyl transferase; HIV, human immunodeficiency virus; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked. (Modified from Pomeranz AJ, Sabnis S, Busey SL, Kliegman RM, eds. *Pediatric Decision-Making Strategies.* 2 ed. Philadelphia: Elsevier; 2016:87-89.)

whites, with a lower prevalence in African Americans and whites of Hispanic descent.

The classic presentation of CSID is severe watery diarrhea, failure to thrive, irritability, and diaper dermatitis in a 9- to 18-month-old infant who has been exposed to sucrose and starch in the form of fruit juices, fruit purees, and starch-laden foods such as crackers and cookies (see Table 11.4). Intrinsic factors that contribute to the severity of presentation during infancy include the shorter length of the colon and a decreased capacity for colonic reabsorption of fluid and electrolytes, more rapid small intestinal transit, a high carbohydrate diet, and lower levels of amylase prior to 2 years of age. Some patients with milder sucrase deficiency may improve with age as their colonic bacteria

develop an increased capacity to ferment residual sucrose and the intestinal tract develops an increased capacity for reabsorption. Patients may be misdiagnosed as having food allergies or irritable bowel syndrome, or may remain undiagnosed. Symptoms may abate with the restriction of carbohydrate in the diet or with the use of enteral sucrase enzyme supplements.

Diagnosis typically requires endoscopy for histologic examination of small bowel morphology and measurement of disaccharidase levels on biopsy specimens. Diagnosis requires the following:
1. Normal small bowel morphology
2. Absent or markedly reduced sucrase activity
3. Isomaltase activity varying from absent to full activity

TABLE 11.11 Diagnostic Studies in the Evaluation of Chronic Diarrhea

Initial Studies

Stool examination for blood, leukocytes, reducing substances, and *Clostridium difficile* toxin; stool examination for ova and parasites and cultures for infectious bacterial pathogens

Complete blood count

Serum electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, albumin, total protein

Urinalysis and culture

Stool electrolytes

Second-Phase Studies

Sweat chloride test

Breath analysis

D-Xylose test

Serum carotene, folate, vitamin B$_{12}$, and iron levels

Fecal alpha-1-antitrypsin level

Fecal fat studies or coefficient of fat absorption studies

Fatty test meal, Lundh test meal

Third-Phase Studies

Fat-soluble vitamin levels: A, 25-hydroxy D, and E

Contrast radiographic studies: upper gastrointestinal series or barium enema

Small intestinal biopsy for histology and mucosal enzyme determination

Bentiromide excretion test

Specialized Studies

Schilling test

Serum/urine bile acid determination

Endoscopic retrograde pancreatography

Provocative pancreatic secretion testing

TABLE 11.12 Typical Age of Presentation of Carbohydrate Malabsorption Syndromes

Carbohydrate Malabsorption Syndrome	Age of Symptom Onset
Congenital glucose-galactose malabsorption Congenital lactase deficiency	Neonatal period
Sucrase-isomaltase deficiency Glucoamylase deficiency	Weaning age
Primary lactase deficiency	Uncommon before 2 or 3 yr of age Around 5 yr of age in Asians, Hispanics, and African American populations Over 5 yr of age, more typically in adolescence in Caucasians of European decent

4. Reduced maltase activity
5. Normal lactase activity, or in the setting of reduced lactase, a sucrase : lactase ratio of <1.0.

Other less invasive methods of diagnosis include sucrose breath hydrogen quantification and differential urinary disaccharide assessment; however, both of these modalities are associated with high false-positive and false-negative rates. Furthermore, differential urinary disaccharide testing requires a 10-hour urine collection specimen, which is often impractical in infants and younger children.

Maltase-glucoamylase deficiency. Maltase-glucoamylase is a brush border hydrolase that serves as an alternate pathway for starch digestion that complements sucrase-isomaltase activity. Congenital maltase-glucoamylase deficiency is rare, with only several cases described in the literature. Genetically, maltase-glucoamylase shares approximately 59% of its sequence with sucrase-isomaltase, and the enzyme has two catalytic sites that are identical to those of sucrase-isomaltase. Symptoms are similar to those seen in CSID. Diagnosis requires the demonstration of reduced glucoamylase activity in the setting of normal small bowel histology and normal pancreatic amylase activity.

Congenital glucose-galactose malabsorption (CGGM). Congenital glucose-galactose malabsorption results from defective sodium-coupled transport of glucose and galactose into enterocytes. It is a rare autosomal recessive disorder that results from mutations in the sodium-glucose cotransporter gene *SGLT1* located on chromosome 22q12.3. CGGM presents as a neonatal-onset profuse, watery diarrhea that ceases immediately following the elimination of glucose and galactose sources from the diet. Symptoms recur if the patient is fed formula containing either of these carbohydrates, including polymers such as sucrose and lactose. The disorder may lead to dehydration and electrolyte abnormalities, both of which can become life-threatening, and patients may be hypoglycemic. Stool-reducing substances are positive secondary to the presence of glucose in the stools. Intestinal morphology is normal. The diagnosis can be further established by an abnormal glucose breath hydrogen test and *SGLT1* sequencing, although neither is required to confirm the diagnosis.

Congenital lactase deficiency. A rare autosomal recessive disorder leading to very low or complete absence of brush border lactase-phlorizin hydrolase activity, **congenital lactase deficiency** usually presents with diarrhea starting soon after the introduction of breast milk or any lactose-containing formula. Most infants manifest within the first 10 days of life. Unless the disorder is recognized and treated quickly, the condition is life-threatening secondary to dehydration and electrolyte abnormalities. Small bowel biopsies reveal normal histology although low or completely absent lactase concentrations. A presumptive diagnosis can be made if osmotic diarrhea in a neonate resolves by introducing lactose-free formula.

Primary lactase deficiency (lactose intolerance). Approximately 65% of the world's population has primary lactase deficiency, although prevalence varies by ethnicity. While primary lactase deficiency is nearly universal in Asian and Native American populations and is as high as 80% in Hispanic, African American, and Ashkenazi Jewish populations, as few as 2% of individuals of northern European ancestry are affected. Age of onset varies by ethnicity as well. Approximately 20% of Hispanic, Asian, and African American children younger than 5 years of age are affected, whereas white children typically do not develop symptoms of lactose intolerance until after 5 years of age. Children with clinical signs of lactose intolerance at an earlier age than would be typical for their ethnicity may warrant an evaluation for an alternate cause.

Symptoms typically develop insidiously over the course of many years, with most affected individuals experiencing onset of symptoms

in late adolescence or adulthood. Within 30 minutes to 2 hours of ingesting lactose, patients develop abdominal cramping and distention, foul-smelling flatulence, nausea, and diarrhea. While the severity of symptoms is directly correlated with the quantity of ingested lactose, each individual exhibits a unique dose threshold beyond which he or she becomes symptomatic.

Diagnosis is suggested historically. When lactose intolerance is suspected, a trial of a lactose-free diet can assist in confirming the diagnosis. Patients must be sure to eliminate all sources of lactose, including some that may be hidden (Table 11.13). Generally, a 2-week trial of a strict lactose-free diet producing resolution of symptoms, followed by a subsequent reintroduction of dairy foods resulting in recurrence of symptoms is diagnostic. In subtler cases, hydrogen breath testing is the least invasive and most helpful test to diagnose lactose malabsorption.

Secondary lactase deficiency. Secondary lactase deficiency develops when an inflammatory process, such as a viral infection, damages the brush border epithelium and leads to the loss of the lactase-containing epithelial cells from the tips of the villi. The immature epithelial cells that replace these are often lactase deficient, leading to lactose malabsorption. Secondary lactase deficiency in most children with acute gastroenteritis is rarely clinically significant. *Most affected children can safely continue breast milk or standard lactose-containing formula without any significant effects, although infants under 3 months of age may develop clinically significant symptoms.* Giardiasis, cryptosporidiosis, and other parasites that infect the proximal small intestine often lead to lactose malabsorption from direct injury to the epithelial cells by the parasite. Secondary lactase deficiency with clinical signs of lactose intolerance can be seen in celiac disease, Crohn disease, and immune-related and other enteropathies and should be considered if children with these diagnoses have symptoms of lactose intolerance.

TABLE 11.13 Hidden Sources of Lactose

- Bread and other baked goods
- Waffles, pancakes, biscuits, cookies, and the mixes to make them
- Processed breakfast foods such as doughnuts, frozen waffles and pancakes, toaster pastries, and sweet rolls
- Processed breakfast cereals
- Instant potatoes, soups, and breakfast drinks
- Potato chips, corn chips, and other processed snacks
- Processed meats such as bacon, sausage, hot dogs, and lunch meats
- Margarine
- Salad dressings
- Liquid and powdered milk-based meal replacements
- Protein powders and bars
- Candies
- Nondairy liquid and powdered coffee creamers
- Nondairy whipped toppings
- Certain medications

If a food label includes any of the following words, the product contains lactose:
- Milk
- Lactose
- Whey
- Curds
- Milk by-products
- Dry milk solids
- Nonfat dry milk powder

From *National Digestive Diseases Information Clearinghouse*. Lactose intolerance. <http://digestive.niddk.nih.gov/ddiseases/pubs/lactoseintolerance>; 2015.

Diagnostic evaluation should be directed toward these entities when secondary lactase deficiency is suspected and an infectious etiology is not found.

Severe malnutrition can also produce secondary lactose intolerance via small bowel atrophy. Most infants and children with malabsorption attributable to malnutrition are able to continue to tolerate dietary carbohydrates, including lactose. However, the World Health Organization recommends avoidance of lactose in children with persistent postinfectious diarrhea lasting more than 14 days, if they fail a dietary trial of milk or yogurt. Treatment of secondary lactase deficiency and lactose malabsorption attributable to an underlying condition generally does not require elimination of lactose from the diet but, rather, treatment of the underlying condition.

Table 11.14 lists additional important causes of chronic neonatal or infantile diarrhea.

CHRONIC NONSPECIFIC DIARRHEA

Chronic nonspecific diarrhea, also known as **functional** or **toddler's diarrhea**, typically affects children between 1 and 3 years of age and is characterized by the passage of several watery and unformed stools each day. Stools are typically relatively well formed in the morning but become looser as the day progresses. The stools often appear to contain undigested vegetable matter but lack blood, mucus, or excessive fat. Children with functional diarrhea, if offered an unrestricted and age-appropriate diet, gain weight normally. However, in an attempt to treat the diarrhea, many children are placed on restrictive diets that may lack dairy, fats, and occasionally starches; such restrictions lead to failure to thrive. Rome-III diagnostic criteria specify that all of the following must be present:

1. Daily painless, recurrent passage of 3 or more large, unformed stools
2. Symptoms that last more than 4 weeks
3. Onset of symptoms that begins between 6 and 36 months of age
4. Passage of stools that occurs during waking hours
5. There is no failure-to-thrive if caloric intake is adequate

Chronic nonspecific diarrhea is thought to be a variant of irritable bowel syndrome (IBS), and a family history of IBS is common. The pathophysiology may involve abnormal intestinal motility with decreased mouth-to-anus transit time. Excessive fruit juice intake may also contribute to the diarrhea by overwhelming the carbohydrate absorptive capacity of the gut. Chronic nonspecific diarrhea is a benign and self-limited condition that usually resolves without intervention by 3-4 years of age. Parents should be reassured and encouraged to place the child on a regular, unrestricted diet to provide adequate calories. The diarrhea often improves with removal of prior dietary restrictions and by limiting fruit juice intake. Some patients may improve with increasing the fat content of the diet (e.g., switching from low fat milk to whole milk), which can slow gastrointestinal transit time.

Small Intestinal Bacterial Overgrowth (SIBO)

The normal small intestine is colonized with relatively few bacteria, typically less than 10^4 organisms/mL. Various conditions such as short bowel syndrome, malnutrition, pseudo-obstruction, bowel strictures, and achlorhydria from medications such as proton pump inhibitors may result in overgrowth of aerobic and anaerobic bacteria in the small bowel. Symptoms of abdominal pain, bloating, abdominal distention, and diarrhea arise as bile acids are deconjugated and fatty acids are hydroxylated by bacteria, leading to an osmotic diarrhea. The diagnosis can be made by breath hydrogen testing showing early and late rise in breath hydrogen after ingestion of lactulose. Quantitative jejunal aspirate cultures showing greater than 10^5 organisms/mL

TABLE 11.14 Disorders Leading to Early-Onset Chronic Diarrhea

Disorder	Pathophysiology and Known Genetic Associations	Characteristic Signs and Symptoms	Diagnostic Evaluation
Disorders of Absorption and Transport of Nutrients and Electrolytes			
Congenital chloride diarrhea	AR, *SLC26A3* Alterations in the intestinal Cl$^-$/HCO$_3^-$ exchanger	Profuse secretory diarrhea Acidic stools Hypochloremic, hypokalemic metabolic alkalosis Fecal chloride concentration >90 mmol/L	Clinical features Molecular genetic testing
Congenital sodium diarrhea	AR, *SPINT2* Impaired jejunal Na$^+$/H$^+$ exchange due to the reduced activity of serine peptidase inhibitor, Kunitz type 2	Profuse watery secretory diarrhea High fecal sodium losses Alkaline stools Hyponatremic, hypokalemic metabolic acidosis	Clinical features Molecular genetic testing
Acrodermatitis enteropathica	AR, *SLC39A4* Impaired duodenal and jejunal zinc transport	Presents around the time of weaning from breast milk (0-9 mo of age in formula-fed infants) Very severe perioral and perianal rash Improvement in rash within 3 wk of oral zinc supplementation	Clinical features Molecular genetic testing
Lysininuric protein intolerance	AR, *SLC7A7* Impaired amino acid transport due to altered light chain of the solute carrier family 7, member 7	Presents around the time of weaning Recurrent vomiting with episodes of diarrhea Episodes of stupor and coma after a protein-rich meal Poor feeding Aversion to protein-rich food Failure to thrive Enlargement of the liver and spleen Muscular hypotonia	Clinical features Elevated ammonia after a protein-rich meal Abnormal urine and serum amino acid profile Molecular genetic testing
Chylomicron retention disease	AR, *SAR1B* Impaired chylomicron transport within enterocytes owing to the altered activity of a small GTPase	Vomiting, osmotic diarrhea, and failure to thrive	Low cholesterol levels and normal triglycerides Low fat-soluble vitamins, in particular vitamin E Endoscopy: lipid accumulation in enterocytes
Abetalipoproteinemia	AR, *MTTP* Impaired microsomal triglyceride transfer protein activity, lower synthesis of VLDL and reduced absorption of lipids	Presents in the first few months of life with FTT, diarrhea, and steatorrhea Fat-soluble vitamin deficiency Hypotonia, abnormal gait Retinitis pigmentosa	Low cholesterol, low triglycerides, absent apolipoprotein B Acanthosis of red blood cells
Primary bile acid diarrhea	AR, *SLC10A2* Reduced enterohepatic reabsorption of bile acids by solute carrier family 10, member 2	Presents in the first few months of life with secretory diarrhea and failure to thrive Diarrhea worse with fatty foods	SeHCAT test with a selenium-labeled bile acid. Retention <10% after 7 days is diagnostic Stool bile acid measurement
Familial diarrhea syndrome	AD, *GUCY2C* Increased activity of guanylate cyclase 2C enhances levels of cGMP, hyperactivating intestinal cystic fibrosis transmembrane conductance regulator	Early-onset chronic secretory diarrhea, abdominal distention and bloating Subset of patients with inflammatory bowel disease and irritable bowel syndrome	Molecular genetic testing
Diarrhea-associated *DGAT1* mutation	AR, *DGAT1* Impaired activity of diacylglycerol O-acyltransferase	Infantile-onset chronic diarrhea and protein-losing enteropathy	Molecular genetic testing
Defects in Enterocyte Structure			
Congenital tufting enteropathy	AR: *EPCAM* (defective activity of epithelial cell adhesion molecule causes altered cell–cell adhesion) AR: *SPINT2* (impaired activity of serine peptidase inhibitor, Kunitz type 2, which is involved in epithelial regeneration)	Presents in the first few months of life with chronic watery diarrhea and impaired growth Some patients have superficial punctate keratitis and choanal atresia	Endoscopy: blunted villi and characteristic focal epithelial "tufts" composed of closely packed enterocytes with rounding of the apical plasma membrane that results in a teardrop configuration of the affected epithelial cell Molecular genetic testing

TABLE 11.14 **Disorders Leading to Early-Onset Chronic Diarrhea—cont'd**

Disorder	Pathophysiology and Known Genetic Associations	Characteristic Signs and Symptoms	Diagnostic Evaluation
Microvillus inclusion disease	AR: *MYO5B* (reduced activity of myosin 5B causes abnormal recycling of endosomes) AR: *STX3* (impaired activity of syntaxin 3, which is involved in membrane fusion of apical vesicles)	Neonatal-onset chronic unremitting diarrhea Some develop cholestatic liver disease that worsens after intestinal transplantation	On higher magnification, the surface enterocytes are focally piled-up and disorganized, with extensive vacuolization of the apical cytoplasm and loss of brush border definition On periodic acid–Schiff (PAS) staining of the apical brush border is poorly defined and there is PAS-positive staining of the apical cytoplasm of enterocytes Molecular genetic testing
Trichohepatoenteric syndrome (syndromic diarrhea)	AR: *TTC37* (impaired synthesis or localization of brush border transporters due to the reduced activity of tetratricopeptide repeat domain 37) AR: *SKIV2L* (unknown mechanism due to the impaired activity of SKI2W helicase)	Chronic infantile diarrhea, facial dysmorphism, and hair abnormalities. Other associated symptoms: IUGR, immunodeficiency, skin abnormalities, liver disease, congenital cardiac defects, and platelet anomalies	Moderate to severe villus atrophy with inconstant infiltration of mononuclear cells Molecular genetic testing
Neuro-Enteroendocrine Diarrhea			
Enteric anendocrinosis	AR, *NEUROG3* Altered neurogenin-3, which regulates the development of gut epithelial cells into endocrine cells	Severe secretory diarrhea in infancy Insulin-dependent diabetes mellitus in childhood	Molecular genetic testing
Mitchell-Riley syndrome	AR, *RFX6* Reduced activity of regulatory factor X6 involved in pancreatic morphogenesis and development	Malabsorptive diarrhea Duodenal atresia and biliary abnormalities Neonatal diabetes mellitus	Molecular genetic testing
X-linked lissencephaly and mental retardation	X-linked, *ARX* Impaired activity of aristaless related homeobox transcriptional factor, which regulates enteroendocrine cell development	Mental retardation, seizures, lissencephaly, abnormal genitalia Occasionally congenital diarrhea	Molecular genetic testing
Defects in Intestinal Immune-Related Homeostasis			
Eosinophilic gastroenteritis and colitis	Various causes, including food allergies (cow's milk protein), medications, infections (e.g., *Helicobacter pylori*), immune dysregulation disorders, and idiopathic	Diarrhea, blood in stools, low albumin, anemia	Endoscopic mucosal biopsies showing more than normal eosinophilic infiltration
Early-onset enteropathy with colitis	AR, mutations of IL-10 or its receptors, IL10RA and IL10RB. Altered IL-10 or its receptor subunits involved in the control of intestinal microbial stimulations	Enterocolitis with ulcerative lesions in the perianal area and in the intestinal mucosa. Most present during the first 6 mo of life Folliculitis	Lack of STAT3 phosphorylation in response to IL-10 Molecular genetic testing
IPEX syndrome	X-linked, *FOXP3* mutation Impaired activity of forkhead box P3 involved in the development of CD4$^+$CD25$^+$ regulatory T cells	Severe neonatal-onset inflammatory diarrhea Eczematous skin rash Endocrinopathy (infantile diabetes mellitus) Peripheral eosinophilia and increased serum IgE Autoimmune hemolytic anemia Autoimmune thrombocytopenia and neutropenia	Flow cytometry might show decreased peripheral FOXP3+ regulatory T cells Molecular genetic testing

TABLE 11.14	Disorders Leading to Early-Onset Chronic Diarrhea—cont'd		
Disorder	**Pathophysiology and Known Genetic Associations**	**Characteristic Signs and Symptoms**	**Diagnostic Evaluation**
IPEX-like disorders	AR: *Il2RA* (impaired synthesis of α chain of IL-2 receptor on regulatory T cells) AR: *STAT5B* (impaired activity of *STAT5B* involved in IL-2 signaling in regulatory T cells) AD: *STAT1* (enhanced or reduced activity of *STAT1* causes the reprogramming of regulatory T cells into Th1-like cells) AR: *ITCH* (altered activity of itchy E3 ubiquitin protein ligase implicated in the development of regulatory T cells) AR: *LRBA* (impaired activity of lipopolysaccharide-responsive beige-like anchor protein stimulates apoptosis of regulatory T cells)	Presentation similar to IPEX	Molecular genetic testing
Pancreatic Insufficiency			
Cystic fibrosis	AR, Mutations involving CFTR. More than 1300 mutations have been described. Most common is ΔF508 mutation	Meconium ileus in neonate Megacolon Chronic diarrhea from pancreatic insufficiency starting from 1 mo of age Failure to thrive Conjugated hyperbilirubinemia	Low stool elastase High sweat chloride (>60 mEq/L) Newborn screening Molecular genetic testing
Shwachman-Diamond syndrome	AR *SBDS* gene in over 90%	Chronic diarrhea from pancreatic insufficiency Bone marrow failure Skeletal changes Pancreatic lipomatosis on diagnostic imaging (ultrasound or computed tomography)	Clinical features Molecular genetic testing
Johanson-Blizzard syndrome	AR *UBRI* gene	Chronic diarrhea from pancreatic insufficiency Dysmorphic features: aplastic alae nasi, extension of the hairline to the forehead with upswept frontal hair, low-set ears, large anterior fontanel, micrognathia, thin lips, microcephaly, aplasia cutis (patchy distribution of hair with areas of alopecia), dental anomalies, poor growth, and anorectal anomalies (mainly imperforate anus)	Clinical features Molecular genetic testing
Pearson syndrome	Sporadic: caused by de novo single, large deletions of mtDNA, which can range from 1000 to 10,000 nucleotides	Chronic diarrhea from pancreatic insufficiency Sideroblastic anemia, variable neutropenia, thrombocytopenia, and vacuolization of bone marrow precursors Lactic acidosis and liver failure	Clinical features Molecular genetic testing

AD, autosomal dominant; AR, autosomal recessive; cGMP, cyclic guanosine monophosphate; IUGR, intrauterine growth restriction; IgE, immunoglobulin E; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked; SeHCAT, selenium homocholic acid taurine; STAT3, signal transducer and activator of transcription 3; IL, interleukin; mtDNA, mitochondrial DNA; VLDL, very low density lipoprotein.

are suggestive of SIBO, although established cutoff ranges and specificity are imperfect.

Irritable Bowel Syndrome (IBS)

Irritable bowel syndrome is characterized by recurrent abdominal pain and altered bowel habits that typically presents in adolescence. Symptoms include abnormal stool frequency (either 4 or more stools per day, or 2 or fewer stools per week), abnormal stool form (either loose and watery or lumpy and hard), abnormal passage of stool (e.g., straining, urgency, feeling of incomplete evacuation), the passage of mucus,

and bloating or distention. Diagnosis requires that patients have a normal physical examination and growth curve and meet both of the following criteria at least once per week for at least 2 months before diagnosis:
1. Abdominal discomfort (an uncomfortable sensation not described as pain) or pain associated with 2 or more of the following at least 25% of the time:
   a. Improvement with defecation
   b. Onset associated with a change in frequency of stool
   c. Onset associated with a change in form (appearance) of stool

2. No evidence of an inflammatory, anatomic, metabolic, or neoplastic process that explains the subject's symptoms

The etiology and pathogenesis of irritable bowel syndrome are not well understood. Visceral hypersensitivity has been well documented in children with IBS. Genetic predisposition, early stressful events, and ineffective coping mechanisms are compounding factors. Additional mechanisms may include infection, inflammation, intestinal trauma, allergy, and disordered gut motility.

Celiac Disease

Celiac disease is an immune-mediated systemic disorder elicited by exposure to gluten and related proteins in genetically susceptible individuals. Clinical presentations vary, although the hallmarks of celiac disease include enteropathy and the presence of disease-specific antibodies. Prevalence is as high as 1% in Western nations, with most affected individuals presenting in childhood. A genetic predisposition is suggested by familial aggregation and the high concordance in monozygotic twins, which approaches 100%. A strong association with human leukocyte antigen (HLA)-DQ2.5, and to a lesser degree HLA-DQ8, has been identified. A family or personal history of autoimmune disease and certain genetic conditions confers a higher risk (Table 11.15).

The pathogenesis of celiac disease first involves exposure to **gliadin**, a protein component of **wheat gluten,** or structurally related storage proteins (**prolamines**) found in rye and barley. Altered processing by intraluminal enzymes, changes in intestinal permeability, and activation of the innate immune response precede the development of an adaptive immune response that results in systemic autoimmunity and an inflammatory enteropathy characterized by **villous atrophy,** elongated crypts, and intraepithelial lymphocytosis.

Celiac disease symptoms are protean and reflect its systemic nature. The age of onset is variable and a high degree of suspicion is needed. Manifestations include recurrent abdominal pain, nausea and vomiting, iron deficiency with or without anemia, short stature, aphthous stomatitis, chronic fatigue, arthritis, raised aminotransferase levels, and reduced bone mineral density. Rare manifestations include ataxia, **dermatitis herpetiformis**, which is a blistering rash with pathognomonic cutaneous IgA deposits, and **celiac crisis**, which is a rare life-threatening syndrome mostly observed in children, that is characterized by severe diarrhea, hypoproteinemia, and metabolic and electrolyte imbalances. The classic presentation of a toddler with chronic diarrhea, abdominal distention, and failure to thrive is uncommon. Most patients are identified via serologic screening in the context of a strong family history or other risk factors.

Serological tests are the cornerstone of screening for celiac disease in patients with risk factors or a suggestive history (Table 11.16). Establishing the diagnosis is dependent on the levels of disease-specific antibodies detected. Total serum IgA should be obtained to exclude IgA deficiency. If total serum IgA is normal and anti-tissue transglutaminase IgA antibodies are negative, celiac disease is unlikely. Patients with positive anti-tissue transglutaminase IgA antibodies that are less than 10 times the upper limit of normal should undergo upper endoscopy with multiple biopsies. If biopsies demonstrate total or partial villous atrophy, elongated crypts, and increased intraepithelial lymphocytes (>25 lymphocytes/100 enterocytes), the diagnosis is confirmed. Patients with positive anti-tissue transglutaminase IgA antibodies that are greater than or equal to 10 times the upper limit of normal should have anti-endomysial IgA antibodies and HLA testing performed. If the patient is positive for anti-endomysial IgA antibodies and is positive for DQ2 or DQ8 HLA testing, the diagnosis is confirmed; if either or both are negative, the patient should undergo biopsy.

Patients with celiac disease experience relief in their symptoms when placed on a strict gluten-free diet. Complications associated with untreated celiac disease include osteoporosis, impaired splenic function, neurologic disorders, infertility or recurrent abortion, ulcerative jejunoileitis, and cancer. Enteropathy-associated T-cell lymphoma and adenocarcinoma of the jejunum are rare complications of celiac disease. **Refractory celiac disease** is diagnosed when there are persistent or recurrent malabsorptive symptoms and signs of villous atrophy on biopsy despite strict adherence to a gluten-free diet for more than 12 months. Refractory celiac disease can be classified as **type 1** (characterized by the presence of normal intraepithelial lymphocytes), or **type 2** (characterized by abnormal intraepithelial lymphocytes; clonal intraepithelial lymphocytes lacking surface markers CD3, CD8, and T-cell receptors; or both). Type 2 refractory celiac disease is associated with a higher risk of ulcerative jejunoileitis and lymphoma.

TABLE 11.15 Conditions Whose Presence Confers a Higher Risk of Celiac Disease

Condition	Incidence of Celiac Disease (%)
First-degree relative with celiac disease	2-20
Type 1 diabetes mellitus	3-12
Juvenile idiopathic arthritis	1.5-2.5
Down syndrome	0.3-5.5
Turner syndrome	6.5
Williams syndrome	9.5
IgA nephropathy	4
IgA deficiency	3
Autoimmune thyroid disease	3
Autoimmune liver disease	13.5

TABLE 11.16 Serologic Tests for Celiac Disease

Test	Sensitivity (Percent)	Specificity (Percent)	Comments
Anti-tissue transglutaminase IgA	>95 (73-100)	>95 (77-100)	Recommended screening test
Anti-tissue transglutaminase IgG	Widely variable (12.6-99.3)	Widely variable (86.3-100)	Useful in patients with IgA deficiency
Anti-endomysial antibody IgA	>90.0 (82.6-100)	98.2 (94.7-100)	Useful in patients with an uncertain diagnosis. Expensive.
Anti-deamidated gliadin peptide IgG	>90.0 (80.1-98.6)	>90.0 (86.0-96.9)	Useful in patients with IgA deficiency and young children

IgA, immunoglobulin A; IgG, immunoglobulin G.

Inflammatory Bowel Disease (IBD)

Inflammatory bowel disease is divided broadly into **ulcerative colitis** and **Crohn disease**, idiopathic systemic chronic inflammatory diseases whose primary symptoms are related to relapsing gastrointestinal tract inflammation. Common signs and symptoms include diarrhea, abdominal pain, blood in the stools, and nutritional compromise. Ulcerative colitis consists of mucosal inflammation restricted to the colon, while Crohn disease consists of **transmural inflammation** that affects all layers of the intestinal wall and may involve any portion of the gastrointestinal tract from the mouth to the anus. Ulcerative colitis involves the colon in a continuous fashion, typically starting in the rectum and extending proximally to variable degrees. Crohn disease is characterized by **skip lesions**, in which there are areas of normal-appearing mucosa interspersed with inflammatory lesions.

The prevalence of ulcerative colitis is as high as 246 per 100,000 persons, and the prevalence of Crohn disease is as high as 199 per 100,000 persons. Approximately 25% of all IBD is diagnosed in children and adolescents, although presentation prior to 6 years of age is rare.

Clinical presentation. Up to 80% of children with Crohn disease will present with diarrhea. Stool may contain microscopic blood, although may not be grossly bloody, especially in the absence of significant left-sided colonic disease. Diarrhea is more common in colonic disease and may be absent altogether in cases of isolated small bowel inflammation. In ulcerative colitis, diarrhea is a more consistent presenting feature, often insidious in its development but eventually progressing to hematochezia. Nocturnal diarrhea with urgency may be a sign of left-sided colonic inflammation in both entities. Gastrointestinal and extraintestinal manifestations otherwise vary between Crohn disease and ulcerative colitis (Table 11.17). Extraintestinal manifestations are present in up to 23% of children at diagnosis, with a higher frequency in those over 6 years of age.

Physical examination should establish nutritional status and include an assessment of growth parameters, including the review of previous growth charts. Pubertal status should also be recorded. Oral cavity examination should look for aphthous ulcers that are present in approximately 10% of IBD patients (more commonly in Crohn disease). An eye examination should look for **episcleritis**, painful inflammation of the outer layer of the sclera, and patients with known IBD should be followed by an ophthalmologist to assess for **uveitis** and **keratopathy**. A detailed abdominal examination should document abdominal distention, mass, tenderness and hyper- or hypoactive bowel sounds. Particular attention should be paid to assessing the perianal region for any abscesses or fistulas. Skin examination should look for **erythema nodosum**, painful raised red lesions about 1-3 cm in diameter typically found on the shins; **pyoderma gangrenosum**, a severe ulcerating rash; and psoriatic lesions. Two clinical features suggest a diagnosis of Crohn disease over ulcerative colitis: the presence of perianal disease and the presence of structuring and fistulizing disease of the bowel. No other systemic or extraintestinal manifestations reliably suggest one diagnosis over the other (Table 11.18).

Diagnosis. IBD is a clinical diagnosis that integrates history and physical findings with objective data from imaging studies, laboratory evaluation, and endoscopic findings including histopathology. Diagnosis should neither be confirmed nor excluded on any one variable or result: up to 54% of patients with mild ulcerative colitis and 21% of patients with mild Crohn disease have normal hemoglobin, albumin, CRP, and ESR levels at the time of initial diagnosis. Important mimics of IBD include irritable bowel syndrome, Behçet disease, infectious enterocolitis (particularly enterovirus and *Yersinia*),

TABLE 11.17 Clinical Manifestations of Inflammatory Bowel Disease

Manifestation	Comments
Gastrointestinal	
Diarrhea with or without blood	Isolated small bowel Crohn disease may not manifest with diarrhea or grossly bloody stools
Abdominal pain	
Hematochezia	More common in ulcerative colitis
Anorexia, weight loss, and fatigue	More common in Crohn disease
Growth failure and pubertal delay	More common in Crohn disease
Abdominal mass	Only in Crohn disease
Fever and night sweats	More common in Crohn disease
Vomiting and nausea	Seen in both but severe would suggest intestinal obstructive process from Crohn disease
Extraintestinal	
Iritis and uveitis	More common in Crohn disease
Aphthous ulceration	More common in Crohn disease
Erythema nodosum	More common in Crohn disease
Pyoderma gangrenosum	More common in ulcerative colitis
Musculoskeletal • Axial arthropathy and ankylosing spondylitis • Polyarticular arthritis • Pauciarticular arthritis • Osteoporosis	
Liver • Primary sclerosing cholangitis • Autoimmune hepatitis and overlap syndrome • Cholelithiasis	
Autoimmune pancreatitis	
Cardiovascular • Myocarditis • Pericarditis	
Pulmonary Crohn disease	Commonly involves large airways, but parenchymal disease, such as organizing pneumonia, interstitial disease, and necrobiotic nodules, has been described
Renal • Nephritis • Amyloidosis • Urolithiasis (especially oxalate stones)	More common in Crohn disease compared to ulcerative colitis
Hematologic • Iron-deficiency anemia, anemia of chronic disease, vitamin B_{12} deficiency or folate deficiency • Immune thrombocytopenia • Deep vein thrombosis	

TABLE 11.18	Comparison of Crohn Disease and Ulcerative Colitis	
Feature	**Crohn Disease**	**Ulcerative Colitis**
Malaise, fever, weight loss	Common	Common
Rectal bleeding	Sometimes	Usual
Abdominal mass	Common	Rare
Abdominal pain	Common	Common
Perianal disease	Common	Rare
Ileal involvement	Common	None (backwash ileitis)
Strictures	Common	Unusual
Fistula	Common	Very rare
Skip lesions	Common	Not present
Transmural Involvement	Usual	Not present
Crypt abscesses	Variable	Usual
Intestinal granulomas	Common	Rarely present
Risk of cancer*	Increased	Greatly increased
Erythema nodosum	Common	Less common
Mouth ulceration	Common	Rare
Osteopenia at onset	Yes	No
Autoimmune hepatitis	Rare	Yes
Sclerosing cholangitis	Rare	Yes

*Colonic cancer, cholangiocarcinoma, lymphoma in Crohn disease.

TABLE 11.19	Differential Diagnoses of Presenting Symptoms of Crohn Disease
Primary Presenting Symptom	**Differential Diagnosis**
Right lower quadrant abdominal pain, with or without mass	Appendicitis, infection (e.g., *Campylobacter, Yersinia* species, tuberculosis or atypical mycobacteria), lymphoma, intussusception, mesenteric adenitis, Meckel diverticulitis, ovarian cyst or ovarian torsion, ectopic pregnancy
Chronic periumbilical or epigastric abdominal pain	Irritable bowel syndrome, constipation, lactose intolerance, peptic ulcer disease, functional dyspepsia
Rectal bleeding, no diarrhea	Fissure, polyp, Meckel diverticulum, solitary rectal ulcer syndrome
Bloody diarrhea	Infection, allergic colitis, hemolytic uremic syndrome, Henoch-Schönlein purpura, ischemic bowel, radiation colitis
Watery diarrhea	Irritable bowel syndrome, lactose intolerance, giardiasis, *Cryptosporidium* infection, sorbitol, laxatives
Perirectal disease	Fissure, hemorrhoid (rare), streptococcal infection, condyloma (rare)
Growth delay	Endocrinopathy
Anorexia, weight loss	Celiac disease, other systemic illnesses, anorexia nervosa
Arthritis	Collagen vascular disease, infection
Liver abnormalities	Chronic hepatitis
Oral ulcers	Celiac disease

and tuberculosis (Tables 11.19 and 11.20). As such, every patient with a history and examination suggestive of IBD should have stool studies for infectious organisms and special request should be made for *Yersinia* culture if multiplex PCR assays that include *Yersinia* testing are not available. Patients presenting with suggestive symptoms prior to 6 years of age may require an evaluation for an underlying immune dysregulation disorder as an additional mimic of IBD (Table 11.21). Stool biomarkers such as calprotectin and lactoferrin should be utilized to exclude non-inflammatory causes before considering endoscopic procedures. The suggested diagnostic evaluation of suspected inflammatory bowel disease is presented in Table 11.22.

TABLE 11.20	Infectious Agents Mimicking Inflammatory Bowel Disease		
Agent	**Manifestations**	**Diagnosis**	**Comments**
Bacteria			
Campylobacter jejuni	Acute diarrhea, fever, fecal blood and leukocytes	Culture or nucleic acid amplification assay	Common in adolescents, may relapse
Yersinia enterocolitica	Acute diarrhea that can become chronic, right lower quadrant pain, mesenteric adenitis—pseudoappendicitis, fecal blood and leukocytes Extraintestinal manifestations may mimic Crohn disease	Culture or nucleic acid amplification assay	Common in adolescents as fever of unknown origin, weight loss, abdominal pain
Clostridium difficile	Onset during or following a course of antibiotics, watery → bloody diarrhea, pseudomembrane on sigmoidoscopy	Cytotoxin assay or nucleic acid amplification assay	May be nosocomial Toxic megacolon possible
Escherichia coli O157:H7	Colitis, fecal blood, abdominal pain	Culture and typing or nucleic acid amplification assay	Hemolytic uremic syndrome possible
Salmonella	Watery → bloody diarrhea, foodborne, fecal leukocytes, fever, pain, cramps	Culture or nucleic acid amplification assay	Usually acute
Shigella	Watery → bloody diarrhea, fecal leukocytes, fever, pain, cramps	Culture or nucleic acid amplification assay	Dysentery symptoms
Edwardsiella tarda	Bloody diarrhea, cramps	Culture	Ulceration on endoscopy
Aeromonas hydrophila	Cramps, diarrhea, fecal blood	Culture	May be chronic May be acquired from contaminated drinking water or swimming in contaminated pools or freshwater sources
Plesiomonas shigelloides	Diarrhea, cramps	Culture	Shellfish source
Tuberculosis	Rarely bovine, now *Mycobacterium tuberculosis* Ileocecal area, fistula formation	Culture, purified protein derivative, biopsy, interferon gamma release assay	Can mimic Crohn disease
Parasites			
Entamoeba histolytica	Acute bloody diarrhea and liver abscess, colic	Trophozoite in stool, colonic mucosal flask ulceration, serologic tests	Travel to endemic area
Giardia lamblia	Foul-smelling, watery diarrhea, cramps, flatulence, weight loss; no colonic involvement	"Owl"-like trophozoite and cysts in stool; rarely duodenal intubation	May be chronic
Opportunistic Organisms in the Setting of Immune Deficiency			
Cryptosporidium	Chronic diarrhea, weight loss	Stool microscopy	Mucosal findings not like inflammatory bowel disease
Isospora belli	Chronic diarrhea, weight loss	Stool microscopy	Tropical location
Cytomegalovirus	Colonic ulceration, pain, bloody diarrhea	Culture, biopsy	More common when on immunosuppressive medications

TABLE 11.21   Chronic Inflammatory-Like Intestinal Disorders Including Monogenetic Diseases

Infection (See Table 11.20)

Idiopathic Pathogen-Negative AIDS Enteropathy

Immune–Inflammatory

Severe combined immunodeficiency
Agammaglobulinemia
Chronic granulomatous disease
Wiskott-Aldrich syndrome
Common variable immunodeficiency
Acquired immunodeficiency
Dietary protein enterocolitis
Polyglandular autoimmune syndrome type 1
Behçet disease
Lymphoid nodular hyperplasia
Eosinophilic gastroenteritis
Omenn syndrome
Graft-versus-host disease
IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome
Interleukin-10 signaling defects
Autoimmune enteropathy*
Microscopic colitis
Hyperimmunoglobulin M syndrom
Hyperimmunoglobulin E syndrome
Mevalonate kinase deficiency
Familial Mediterranean fever
Phospholipase Cγ2 defects
Familial hemophagocytic lymphohistiocytosis type 5
X-linked lymphoproliferative syndromes types 1, 2
Congenital neutropenias
Leukocyte adhesion deficiency 1

Vascular–Ischemic Disorders

Systemic vasculitis (systemic lupus erythematosus, dermatomyositis)
Henoch-Schönlein purpura
Hemolytic uremic syndrome
Granulomatosis with angiitis

Other

Glycogen storage disease type 1b
Dystrophic epidermolysis bullosa
X-linked ectodermal dysplasia and immunodeficiency
Dyskeratosis congenita
ADAM-17 deficiency
Prestenotic colitis
Diversion colitis
Radiation colitis
Neonatal necrotizing enterocolitis
Typhlitis
Sarcoidosis
Hirschsprung colitis
Intestinal lymphoma
Laxative abuse
Endometriosis
Hermansky-Pudlak syndrome
Trichohepatoenteric syndrome
PTEN hamartoma syndrome

*May be the same as IPEX.

From Grossman AB, Baldassano RN. Chronic ulcerative colitis. In: Kliegman RM, Stanton BF, St. Geme JW III, Schor NF, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016:18, Table 336-5.

TABLE 11.22   Suggested Evaluation in Suspected Inflammatory Bowel Disease

Test	Common Abnormalities/Comments
Complete blood count with differential	Anemia, especially iron deficiency
Comprehensive metabolic panel	Hypoalbuminemia, elevated liver enzymes, low alkaline phosphatase (likely secondary to associated zinc deficiency)
Erythrocyte sedimentation rate	Elevated in CD > UC
C-reactive protein	Elevated in CD > UC
Stool cultures with *Yersinia*; ova and parasites	Always rule out infectious causes as the likely reason for symptoms
Clostridium difficile toxin assay or polymerase chain reaction assay	Could be an isolated reason for symptoms or could be a superimposed illness
Fecal occult blood	Positive in vast majority of patients. No need for this test if patient has grossly bloody stools
Fecal calprotectin (or lactoferrin)	To distinguish inflammatory bowel disease from irritable bowel syndrome (IBS) prior to considering invasive procedures such as enodoscopy
Esophagogastroduodenoscopy and ileocolonoscopy	After ruling out other causes of patient's symptoms
Imaging studies • MRI and MR-enterography (MRE) • CT abdomen • Abdominal ultrasound	Consider for evaluation of patients presenting with fistulizing or structuring disease. Also used for evaluation of small bowel after endoscopic procedures
Wireless capsule endoscope	Consider for evaluation of small bowel in very young children in whom MRE is difficult or in situations where conventional endoscope and imaging tools have been nondiagnostic

CD, Crohn disease; CT, computed tomography; MRI, magnetic resonance imaging; UC, ulcerative colitis.

SUMMARY AND RED FLAGS

Acute diarrhea is a common childhood illness. For most children, the etiologic agent is of no therapeutic significance. Exceptions are giardiasis, pseudomembranous colitis, dysentery suggestive of *Shigella* infection, amebiasis, or *Campylobacter* infection, all of which necessitate specific treatment. Oftentimes of greater importance are the secondary complications associated with fluid and electrolyte losses and the reduced oral fluid intake, which may result in shock and its systemic complications.

Red flags for acute diarrhea are the manifestations of dehydration (see Table 11.6). Young age (<6 months) is associated with a greater risk of dehydration, as are 10 or more stools a day and frequent emesis and fever.

Chronic diarrhea may be benign or may signify a more serious illness associated with malabsorption, inflammation, or congenital defects. Red flags include onset of diarrhea in the neonatal period, weight loss, growth stunting, anorexia, fever, fatty stools, blood in stools, extraintestinal manifestations associated with intestinal disease, history of travel to countries with poor sanitation and water supply, and specific nutritional deficiencies associated with malabsorption.

Vomiting and Regurgitation

Richard J. Noel

DEFINITIONS

Vomiting encompasses all retrograde ejection of gastrointestinal (or esophageal) contents from the mouth. Vomiting is subdivided according to its forcefulness; thus, effortless or nearly effortless regurgitation is distinguished from true vomiting, which is propelled both by forceful abdominal wall contractions and by retrograde intestinal peristalsis (Table 12.1).

True vomiting is often accompanied by nausea and retching. **Nausea** is an unpleasant, vaguely epigastric or abdominal sensation accompanied by a variety of autonomic changes: decreases in gastric tone, contractions, secretion, and mucosal blood flow; increases in salivation, sweating, pupil diameter, and heart rate; and changes in respiratory rhythm. During nausea, retrograde peristalsis from the small intestine to the gastric antrum or generalized simultaneous contractions of antrum and duodenum may produce duodenogastric reflux.

Retching is defined as strong, involuntary efforts to vomit, which may be seen as preparatory maneuvers to vomiting. These efforts consist of spasmodic contractions of the diaphragm and abdominal wall at the same time that the lower esophageal sphincter relaxes. This sphincter is also pulled cephalad by contraction of the longitudinal muscles of the upper esophagus and may herniate through the diaphragmatic hiatus, preventing the increased intraabdominal pressure from augmenting the sphincter pressure. During retching, gastric material is moved into the esophagus by the combination of increased abdominal pressure and decreased intrathoracic pressure, but this material may be returned to the stomach by secondary (non-swallow) esophageal peristalsis.

Vomiting (emesis) differs from retching in that material is expelled from the mouth. This is fostered by relaxation of the diaphragm and reversal of intrathoracic pressure from negative to positive. The upper esophageal sphincter also relaxes, perhaps in response to the increase of intraluminal pressure in the esophagus.

Regurgitation is considered a form of gastroesophageal reflux and, as such, is caused predominantly by lower esophageal sphincter dysfunction. Although apparently effortless, it may be propelled by contraction of abdominal wall musculature; this propulsion perhaps distinguishes regurgitant from nonregurgitant reflux, which remains in the esophagus.

Rumination is similar to regurgitation in its effortless appearance and its probable propulsion by somatic muscle contraction. However, ruminated material is usually reswallowed rather than ejected from the mouth, and psychological or behavioral problems are considered the cause.

NEUROANATOMY OF VOMITING

The stereotypical motor response of vomiting is mediated by efferent fibers in the vagal, phrenic, and spinal nerves. Input to these nerves rises from the brainstem "vomiting center." The final common pathway for this centrally programmed complex reflex is through medullary interneurons in the solitary tract nucleus and a variety of sites in the nearby reticular formation. These interneurons receive input from the cortex, vagus, vestibular system, and area postrema. The area postrema, the "chemoreceptive trigger zone," is located on the dorsal surface of the floor of the fourth ventricle, outside the blood–brain barrier, and has been identified as a crucial source for neural input that causes vomiting, particularly as a response to circulating drugs and toxins. Brain tumors, other central nervous system disease, and emotional stress, in contrast, cause vomiting via cortical afferent nerves, whereas intraabdominal disease, such as luminal obstruction or distention, causes vomiting via vagal afferent nerves. Vomiting may be classified by the origin of the afferent nerves (Table 12.2). When vomiting is a result of intraabdominal disease, it is useful to define whether obstruction, dysmotility, inflammation, or ischemia is the mechanism. Vomiting may also be acute, chronic, or cyclic (Tables 12.3 and 12.4).

DATA TO GUIDE THE DIAGNOSIS

◆ History

Demographics

The child's age is a major determinant of the diagnostic possibilities (Table 12.5). Affected neonates present with congenital disorders and, in particular, structural abnormalities of the gastrointestinal tract or severe metabolic diseases. Sepsis is also an important neonatal consideration. Older infants with vomiting may have less severe structural or metabolic disorders, or they may have common acquired disorders such as gastroenteritis, mild systemic infections, gastroesophageal reflux, or allergies. Some metabolic disorders first manifest in older infants when dietary changes expose them to provocative foods for the first time; gastroenteritis and other infections are important considerations in these relatively immunocompromised younger patients.

Toddlers frequently experience gastroenteritis, because they are repeatedly exposed to organisms to which they have no immunity; this age group also presents with acquired obstructive gastrointestinal disorders, such as intussusception or volvulus or with vomiting caused by ingested poisons. Throughout childhood and adolescence, a wide variety of acquired disorders become symptomatic, and some subtle congenital malformations may also first become evident at these older ages. Metabolic disorders continue to be an important but infrequent cause of recurrent vomiting throughout childhood. In adolescents, pregnancy, drug ingestion, chronic marijuana use, and eating disorders are added to the diagnostic considerations.

Characteristics of Vomiting

The contents (Table 12.6) and forcefulness (see Table 12.1) of the vomitus narrow the diagnostic possibilities. Hematemesis and bilious

(See *Nelson Textbook of Pediatrics,* p. 867.)

TABLE 12.1 Force of Vomiting

Force	Cause	Example
None	Esophageal emptying	Achalasia; some reflux
Minimal	Regurgitation	Regurgitant reflux; rumination
Moderate	Vomiting	Most vomiting diseases
Severe	Projectile vomiting with retching	Obstructions; metabolic; poisons

vomiting, in particular, are approached in a manner very different from that of vomiting without these characteristics, and they represent more serious underlying disorders.

Associated symptoms. Vomiting must be characterized as acute, chronic, or recurrent. Temporal associations of chronic or recurrent vomiting are important (Table 12.7). Associated symptoms must be described (Tables 12.8 and 12.9); they are crucial, for example, in distinguishing life-threatening intracranial and metabolic disorders (Table 12.10). Abdominal pain is a central symptom that, if present, narrows the diagnosis. Vomiting associated with neurologic symptoms requires very careful evaluation. Post-tussive emesis is not usually confused with vomiting of other causes; it should direct diagnostic attention to the cause of the cough itself. Regurgitation in an infant with apnea may signal reflux-associated apnea, although many infants with reflux-associated apnea have minimal regurgitation. Additionally, infant regurgitation is so common that it is quite nonspecific.

Medical, family, and social history. Previous surgery, hospitalizations, and medications may provide important clues. A family history of fetal or neonatal deaths suggests a genetic or metabolic cause; similar illness in the family members or other contacts may suggest infections or common toxic exposures. Psychosocial stressors may be found in adolescents with bulimia, peptic ulcer disease, chronic marijuana use, or intentional self-poisonings.

◆ Physical Examination

Although vomiting is a "gastrointestinal" symptom, it can be a manifestation of disease in multiple systems of the body (see Tables 12.8, 12.9). Vital signs identify fever, which is important in narrowing the differential diagnosis. Tachypnea may signify acidosis, which is seen with vomiting from metabolic causes or poisoning or with vomiting associated with marked diarrhea and dehydration or shock. Examination of the fundi is often inappropriately neglected. The absence of venous pulsations or sharp optic disk margins may be the only evidence of a brain tumor or other intracranial lesion causing vomiting. When in doubt, a formal ophthalmologic examination is warranted.

Abdominal Examination

Simple observation of operative scars may suggest the possibility of obstruction from intestinal adhesions, and visible distention may represent ascites caused by liver disease or intraluminal distention caused by intestinal obstruction or ileus. The order of the examination is important because auscultation performed after stimulation of intestinal motility by palpation may artifactually change the auscultatory findings. An important distinction in the vomiting child is whether bowel sounds are increased, as in gastroenteritis or in bowel obstructions, or absent, as in ileus caused by peritonitis or in pseudoobstruction. Increased bowel sounds resulting from luminal obstruction are often characterized by intermittent "rushes" of high-pitched sounds that are coordinated with episodes of colicky pain.

Abdominal pain and tenderness associated with vomiting often represent disorders necessitating further imaging and/or surgery.

TABLE 12.2 Differential Diagnosis of Vomiting by Anatomic Locus of Stimulus

I. Stimulation of Supramedullary Receptors
  A. Psychogenic vomiting
  B. Increased intracranial pressure (subdural effusion or hematoma, cerebral edema or tumor, hydrocephalus, meningoencephalitis, Reye syndrome)
  C. Vascular (migraine, severe hypertension)
  D. Seizures
  E. Vestibular disease, "motion sickness"
II. Stimulation of Chemoreceptive Trigger Zone
  A. Drugs: opiates, ipecac, digoxin, anticonvulsants
  B. Toxins
  C. Metabolic products (acidemia, ketonemia, hyperammonemia, uremia, etc.):
    Acidemia, ketonemia (diabetic ketoacidosis, lactic acidosis, phenylketonuria, renal tubular acidosis)
    Aminoacidemia (tyrosinemia, hypervalinemia, hyperglycinemia, lysinuria, maple syrup urine disease)
    Organic acidemia (methylmalonic acidemia, propionic acidemia, isovaleric acidemia)
    Hyperammonemia (urea cycle defects, Reye syndrome)
    Uremia (renal failure)
    Other (hereditary fructose intolerance, galactosemia, fatty acid oxidation disorders, diabetes insipidus, adrenal insufficiency, hypercalcemia, hypervitaminosis A)
III. Stimulation of Peripheral Receptors and/or Obstruction of the Gastrointestinal Tract
  A. Pharyngeal: gag reflex (sinusitis secretions, post-tussive, self-induced, rumination)
  B. Esophageal:
    Functional: reflux, achalasia, other esophageal dysmotility
    Structural: stricture, ring, atresia, etc.
  C. Gastric:
    Peptic ulcer disease (including Zollinger-Ellison syndrome), infection, dysmotility/gastroparesis
    Obstruction (e.g., bezoar, pyloric stenosis, web, chronic granulomatous disease, eosinophilic gastroenteritis)
  D. Intestinal:
    Infection, enteritis, enterotoxin, appendicitis
    Dysmotility (e.g., metabolic or diabetic neuropathy; intestinal pseudoobstruction)
    Nutrient intolerance (e.g., cow's milk, soy, gluten, eosinophilic enteropathy)
    Obstruction (e.g., atresia, web, stenosis, adhesions, bands, volvulus, intussusception, superior mesenteric artery syndrome, duplication, meconium plug, meconium ileus, Hirschsprung disease, distal intestinal obstruction syndrome in cystic fibrosis)
  E. Hepatobiliary, pancreatic: hepatitis, cholecystitis, pancreatitis, cholelithiasis
  F. Cardiac: intestinal ischemia
  G. Renal: pyelonephritis, hydronephrosis, renal calculi, glomerulonephritis
  H. Respiratory: pneumonia, otitis, pharyngitis, sinusitis, common cold
  I. Miscellaneous: peritonitis, sepsis, pregnancy; improper feeding techniques

TABLE 12.3   Differentiating Acute, Chronic, and Cyclic Patterns of Vomiting

Clinical Feature	Acute	Chronic Recurrent	Cyclic Recurrent
Epidemiology	Most common	Two-thirds of recurrent vomiting cohort	One-third of recurrent vomiting cohort
Acuity	Moderate-severe, ± dehydration	Not acutely ill or dehydrated	Severe, dehydrated
Vomiting intensity	Moderate to high	Low, 1-2 emeses/hr at the peak	High frequency, ~6 emeses/hr at peak
Recurrence rate	No	Frequent, >2 episodes per week	Infrequent, ≤2 episodes per week
Stereotypy	Unique—*if child has had 3 similar episodes, consider cyclic pattern*	No	Yes
Onset	Variable	Daytime	Early morning
Symptoms	Fever, diarrhea	Abdominal pain, diarrhea	Pallor, lethargy, nausea, abdominal pain
Household contacts affected	Usually	No	No
Family history of migraine headaches		14% positive	82% positive
Causes	Viral infections	Ratio of GI to extra-GI causes 7:1; upper GI tract mucosal injury most common (esophagitis, gastritis)	Ratio of extra-GI to GI causes 5:1; cyclic vomiting syndrome most common (also hydronephrosis, metabolic)

From Li BUK, Kovacic K. Vomiting and nausea. In: Wyllie R, Hyams JS, Kay M, eds. *Pediatric Gastrointestinal and Liver Disease*. 5th ed. Philadelphia: Elsevier; 2016:87.

TABLE 12.4   Causes of Vomiting by Temporal Pattern

Category	Acute	Chronic	Cyclic
Infectious	Gastroenteritis* Otitis media* Streptococcal pharyngitis Acute sinusitis Hepatitis Pyelonephritis Meningitis	*Helicobacter pylori** Giardiasis Chronic sinusitis*	Chronic sinusitis*
Gastrointestinal	Inguinal hernia Intussusception Malrotation with volvulus Appendicitis Cholecystitis Pancreatitis Distal intestinal obstruction syndrome	Anatomic obstruction GERD ± esophagitis* Eosinophilic esophagitis* Gastritis* Peptic ulcer or duodenitis* Achalasia SMA syndrome Stricturing Crohn disease	Malrotation with volvulus
Genitourinary	Pyelonephritis UPJ obstruction	Pyelonephritis Pregnancy Uremia	Acute hydronephrosis secondary to UPJ obstruction
Endocrine, metabolic	Diabetic ketoacidosis	Adrenal hyperplasia	Diabetic ketoacidosis Addison disease MCAD deficiency Partial OTC deficiency MELAS syndrome Acute intermittent porphyria
Neurologic	Concussion Subdural hematoma Encephalitis Migraine	Arnold-Chiari malformation Subtentorial neoplasm	Abdominal migraine* Migraine headaches* Arnold-Chiari malformation Subtentorial neoplasm Metabolic encephalopathy
Other	Toxic ingestion Chronic marijuana use Food poisoning	Rumination Functional Bulimia Pregnancy	Cyclic vomiting syndrome* Factitious disorder by proxy (e.g., ipecac poisoning)

*Most common disorders.

GERD, gastroesophageal reflux disease; MCAD, medium-chain acyl-CoA dehydrogenase deficiency; MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes; OTC, ornithine transcarbamylase deficiency; SMA, superior mesenteric artery; UPJ, ureteropelvic junction.

From Li BUK, Kovacic K. Vomiting and nausea. In: Wyllie R, Hyams JS, Kay M, eds. *Pediatric Gastrointestinal and Liver Disease*. 5th ed. Philadelphia: Elsevier; 2016:88.

TABLE 12.5 Differential Diagnosis of Vomiting by Age

I. Newborn
  A. Congenital obstructive gastrointestinal malformations:
     Atresias or webs of esophagus or intestine
     Meconium ileus or plug; Hirschsprung disease
  B. Inborn errors of metabolism:
     Organic acidemias, amino acidemias, hyperammonemias (urea cycle), adrenogenital syndromes
II. Infant
  A. Acquired or milder obstructive lesions:
     Pyloric stenosis, malrotation and volvulus, intussusception
  B. Metabolic diseases, inborn errors of metabolism
  C. Nutrient intolerances
  D. Functional disorders:
     Gastroesophageal reflux
  E. Psychosocial disorders:
     Rumination, injury from child abuse
III. Child
   Most causes in Table 12.8
IV. Adolescent
   Most childhood causes, plus pregnancy, drugs (of abuse, suicide), eating disorders

Modified from Orenstein SR. Dysphagia and vomiting. In: Wyllie R, Hyams JS, eds. *Pediatric Gastrointestinal Disease: Pathophysiology, Diagnosis, Management*. Philadelphia: WB Saunders; 1993:147.

TABLE 12.6 Contents of Emesis

Material	Source	Examples
Undigested food	Esophageal	Stricture, achalasia
Digested food: curds	Gastroduodenal	Pyloric stenosis, bezoar
Bile: green/yellow	Postampullary	Small bowel obstruction
Blood: red/brown	Lesion above ligament of Treitz	See Tables 12.13 and 12.14
Feculent: malodorous	Bacterial overgrowth Colon obstruction Necrotic bowel	Stasis syndrome Gastrocolic fistula Ischemic injury, peritonitis
Acid: clear (voluminous)	Gastric outlet obstruction Increased gastric secretion	Pyloric stenosis Zollinger-Ellison syndrome
Mucus	Gastric, respiratory mucus	Sinusitis, eosinophilic esophagitis

TABLE 12.7 Temporal Associations of Chronic or Recurrent Vomiting

Temporal Associations	Diagnosis	Other Clues	Temporal Associations	Diagnosis	Other Clues
Time of day: early morning	Increased intracranial pressure Sinusitis with postnasal mucus Pregnancy Uremia	Headache, papilledema Sinus tenderness Secondary amenorrhea	Vestibular stimulation	Motion sickness	Nystagmus Vertigo
During or after meals			Hyperhydration	Ureteropelvic junction obstruction ("beer drinker's kidney," Dietl crisis)	Spontaneous resolution with normal hydration
Any meals	Peptic ulcer disease, reflux	Epigastric pain, heartburn	Menses	Dysmenorrhea-associated vomiting Acute intermittent porphyria Pelvic inflammatory disease	Relief with NSAIDs Nonperitonitis pain, distention, tachycardia, constipation Vaginal discharge
Specific foods		See Tables 12.10, 12.17, 12.18			
Fructose Galactose High protein	Hereditary fructose intolerance Galactosemia Metabolic inborn error	Hyperammonemia, acidosis	Medications, toxins	Medication side effect: pancreatitis, hepatitis Acute intermittent porphyria Steroid withdrawal: Addison disease Poisonings; NSAID stricture; laxative, etc. Ipecac abuse in anorexia nervosa	Opiate withdrawal
Specific protein Cow, soy Gluten	Cow's or soy milk intolerance Gluten-sensitive enteropathy (celiac)	Failure to thrive			
Various (especially egg, wheat, fish, nut, chocolate, strawberry)	Miscellaneous allergic, eosinophilic gastroenteropathies	History of asthma, hives, ↑eosinophils, family history of allergies	Episodic/cyclic	Abdominal migraine, abdominal epilepsy Pheochromocytoma Porphyria Familial dysautonomia Metabolic inborn error Familial Mediterranean fever Malrotation and intermittent volvulus Intermittent intussusception Self-induced Cyclic vomiting	
After fasting Food vomited Food not vomited	Gastric stasis/obstruction Metabolic disease	Distention, tympany See Tables 12.10, 12.17, 12.18			
Other precipitants Cough Infections	Post-tussive Metabolic Recurrent gastroenteritis	Respiratory disease See Tables 12.10, 12.17, 12.18			

NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 12.8 Clues to the Diagnosis and Localization of the Cause of Emesis

Associated Symptoms	Diagnoses to Consider
Local abdominal pain	
Epigastric	Peptic ulcer disease, reflux, pancreatitis
Periumbilical	Nonspecific or small intestinal obstruction
Pelvic	Cystitis, pelvic inflammatory disease, ovarian torsion
Right upper quadrant	Hepatitis, pancreatitis, cholecystitis, biliary colic, duodenal hematoma/ulcer, right pyelonephritis, pneumonia, perihepatitis
Left upper quadrant	Peptic ulcer disease, pancreatitis, splenic enlargement or torsion, left pyelonephritis, pneumonia
Right lower quadrant	Appendicitis, right tuboovarian disease
Left lower quadrant	Left tuboovarian disease, sigmoid disease
Right flank	UPJ/renal obstruction or infection, biliary obstruction, adrenal hemorrhage
Left flank	UPJ/renal obstruction or infection, adrenal hemorrhage
Other pain	
Headache	Increased intracranial pressure
	Sinusitis with postnasal mucus
	Migraine
Chest pain, dysphagia	Esophagitis, achalasia
	Pneumonia
Joint pain	SLE, FMF, IBD
Diarrhea	Partial intestinal obstruction
	Infectious enteritis
	Poison, inborn error of metabolism
Constipation	Intestinal obstruction or dysmotility (pseudoobstruction)
	Hypercalcemia, hypokalemia, porphyria, lead poisoning
Jaundice	Hepatitis, cholecystitis
	Hepatobiliary obstruction
	Metabolic disease
	Urinary obstruction or infection, pyloric stenosis (neonate)
Neurologic	Metabolic, toxic (lead), central nervous system disease, porphyria, hepatic failure
	Encephalopathy
	Vertigo
	Visual changes
	Abnormal tone, seizure
	Full fontanel
Cardiac	
Valvular disease	Mesenteric arterial thrombosis (or embolism)
Hypotension	Mesenteric thrombosis, intestinal ischemia
Hypertension	Pheochromocytoma
Respiratory	Pneumonia, otitis, aspiration of vomitus
Urinary	Pyelonephritis, hydronephrosis, calculi, renal hypertension, cholestasis, porphyria
Gynecologic	
Menstrual irregularity	Pregnancy, ectopic pregnancy
Vaginal discharge	Pelvic inflammatory disease
Menses-associated	Porphyria, endometriosis, dysmenorrhea

FMF, familial Mediterranean fever; IBD, inflammatory bowel disease; SLE, systemic lupus erythematosus; UPJ, ureteropelvic junction.

Vague periumbilical pain is quite nonspecific, but the localized, very sharp pain signifying inflammation of the peritoneum requires immediate attention. Initial luminal obstruction may progress to later ileus as peritonitis intervenes. Localization of nonperiumbilical pain or tenderness helps a great deal in determining the diseased intraabdominal organ (see Tables 12.8 and 12.9).

Abdominal pain often represents luminal obstruction, ischemia, or perforation (surgical disease), but nonsurgical diseases must also be considered. These disorders include nonobstructive inflammatory diseases (infectious gastroenteritis, pancreatitis), metabolic crises (e.g., adrenal crisis), and poisonings (e.g., lead, narcotics, insecticides).

Rectal Examination

A rectal examination may be helpful in the vomiting child as the presence and consistency of rectal stool may be determined. Simple fecal impaction may theoretically contribute to vomiting in young children, whereas liquid stools may suggest gastroenteritis. Pelvic masses and tenderness identified rectally may represent appendicitis, ovarian torsion, or pelvic inflammatory disease. The stool should always be tested for blood and should be considered for testing for pH, reducing substances, fat, leukocytes, and infectious organisms, depending on the situation.

Laboratory Data

Well-appearing infants with typical regurgitant reflux usually require no laboratory evaluation, except probably an upper gastrointestinal study if they do not respond readily to conservative therapy (see later discussion). Similarly, a single, brief episode of mild vomiting with a clear etiology and no suggestion of dehydration or other complications may necessitate no laboratory studies. Most other children—those with severe acute vomiting or with chronic or recurrent vomiting—should have screening studies of blood or urine (Table 12.11). Blood and urine screening for several metabolic disorders are positive only during an actual vomiting episode; therefore, attempts to obtain specimens at these times may increase the diagnostic yield. Examples include measuring serum lactate, serum and urine carnitine (possible fatty acid oxidation defect), and urine δ-aminolevulinic acid and porphobilinogen (possible acute intermittent porphyria).

Radiographic and Procedure Data

If the history and physical examination suggest the possibility of abdominal disease, endoscopic evaluation or abdominal plain films (including a second image such as an upright film) are usually warranted (Table 12.12). Endoscopy is particularly useful in hematemesis, in suspected peptic ulcer disease, or when tissue is needed for histologic study (e.g., establishing a diagnosis of *Helicobacter pylori* gastritis or of eosinophilic gastroenteropathy). Radiographic testing is useful in most other situations. Further evaluation, such as contrast studies, ultrasonography, computed tomography (CT), or magnetic resonance imaging, is tailored to the suspected diagnoses. It should be noted that endoscopy may not be performed when barium contrast remains in the areas to be examined; therefore, if it is thought that contrast fluoroscopy studies need to be followed by endoscopy, imaging should be performed with water-soluble contrast. In rare cases, manometric evaluation is prompted by the suggestion of motor dysfunctions, such as achalasia and chronic intestinal pseudoobstruction.

◆ Differential Diagnosis
General Approach

Cardinal symptoms or signs accompanying the vomiting direct the differential diagnosis. Abdominal pain, which frequently accompanies vomiting, can suggest both the type of disorder (e.g., luminal

TABLE 12.9   Clinical Clues to Diagnosis

Associated Symptom or Sign	Diagnostic Consideration	Associated Symptom or Sign	Diagnostic Consideration
Systemic Manifestations		Abdominal pain	Substernal, esophagitis; epigastric, upper GI tract, pancreatic; right upper quadrant, cholelithiasis
Acute illness, dehydration	Infection, ingestion, cyclic vomiting, possible surgical emergency	Diarrhea	Gastroenteritis, bacterial colitis
Chronic malnutrition	Malabsorption syndrome	Constipation	Hirschsprung disease, pseudoobstruction, hypercalcemia
Temporal Pattern		Dysphagia	Eosinophilic esophagitis, achalasia, esophageal stricture
Low-grade, daily	Chronic vomiting pattern, e.g., upper GI tract disease (e.g., gastroesophageal reflux, functional disorders)	Visible peristalsis	Gastric outlet obstruction
Postprandial	Upper GI tract disease (e.g., gastritis), gastroparesis, rumination, biliary disorders	Surgical scars	Surgical adhesions, surgical vagotomy
		Succussion splash	Gastric outlet obstruction with gastric distention
Relationship to diet	Fat, cholecystitis, pancreatitis; protein allergy; hereditary fructose intolerance	Bowel sounds	Decreased: paralytic ileus; increased: mechanical obstruction
Early morning onset	Sinusitis, cyclic vomiting syndrome, increased intracranial pressure	Severe abdominal tenderness with rebound	Perforated viscera and peritonitis
High intensity	Cyclic vomiting syndrome, food poisoning	Abdominal mass	Pyloric stenosis, congenital malformations, Crohn, ovarian cyst, pregnancy, abdominal neoplasm
Stereotypical (well between episodes)	Cyclic vomiting syndrome		
Rapid onset and subsidence	Cyclic vomiting syndrome	**Neurologic Symptoms**	
		Headache	Allergy, chronic sinusitis, migraine, increased intracranial pressure
Character of Emesis		Postnasal drip, congestion	Allergy, chronic sinusitis
Effortless	Gastroesophageal reflux, rumination		
Projectile	Upper GI tract obstruction	Vertigo	Migraine, inner ear disease
Mucous	Allergy, chronic sinusitis	Seizures	Epilepsy
Bilious	Postampullary obstruction, cyclic vomiting syndrome	Abnormal muscle tone	Cerebral palsy, metabolic disorder, mitochondrial disorder
Bloody	Esophagitis, prolapse gastropathy, Mallory-Weiss injury, allergic gastroenteropathy, bleeding diathesis	Abnormal funduscopic exam or bulging fontanel	Increased intracranial pressure, pseudotumor cerebri
Undigested food	Achalasia		
Clear, large volume	Ménétrier disease, Zollinger-Ellison syndrome	**Family History and Epidemiology**	
Malodorous	*H. pylori*, giardiasis, sinusitis, small bowel bacterial overgrowth, colonic obstruction	Peptic ulcer disease	Peptic ulcer disease, *H. pylori* gastritis
		Migraine headaches	Abdominal migraine, cyclic vomiting syndrome
Gastrointestinal Symptoms		Contaminated water	*Giardia*, *Cryptosporidium*, other parasites
Nausea	Absence of nausea can suggest increased intracranial pressure	Travel	Traveler's *(Escherichia coli)* diarrhea, giardiasis

H. pylori, Helicobacter pylori.

TABLE 12.10 When to Consider Metabolic Work-up*

Nutritional abnormalities	Failure to thrive, anorexia
Dietary provocations	Fructose, galactose, protein, fasting
Neurologic abnormalities	Lethargy, coma Tone ↑ or ↓, developmental delay Seizures
Liver abnormalities	Hepatosplenomegaly Jaundice
Respiratory abnormalities	Apnea Hyperpnea (caused by metabolic acidosis or hyperammonemia)
Odd odors (breath, urine, ear wax)	Cabbage: tyrosinemia Sweaty feet: isovaleric acidemia Musty: phenylketonuria, hepatic coma (fetor hepaticus) Fruity: ketones (many, nonspecific) Maple syrup; maple syrup urine disease Other: 3-methylcrotonyl-CoA carboxylase deficiency Multiple carboxylase deficiency Acyl-CoA dehydrogenase deficiency Putrid: sinusitis Alcohol: alcohol ingestion
Miscellaneous abnormalities	Eye abnormalities (cataracts) Hair abnormalities (fragile) Pigmentation of skin ("tan") and mucosa Adrenal calcifications Ambiguous genitalia Cardiomyopathy Family history of fetal or neonatal deaths; consanguinity
Screening study abnormalities	Metabolic acidosis Hypoglycemia (hyperketonuric or hypoketonuric) Hyperkalemia (with hyponatremia) Hyperammonemia Hypertransaminasemia Anemia, leukocytopenia, thrombocytopenia Urinary non–glucose-reducing substance Urinary Fanconi syndrome

*See also Tables 12.17 and 12.18.

obstruction, inflammation, ischemia, or peritonitis) and the organ involved (see Table 12.8). Hematemesis leads to the considerations indicated in Tables 12.13 and 12.14. Symptoms referable to nongastrointestinal organ systems direct attention to those systems. For example, accompanying neurologic symptoms may direct attention to central nervous system disorders, metabolic disease, poisonings, or psychobehavioral disease.

Gastrointestinal Obstruction
Esophageal Obstruction
Esophageal lesions produce welling up or drooling of oropharyngeal secretions or esophageal contents rather than actual vomiting; the material is, of course, undigested. Respiratory symptoms from aspiration may be prominent.

Esophageal atresia. Infants with esophageal atresia present at birth with a prenatal history of polyhydramnios and intolerance of initial feeding. The esophageal atresia is accompanied by a distal tracheoesophageal fistula in 85% of cases, by a proximal fistula in a small percentage, and by no fistula in the remainder (Fig. 12.1). Esophageal atresia is associated with other anomalies in 15-50% of patients; cardiac, anorectal, and genitourinary defects are most common. Ten percent of all esophageal atresia patients and 25% of those without a fistula have the VATER or VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal, radial, limb) association. Others may have Fanconi anemia, where esophageal atresia may provide an early sign for making the diagnosis. As many as 33% of affected infants are premature. Diagnosis can usually be made by plain films after passage of an opaque rubber catheter, which coils in the upper pouch (Fig. 12.2). Treatment is surgical.

Esophageal stenosis. Children with esophageal stenoses present in later infancy and occasionally in adulthood. Stenoses are divided into tracheobronchial rings that often contain cartilage, fibromuscular stenoses, and membranous webs. Diagnosis is by contrast radiography and may require pressure injections of contrast material if the stenosis is not tight. Tracheobronchial rings generally necessitate surgery, membranous webs can be treated with endoscopic dilation, and muscular stenoses may respond to dilation or may necessitate surgery.

Esophageal strictures. Esophageal strictures are acquired lesions that may be caused by reflux esophagitis, but more commonly result from caustic ingestions (acid, alkali) or other causes (Fig. 12.3). The strictures are best demonstrated with contrast radiography; endoscopic biopsies may be important for diagnosis of the etiology. Gastroesophageal reflux disease (GERD) may be treated pharmacologically, but may also require a fundoplication; endoscopic dilation of the stricture is performed repeatedly with balloons or bougies until the strictured site remains patent.

Pyloric Stenosis
Pyloric stenosis manifests with nonbilious projectile vomiting beginning at 2-3 weeks of age and increasing during the next month or so, usually in a firstborn male child. The vomitus may contain some blood, and propulsive gastric waves can be seen on the abdominal wall. Dehydration, poor weight gain, metabolic alkalosis, and mild jaundice are sometimes evident. A palpable "olive" in the epigastrium (felt best during or after feeding) represents the hypertrophied pyloric muscle.

Gastric distention is seen on the plain film, and a contrast study shows the "string sign" of contrast passing through the narrowed pyloric channel. Ultrasound diagnosis is less invasive (Fig. 12.4). Eosinophilia, eosinophilic infiltration of endoscopic antral biopsy specimens, and an excellent response to treatment with a casein hydrolysate or elemental "hypoallergenic" formula are suggestive of an allergic or idiopathic eosinophilic gastroenteropathy and not pyloric stenosis. In older children, gastric outlet obstruction may result from ulceration, chronic granulomatous disease, foreign bodies, and bezoars. Bezoars may be caused by hair, vegetable matter, milk curds, or medications. Long-acting formulated oral medications may also become bezoars in the distal intestine and cause obstruction.

Intestinal Obstruction
Rushes of bowel sounds associated with cramping and colic often indicate intestinal obstruction. Vomiting is a cardinal sign of intestinal obstruction, being more prominent in high small bowel obstruction than in low small bowel or colon obstruction. With high obstructions, vomiting is not feculent, the onset is often acute, and crampy pain may occur at frequent intervals; abdominal distention is minimal. With low obstructions, in contrast, the vomiting may be feculent and less acute in onset, the interval between cramping is longer, and distention is

TABLE 12.11   Diagnostic Tests: Blood and Urine

	Findings	Possible Significance		Findings	Possible Significance
Blood Test			Amylase, lipase	↑	Pancreatitis
CBC			NH$_4$	↑	Metabolic, liver failure, *Proteus* urinary infection
Hct/Hb	↑	Dehydration: general vomiting			
	↓	Hematemesis; metabolic; chronic malnutrition; hypersplenism; hemolysis (e.g., sickle cell)	Ketones	↑	Metabolic, fasting/starvation
			Amino acids	↑	Metabolic
			Organic acids	↑	Metabolic
WBC (PMNs, bands)	↑	Sepsis; inflammatory/ischemic lesions	IgE, RAST (especially foods)	↑	Allergic enteropathies
	↓	Metabolic; sepsis; viral; hypersplenism; malnutrition			
Eosinophils	↑	Allergic (eosinophilic gastroenteropathy), parasitic, Addison disease	PT, PTT	↑	Hematemesis, coagulopathy, liver failure, poisoning
Platelets	↑	Inflammatory (e.g., inflammatory bowel disease)	Toxicology	+	Drug; poison
	↓	Hematemesis; metabolic; hypersplenism	Culture	+	Sepsis; ischemic/perforated bowel
Electrolytes			**Urine Test**		
Na	↓ (↓)	Adrenal insufficiency; general vomiting	pH	↑	General vomiting
	↑	Salt poisoning, dehydration	WBC	+	Urinary tract infection
K	↓	General vomiting	Protein, casts	+	Renal disease
	↑	Adrenal insufficiency; uremia; bleeding; digitalis; diuretics (e.g., spironolactone)	Blood	+	Urinary tract infection or bleeding
			Bilirubin	+	Liver disease, hemolysis
Cl	↓ (↓)	Adrenal insufficiency; general vomiting	Electrolytes		
	↑	Salt poisoning, hypernatremic dehydration	Na	↓	General vomiting
Bicarbonate	↑ (pH ↑)	General vomiting, pyloric stenosis	K	↑	General vomiting
	↓ (pH ↓)	Metabolic; adrenal insufficiency; poison; renal tubular acidosis; severe diarrhea; shock	Cl	↓	General vomiting
			Bicarbonate	↑	General vomiting
Glucose	↑	Metabolic: diabetic ketoacidosis	Ketones	+	Metabolic, fasting/starvation
	↓	Metabolic, toxins	Reducing substance		
BUN	↑	Dehydration, hematemesis	Glucose	+	Diabetic ketoacidosis
Creatinine	↑	Dehydration, renal failure	Nonglucose	+	Galactosemia
Calcium	↑	Hypercalcemia	Fanconi syndrome	+	Metabolic
Blood gas	↓ pH, ↓ P$_{CO_2}$	Metabolic disease; adrenal insufficiency; poison; severe diarrhea; shock			
			FeCl	+	Metabolic
ALT, AST	↑	Hepatitis; metabolic	Amino acids	↑	Metabolic
GGT, ALP	↑	Biliary obstruction	Organic acids	↑	Metabolic
Bilirubin	↑	Hepatitis; metabolic; hemolysis (e.g., sickle cell)	Toxicology	+	Drug; poison
			Culture	+	Urinary tract infection; sepsis
Conjugated	↑	Biliary obstruction			

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count; Cl, chloride; FeCl, iron chloride; GGT, γ-glutamyltransferase; Hct/Hb, hematocrit/hemoglobin; IgE, immunoglobulin E; K, potassium; metabolic, inborn error of metabolism; Na, sodium; NH$_4$, ammonium; P$_{CO_2}$, partial pressure of carbon dioxide; PMNs, polymorphonuclear neutrophils; PT, prothrombin time; PTT, partial thromboplastin time; RAST, radioallergosorbent test; WBC, white blood cell count; +, present; ↑, increased; ↓, decreased; (↓), may or may not be decreased.

more notable. Identification of the site of obstruction is aided by the plain film and by other radiographic studies (see Table 12.12).

Obstructions may be categorized by type and site. Intraluminal lesions (e.g., tumors; intussusceptions; or extrinsic material such as feces, foreign bodies, bezoars, and gallstones) can be differentiated from bowel wall lesions (strictures, stenoses, atresias) and from extraluminal lesions (adhesions, congenital bands, tumors, volvulus). Radiographic studies are useful, beginning with the plain film and progressing to ultrasonography or CT. Fluoroscopy with contrast material such as barium or diatrizoate (Gastrografin, Hypaque, water-soluble contrast) is very helpful in identifying both the site and the type of obstruction, but the decision to introduce contrast into an intestine that may perforate or be operated on must be made with surgical and radiologic consultation. Often the decision to operate can be made without certain identification of the lesion, and contrast studies are unnecessary.

Infantile bilious vomiting is an important symptom of intestinal obstruction, which often signals a congenital gastrointestinal anomaly, particularly intestinal obstruction below the ampulla of Vater. Surgical consultation is needed early in these infants because they often require emergency therapy (Table 12.15).

Duodenal atresia, stenosis, and web; annular pancreas. The juxtaampullary duodenum is susceptible to a cluster of obstructing congenital anomalies. Infants with complete duodenal obstruction, most commonly atresia, present with bilious vomiting and a radiographic "double-bubble" sign (Fig. 12.5). Associated prematurity (and polyhydramnios) or anomalies, including renal, cardiac, and vertebral defects, occur in approximately 75% of infants; trisomy 21 is seen in about 50%. Double atresias, duplications, and malrotations are frequently seen. Infants with a partial duodenal obstruction caused by a stenosis or web may have such mild symptoms that they do not come to medical attention until regurgitation produces esophagitis or until a foreign body or bezoar is trapped at the obstruction. Treatment is surgery.

Duodenal hematoma. Blunt abdominal trauma (seatbelt injury, child abuse), or even endoscopic biopsies in the context of a coagulopathy, can produce an obstructing duodenal hematoma. Endoscopy in the setting of stem cell transplantation or other hematopoietic disease may place a patient at greater risk of such hematoma, requiring special consideration of the need for duodenal biopsies in these individuals. Therapy is symptomatic; jejunal feeding that bypasses the obstruction or parenteral nutrition may be required as the problem resolves.

Jejunal atresia, ileal atresia, and ileal stenosis. Patients with these congenital lesions present with bilious vomiting and more abdominal distention than those with duodenal lesions. The atresias are readily suspected and diagnosed in the neonatal period. Stenotic lesions may require radiography for diagnosis. Treatment is surgical.

Intestinal strictures. Strictures produce partial obstruction of the gastrointestinal tract and may be located from the esophagus to the anus. They may occur postsurgically (anastomotic), may follow necrotizing enterocolitis, may be caused by Crohn disease, or may result from ingestion of nonsteroidal antiinflammatory medications or high-dose pancreatic enzymes. Some patients may be treated with endoscopic dilatation, but many require surgical stricturoplasty (opening the bowel longitudinally and closing it transversely) or resection.

Adhesions. Obstructive symptoms in the child with a history of prior abdominal surgery may be caused by adhesive bands.

Duplications. These uncommon lesions may cause vomiting by extrinsic obstruction of the intestine or by intussusception. An abdominal mass may be palpable.

TABLE 12.15	Causes of Gastrointestinal Obstruction

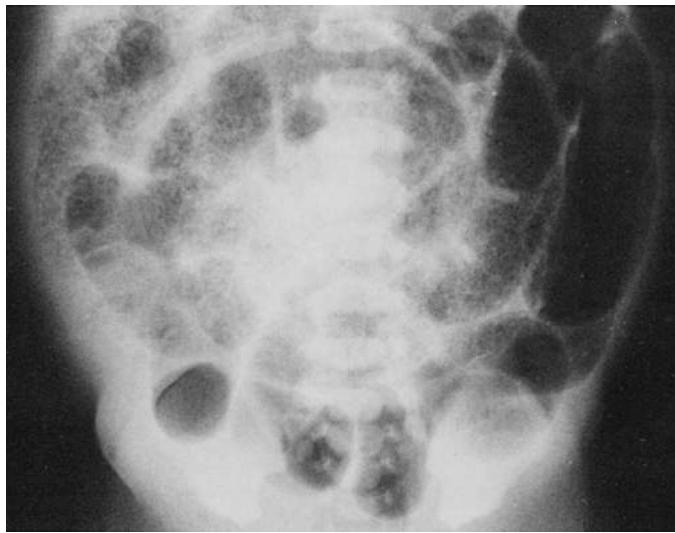
FIGURE 12.7 Intestinal obstruction.


FIGURE 12.6 Meconium ileus.

Meconium ileus and distal intestinal obstruction syndrome (DIOS). Ten percent of infants with cystic fibrosis present in the newborn period with failure to pass meconium, caused by meconium ileus (Fig. 12.6). The inspissated meconium may be treated by diatrizoate (Gastrografin) enema, but some infants require surgery, particularly if they have a perforated viscus, which occurs prenatally in 10% and produces a calcified meconium peritonitis. Virtually all infants with meconium ileus have cystic fibrosis; the diagnosis should be confirmed by sweat test or DNA analysis. Older children with cystic fibrosis who stop defecating and have abdominal pain and occasionally vomiting are said to have distal intestinal obstruction syndrome (DIOS), formerly termed meconium ileus equivalent.

The sticky, poorly hydrated intestinal mucus plays a role. Initial treatment with intestinal lavage and enemas may be successful, but, if not, diatrizoate (Gastrografin) enemas (at times mixed with

N-acetylcysteine) are nearly always successful. Surgery is rarely required. Close attention to fluid and electrolyte balance is vital in all infants and children treated with a hypertonic contrast medium such as diatrizoate (Gastrografin).

Incarcerated hernia. Whenever vomiting is accompanied by signs of obstruction, sites of potential herniation should be examined for incarceration of a loop of bowel (Fig. 12.7). Inguinal incarceration is most common, but other types of hernias are femoral, obturator, spigelian, umbilical (1 in 1500 incarcerate), epigastric, mesenteric, and postoperative incisional hernias.

Inguinal hernias are often reduced by gentle, firm, constant pressure that is directed through the scrotum toward the inguinal canal. Sedation and the Trendelenburg position may facilitate reduction.

Malrotation and volvulus. Volvulus is the twisting of a loop of bowel on the mesentery. Midgut volvulus occurs most often in the context of congenital intestinal malrotation, in which the small intestine is not normally fastened in place. This may only be clinically apparent on upper GI fluoroscopy when the duodenum and distal small bowel is seen to fill with contrast right of midline without crossing to the left upper quadrant (Fig. 12.8). More than half of patients found to have malrotation present symptomatically (the rest of such cases are discovered incidentally), and about half of the symptomatic patients present in the neonatal period with bilious vomiting caused by volvulus. Those presenting later often do not have bilious vomiting; the vomiting may be intermittent for years.

Volvulus is an extremely hazardous obstructing lesion. The luminal obstruction is closed at both ends, which leads to sepsis from rapidly proliferating and translocating bacteria. There is also vascular obstruction in which the root of the mesentery is twisted, which quickly produces ischemia of the small intestine. Even if volvulus is diagnosed and repaired promptly, massive intestinal resection may be necessary; this produces short bowel syndrome. Because volvulus may be intermittent, it may produce episodic or chronic intermittent vomiting or nonspecific abdominal pain before a lethal event. Upper intestinal contrast radiographs should be considered in the intermittently regurgitating infant, and surgery must be performed if a malrotation is

FIGURE 12.8 Contrast fluoroscopy (upper GI series) demonstrating malrotation. Note the small bowel fills with contrast all to the right of midline and does not cross over the left upper quadrant where the ligament of Trietz would be normally located.

FIGURE 12.9 Enteroenteric intussusception *(arrows)*.

found (i.e., if the ligament of Treitz is not to the left of the spine), even if volvulus is not present at the time of the examination. In an infant in whom an ongoing volvulus is suspected, an abdominal flat plate may show a "double bubble with distal air" or a "volvulus/corkscrew" pattern. In the sick infant or child in whom volvulus seems likely, surgery without contrast studies may be preferred. Surgery deals both with the malrotation and with the often-accompanying, potentially obstructing Ladd bands.

Other types of volvulus not associated with malrotation include cecal, sigmoid, and transverse colonic volvulus. They are less common in children and less apt to produce short bowel syndrome, but they, too, may manifest with vomiting and result in death if untreated. Sigmoid volvulus is sometimes treated nonoperatively.

Meckel diverticulum. Meckel diverticula may cause obstructive vomiting by intussusception (Fig. 12.9) or by intestinal volvulus around a fibrous band. They may also cause vomiting by inflammatory changes, and they may bleed. This fibrous remnant of the omphalomesenteric duct is a small intestinal diverticulum. The "rule of 2s" identifies characteristic findings: These diverticula are present in 2% of the population; the male-female ratio is 2:1; the diverticula occur within 2 feet of the ileocecal valve and are 2 inches long; there are 2 major types of heterotopic mucosa (50% of patients have gastric mucosa, and a minority have pancreatic mucosa; in rare cases, colonic mucosa is present); the condition is confused with 2 diseases (appendicitis and peptic ulcer); and there are 2 complications (hemorrhage occasionally with perforation or intussusception).

Diagnosis of the ectopic gastric mucosa is by Meckel scan (technetium 99m pertechnetate); it has imperfect sensitivity, which may be improved by pentagastrin, glucagon, and cimetidine. Treatment is surgical.

Intussusception. The normal function of the intestine is to constrict above and relax below an intraluminal bolus. When such a bolus (a "lead point") is attached to the intestinal wall, the propulsive activity of the intestine produces telescoping of proximal intestine

(intussusceptum) into distal intestine (intussuscipiens), causing both luminal obstruction, and mesenteric vascular compromise. Abdominal pain occurs in nearly all children with intussusception, whereas vomiting results in about 65%, and "currant-jelly stools" (from mucosal hemorrhage) occur in fewer than 20%. The pain is severe, crampy, and often contemporaneous with the vomiting. Between cramps, the child may be listless, may sleep, or may even play. Vomiting and bloody stools are more common in younger infants and in those with longer duration of symptoms. An abdominal mass is palpable in about 25% of patients.

The lead point of the intussusception is usually ileal, with the intussusception ileocecal or ileocolonic. It is probable that prominent ileal lymphoid nodules provide the lead point for most young children presenting with intussusception, 66% of whom are younger than 2 years, with a peak incidence late in the 1st year of life. Other lead points (Meckel diverticulum [see Fig. 12.9], appendix, duplication, polyp, lymphoma, hematoma from trauma or from Henoch-Schönlein purpura) or disorders (cystic fibrosis) must be considered in the very young or older child presenting with intussusception. Transient recurrent small bowel intussusception may also be a feature of celiac disease.

Visualization may be by ultrasonography if the diagnosis is uncertain but is more often by radiographic studies, inasmuch as radiologic reduction enemas are usually curative in infants.

Treatment is by hydrostatic reduction with barium; rectal insufflation of air has also been used but may be less able to document a lead point that necessitates surgical resection. Contraindications to reduction by hydrostatic enemas include the presence of symptoms for longer than 48-72 hours, peritonitis, and intestinal perforation. Approximately 10% of patients experience recurrences.

Superior mesenteric artery syndrome. Superior mesenteric artery (SMA) syndrome is caused by extrinsic compression of the duodenum, which is trapped between the SMA anteriorly and the aorta posteriorly as the SMA crosses over the duodenum in the root of the mesentery. The compression is usually just to the right of midline, where it produces a cutoff of the duodenum that is visible radiographically, often with proximal dilation. Synonyms include Wilkie syndrome, arteriomesenteric duodenal compression, and cast syndrome.

SMA syndrome may be suspected when bilious emesis and epigastric discomfort relieved by vomiting occur in the context of weight loss, lordosis, body casts, lengthy bed rest, or prior abdominal surgery, particularly when crampy pain is relieved by prone or knee-chest positions. Adolescents and young adults are most often affected.

Nutritional rehabilitation, either intravenously or by the enteral route, is important in SMA syndrome. The prone position may improve duodenal emptying. Surgery may be needed if there are chronic symptoms despite nutritional rehabilitation.

Constipation, meconium plug, and anal stenosis. These distal colonic problems produce obstipation primarily, but if they are severe and persistent, vomiting may result. Rectal examination provides the diagnosis. Enemas, laxatives, dietary changes, and behavioral modification are useful in treating constipation, whereas surgery is usually necessary to treat anal atresia or stenosis. Infants with meconium plug syndrome need clinical follow-up to monitor for the presence of coexistent Hirschsprung disease.

Gastrointestinal Dysmotility
Achalasia
Achalasia, like esophageal stenoses and strictures, produces effortless retrograde emptying of undigested food from the esophagus. Contrast radiography and esophageal manometry are needed for diagnosis. Nifedipine, sildenafil, and botulinum toxin have been reported to produce at least temporary clinical benefit in many patients, but ultimately balloon pneumatic dilation or surgical myotomy are required for sustained benefit.

Gastroesophageal Reflux
The apparently effortless *regurgitation* that represents gastroesophageal reflux in infants is of particular importance because (1) it is the most common cause of "vomiting" in infants; (2) physiologic reflux must be distinguished from reflux necessitating evaluation and therapy; and (3) the practitioner must be vigilant to avoid misdiagnosing other infantile vomiting diseases as reflux. Lethal malrotation with volvulus, partially obstructing duodenal web, and metabolic disorders are 3 examples of such misdiagnoses. Children with primary neurologic disease may be more likely to regurgitate and suffer from reflux disease; it must be remembered that many metabolic disorders manifest both as neurologic dysfunction and as regurgitation.

Reflux typically is a benign feature in healthy infants that improves and resolves in a predictable manner as a function of growth, development, acquiring upright positions, and introducing some solids in the diet. In these infants, regurgitation will be effortless and will not have associated failure to gain weight, feeding problems, or airway symptoms.

Infants with more problematic regurgitant reflux who come to medical attention should undergo upper gastrointestinal radiography to rule out the possibility of malrotation. Reflux may cause failure to gain weight (resulting from regurgitation of caloric feedings, odynophagia from esophagitis, or parental reluctance to feed a recurrently spitting infant), apnea, chronic respiratory disease, hoarseness or stridor, abdominal or chest pain, infantile irritability, or **Sandifer syndrome** (arching of the spine and turning of the neck). Regarding Sandifer syndrome, while the term is still utilized in the description of infants with reflux by some, one should recall that the original published description from 1964 described the sign in older children with profound neurologic impairment, and not in otherwise unremarkable healthy infants. Diagnostic evaluation should be tailored to the presentation: Regurgitation prompts barium contrast radiography with fluoroscopy; anorexia or infantile irritability prompts evaluation for esophagitis by endoscopy with esophageal biopsy, esophageal biopsy

alone if feasible, or possibly pH study if no response to a 2-week trial of hypoallergenic formula and/or acid suppression is noted; apnea prompts pH or impedance study to be conducted with a sleep study (especially if the apnea is repetitive); hoarseness or stridor prompts laryngoscopy, endoscopy for esophageal histologic study, or possibly a trial of aggressive therapy that may include proton pump inhibitor (PPI) agents; heartburn prompts a 2- to 4-week trial of either histamine-blocking or PPI agents, followed by endoscopy if no response is seen or if symptoms resume as medication is tapered. In the setting of asthma, signs or symptoms of reflux should prompt evaluation by endoscopy with biopsies and pH/impedance testing. Coincident reflux disease or eosinophilic esophagitis require treatment; in settings where these are not found, empirical treatment of asthma with acid suppression is not effective and therefore not warranted.

Treatment of regurgitant reflux in infants is initiated with avoidance of seated or supine positioning (particularly postprandially) and with thickening of the feedings with 1 tablespoon of dry rice cereal per ounce of formula. In many infants, this reduces regurgitation remarkably. Problematic regurgitation persisting during this treatment, particularly if associated with poor weight gain or other signs of illness, necessitates upper gastrointestinal fluoroscopic evaluation and consideration of other causes for the vomiting, such as metabolic or allergic disease. A 2-week trial of a protein hydrolysate or elemental formula as empirical therapy for allergic vomiting (formula protein intolerance) may be helpful, particularly if there is a family history of allergy or if there is peripheral eosinophilia. If the diagnosis remains reflux, a prokinetic agent is frequently begun. Metoclopramide may be used; although its efficacy in reflux has never been proved, its therapeutic margin is narrow, and its side effect profile is concerning. An oral H_2-receptor antagonist or proton pump inhibitor is added if esophagitis is suspected or documented. In view of the current limitations and uncertainties surrounding prokinetic agents, however, many infants and children may be adequately managed with aggressive acid suppression alone.

Management is re-evaluated at least every 2 months for the need to increase doses, to discontinue medications, or to re-evaluate the diagnosis. Infants with reflux usually improve on this management, which can usually be discontinued between 8 and 18 months of age, as symptoms resolve. The rare infant who does not improve and develops nutritional, respiratory, or peptic complications from reflux is evaluated for surgical fundoplication (Fig. 12.10).

Gastric Stasis and Gastroparesis
Gastric stasis is suggested by the vomiting of food eaten hours earlier and by the presence of food in the stomach of a fasting patient undergoing an upper gastrointestinal series. If the contrast study excludes gastric outlet obstruction, gastroparesis is likely. Diabetic gastroparesis, in which autonomic neuropathy resulting from diabetes causes gastric atony, is the classic example of this disorder but is rare in childhood. Surgical vagotomy produces similar symptoms (typically in the setting of operated congenital heart disease). Other causes of generalized ileus or pseudoobstruction can involve the stomach primarily. Viral infections, perhaps including gastric cytomegalovirus, and drugs such as anticholinergics may also produce gastric stasis.

Gastric stasis may respond to the prokinetic agents, erythromycin or metoclopramide, particularly if the cause is neurogenic. These medications may have additive effects.

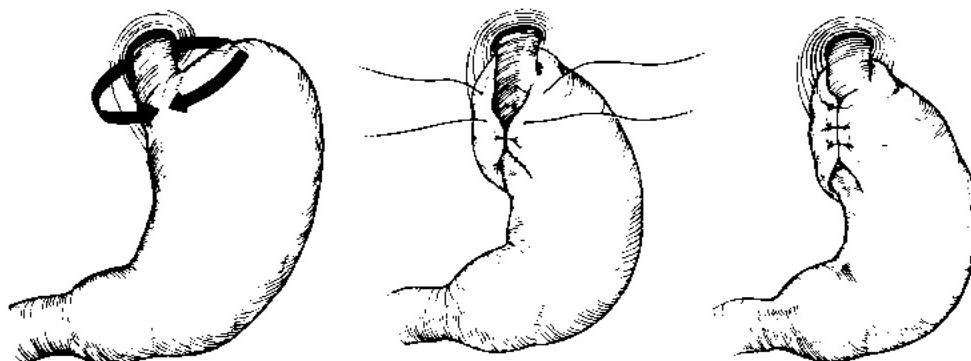
Ileus
Paralytic ileus, typified by the postoperative ileus that follows most abdominal surgery, is very common. As in intestinal obstruction,


FIGURE 12.10 Diagrams of a Nissen fundoplication.

intestinal contents fail to progress, causing abdominal pain and vomiting. Typically, the bowel sounds are decreased or absent; there may be abdominal distention. Other causes of ileus include unrelieved intestinal obstruction, peritonitis, intestinal ischemia, and sepsis. Signs of ileus may follow signs of intestinal obstruction; in this context, ileus is an ominous sign. Other causes of paralytic ileus are drugs (phenothiazines, narcotics, laxative abuse, atropine), electrolyte disturbances (hypokalemia, hypercalcemia), endocrinopathies (hypothyroidism), or injuries (spinal fractures). Both chemotherapy and radiation therapy can produce reversible acute symptoms of vomiting, abdominal pain, and diarrhea within a few days to several weeks of the insult; intestinal motor disturbances are the suggested cause.

Treatment of ileus requires correction of any correctable provocative abnormalities and nasogastric tube decompression until normal peristalsis begins.

Pseudoobstruction

Intestinal pseudoobstruction represents intestinal dysmotility rather than obstruction. Pseudoobstruction is a chronic illness, sometimes with remissions and relapses, and is far rarer than acute ileus. Enteroclysis radiographic studies may be necessary to confirm the absence of partial obstruction. There is a family history in 20-30% of patients, and nearly 50% of children with the disorder are symptomatic in the 1st month of life, although diagnosis is often quite delayed. **Malrotation** may be found in up to 40% of patients with pseudoobstruction. The disorder may involve any part or the entire luminal gastrointestinal tract and occasionally (in up to 10% of patients) involves the urinary tract. A relatively quiet abdomen or prominent borborygmi may be present, and abdominal distention (in 70% of patients) is often associated with succussion splashes when the patient moves. Vomiting occurs in 50% of patients, and constipation may be prominent (in >50%). Weight loss is caused by both vomiting of nutrients and by bacterial overgrowth–induced malabsorption.

Several causes for pseudoobstruction have been identified; they are generally classified as either **neuropathic** or **myopathic**. Familial versus nonfamilial and primary versus secondary are 2 other classifications. Differentiation between neuropathic and myopathic types is best made by small intestinal manometry; esophageal manometry may contribute as well. Full-thickness intestinal biopsy is sometimes useful for distinguishing specific entities causing the disorder; special silver stains of the myenteric plexus are particularly helpful. The myopathic causes (in 10% of pediatric patients, a much lower proportion than that of adults) include collagen vascular causes of myositis or muscle fibrosis (progressive systemic sclerosis), various muscular dystrophies, megacystis-microcolon, and "familial visceral myopathies." The neuropathic causes (90%) include Hirschsprung disease, Chagas disease,

diabetic and other autonomic neuropathies, autoimmune disorders producing inflammatory neurodegeneration, multiple endocrine neoplasia, and "familial visceral neuropathies." Both types of pseudoobstruction are difficult to manage; the myopathic form, representing dysfunction of the "end organ," is particularly difficult.

A 3rd category that is sometimes included in the myopathic type is fibrotic involvement of the muscularis propria. It may follow collagen vascular diseases, radiation therapy (>6 months after), or chemotherapy by months or years, causing either myopathic pseudoobstruction or obstruction resulting from inflammatory strictures.

Functional failure of intestinal propulsion can be treated with erythromycin or metoclopramide. These medications are more apt to be useful in neurogenic disorders than in myogenic ones. Because of their different sites of action, they may have additive effects. Patients with pseudoobstruction also benefit from antibiotic treatment of bacterial overgrowth syndrome, when present, or from nutritional rehabilitation with total parenteral nutrition. Collagen vascular or autoimmune causes of pseudoobstruction may respond to steroids. Cautious surgery is occasionally beneficial; some patients eventually require intestinal transplantation.

Gastrointestinal Inflammation
Esophagitis
Esophagitis may be associated with vomiting in the setting of eosinophilic esophagitis (EoE), where patients may also experience nausea and/or dysphagia. With regard to reflux disease, esophagitis is associated with vomiting, but it is usually not the primary cause.

Gastroenteritis
Gastroenteritis is a frequent cause of acute vomiting illness in childhood. The vomiting is often associated with diarrhea and sometimes with crampy abdominal pain or fever. Rotavirus, especially in infants, is notable for its prominent vomiting, which often precedes the diarrhea. "Food poisoning" also produces vomiting and diarrhea, often caused by bacterially derived toxin. The time course and symptoms suggest which organism is involved. Gastroenteritis, like regurgitant reflux, is common and often necessitates minimal diagnostic procedures and therapy; however, the examiner must constantly guard against making this diagnosis in a child who might have metabolic or surgical disease.

Treatment of acute gastroenteritis mandates attention to hydration. Oral rehydration is feasible in many children with gastroenteritis, but prominent vomiting may make intravenous rehydration necessary. A common error is to use clear liquids longer than 24 hours; this leaves nutritional needs unmet. Early refeeding in gastroenteritis is most successful when the food is low in fat and lactose and high in complex carbohydrates.

Peptic Ulcer Disease

The term *peptic ulcer disease* includes gastritis, gastric ulcer, duodenitis, and duodenal ulcer. In children, in contrast to adults, these disorders frequently cause vomiting. Defined causes for peptic ulcer disease include *H. pylori* infections, bile reflux gastritis, nonsteroidal anti-inflammatory agents, and rare gastrin-secreting tumors (Zollinger-Ellison syndrome). Stress ulcers occur in the context of sepsis, burns, surgery, head trauma, and severe acute illness.

The optimal diagnostic method is endoscopy, with evaluation for *H. pylori* or elevated gastrin in appropriate cases. Acid suppression is the preferred treatment. Discontinuation of tobacco smoke exposure is important. *H. pylori* infections are treated with evolving regimens of double or triple antibiotics plus acid suppression drugs; eradication rate is approximately 85% for most treatments. Zollinger-Ellison syndrome is optimally treated by tumor resection and evaluation for related endocrine tumors; PPI treatment is helpful if complete tumor resection is impossible.

Meckel Diverticulitis

In addition to presenting as gastrointestinal obstruction, via volvulus or intussusception, Meckel diverticula may become inflamed and mimic appendicitis.

Treatment is surgical, so preoperative distinction of Meckel diverticulitis from other causes of an acute abdomen is not crucial.

Mesenteric Adenitis

Mesenteric adenitis is often found on CT scans and refers to inflammation of lymph nodes in the mesentery. It is probably caused by viral (adenovirus, measles) or bacterial (*Yersinia enterocolitica*) infection, but the symptoms are similar enough to appendicitis that the diagnosis is usually not made before surgery. Ultrasonography can readily distinguish mesenteric adenitis from appendicitis.

Appendicitis

When vomiting occurs in appendicitis, it follows the periumbilical pain but may precede the localization of the pain to the McBurney point, two-thirds of the way between the umbilicus and the right anterior iliac spine. Before perforation, there is only occasional vomiting. After perforation, the fever may be higher; the child lies still with the right hip flexed, and vomiting may be more frequent and more feculent. In appendicitis, there is later vomiting, less diarrhea, fewer bowel sounds, and

more rectal or rebound tenderness than in gastroenteritis. It is also associated with less diarrhea, less fever, and less leukocytosis than is bacterial enteritis, although *Yersinia,* in particular, has caused right lower quadrant pain mimicking appendicitis. Crohn disease is usually more chronic than is appendicitis but sometimes is diagnosed by surgeons at the time of appendectomy based on serosal changes to the bowel.

Inflammatory Bowel Disease

Crohn disease, in particular, may produce vomiting on occasion, particularly when obstructing intestinal strictures develop. Other extraintestinal manifestations of Crohn disease also, in rare cases, produce vomiting.

Allergic Enteropathy, Eosinophilic Gastroenteropathy, and Eosinophilic Esophagitis

Vomiting is a frequent response to ingestion of allergens and may be seen as early as the 1st weeks of life in infants with allergy to cow's milk or soy and in older children as potentially allergenic foods are introduced. There may be associated diarrhea and hematochezia and, in some children, urticaria or other systemic signs of allergy. A strong family history for allergic diathesis is very suggestive. Laboratory studies may show peripheral blood eosinophilia or an elevated serum immunoglobulin E level; positive radioallergosorbent test results to individual foods are helpful if present.

In infants, the simplest diagnostic test is a change to a protein hydrolysate or elemental formula for at least 2 weeks. If the vomiting (and other symptoms) resolve, it is generally not necessary to rechallenge for diagnosis, but empirical treatment can be continued for several months. Because infants usually outgrow these formula protein intolerances between 10 and 24 months of age, a normal diet can later be gradually introduced as tolerated. Older children with vomiting that represents eosinophilic gastroenteropathy or other immunoglobulin E–mediated food allergy are less likely to lose the allergy over time. Diagnosis otherwise is by upper intestinal endoscopy with biopsies, which demonstrate an increased number of mucosal and intraepithelial eosinophils and, possibly, varying degrees of villous injury. Eosinophilic esophagitis, which may occur independently of eosinophilic gastroenteropathy, should be kept in mind, particularly with patients manifesting dysphagia or reflux symptoms poorly responsive to standard therapy. At endoscopy, the esophageal mucosa displays a ringed or furrowed appearance with granularity (Fig. 12.11).

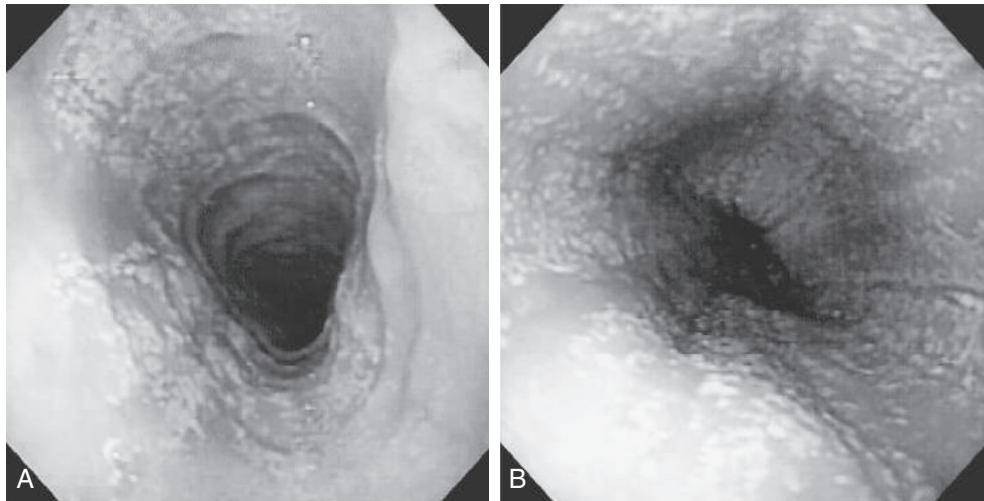

FIGURE 12.11 Endoscopic appearance of eosinophilic esophagitis, demonstrating concentric rings in proximal esophagus *(A)* and granularity with mucosal furrowing in distal esophagus *(B)*.

(See *Nelson Textbook of Pediatrics,* p. 1819.)

If sensitization to particular foods is identified through radioallergosorbent or skin testing, an elimination diet is employed; patients with prohibitive numbers of food allergies may require an amino acid–based diet. Steroids may be necessary for children with negative investigation findings for food allergy or for whom compliance with a restricted diet is problematic.

Gastrointestinal Ischemia and Vascular Insufficiency

Some of the causes of gastrointestinal ischemia can produce perforation, peritonitis, and death quite rapidly. Chronic low-grade gastrointestinal ischemia has also been described in high-level endurance athletes. A high degree of suspicion is useful because the signs are nonspecific.

Abdominal Migraine

In this periodic syndrome of abdominal symptoms, epigastric or periumbilical pain may accompany nausea and vomiting. Diarrhea, fever, chills, vertigo, irritability, and polyuria have also been reported. The symptoms are probably a result of muscular constriction of the mesenteric arteries, which causes ischemia. Some pathophysiologic overlap with cyclic vomiting syndrome also has been proposed. When these abdominal symptoms coexist with head pain, which occurs in 30-40% of patients with migrainous headaches, the diagnosis is simpler than when they occur in isolation, which happens in about 3% of patients who later experience typical migrainous headaches. Usually, isolated abdominal migrainous attacks occur suddenly, last an hour to days, and are consistent in character within the same individual. There is usually a family history of migraine, and patients are asymptomatic between attacks. A personal history of car (motion) sickness may be present. Abdominal migraine is closely associated with the cyclic vomiting syndrome (Table 12.16). Symptoms of abdominal migraine often respond to prophylactic propranolol, cyproheptadine, or amitriptyline.

Vasculitis

Inflammation of the mesenteric vessels is uncommon but may cause gastrointestinal complaints, including vomiting, abdominal pain, diarrhea, and gastrointestinal bleeding. Henoch-Schönlein purpura is the most common pediatric vasculitis; systemic lupus erythematosus, dermatomyositis, polyarteritis nodosa, and other hypersensitivity vasculitides are occasional causes. The most diagnostic sign of **Henoch-Schönlein purpura** is the palpable purpuric rash, typically found on the buttocks, posterior legs, and feet in 97% of patients. However, because the vomiting or hematemesis and the nonspecific abdominal pain (found in nearly 90%) may precede the rash, the

diagnosis may initially be obscure. Repeated examination of the skin of a child with persistent vomiting and pain is therefore useful, particularly when the gastrointestinal symptoms are accompanied by polyarthritis, which occurs in 65% of such patients. Platelet function and coagulation studies are normal; hematuria is often present. Steroids may shorten the abdominal pain by 1 or 2 days, but they might also mask symptoms of accompanying intussusception or perforation.

Volvulus and Intussusception

Volvulus and intussusception have been discussed earlier, but, as noted, some of the symptoms and complications result from vascular obstruction and ischemia.

Mesenteric Ischemia

The mesenteric arteries may be occluded by emboli from a diseased heart or from thrombi formed locally. Nonocclusive ischemia may be caused by poor cardiac output, hypotension, dehydration, or endotoxemia. Mesenteric venous occlusion is very rare. Severe, crampy, diffuse abdominal pain may be accompanied by vomiting, diarrhea, or constipation. The crampy pain becomes continuous, and gangrene, peritonitis, sepsis, and shock supervene.

In a suggestive setting (e.g., heart disease), vomiting accompanied by diffuse severe abdominal pain should suggest the possible need for mesenteric and celiac angiography and emergency surgery. Acute arterial insufficiency may be preceded by chronic symptoms of "abdominal angina," which are episodes of several hours of crampy pain beginning about 20 minutes after meals. Such premonitory symptoms in suggestive settings should receive serious attention.

Gastrointestinal Perforation and Peritonitis

Gastrointestinal perforation is often the end stage of obstructing, inflammatory, or ischemic disorders. Perforation is heralded by sudden abdominal pain, with subsequent signs of peritonitis. Perforated peptic ulcer pain may track to the right lower quadrant and mimic appendicitis, but the onset is more sudden, and the child is sicker than with appendicitis. Shock, metabolic acidosis, sepsis, and disseminated intravascular coagulopathy may ensue. Vomiting is not prominent.

When luminal obstruction leads to perforation and peritonitis, the abdominal findings change in characteristic ways. Vague, crampy, periumbilical pain becomes sharp, continuous, and localized. Rushes of increased, high-pitched bowel sounds disappear, leaving the abdomen silent. The active, sometimes writhing child becomes still. Vomiting previously associated with cramping pain is no longer present. The physical examination discloses point tenderness, abdominal rigidity, involuntary guarding, and rebound tenderness.

Hepatobiliary Disorders
Hepatitis

The presence of acute viral hepatitis is usually suspected in patients who have jaundice, but up to 50% of patients with hepatitis A are anicteric, and even those in whom jaundice develops have a preicteric prodrome lasting up to a week. In children with acute hepatitis, therefore, the presenting symptom may be vomiting, another reason for including liver enzymes in the screening evaluation of the ill-appearing vomiting child. The vomiting is often accompanied by fatigue, fever, headache, rhinorrhea, sore throat, and cough.

The findings of serum antigens and antibodies to hepatitis viruses establish the diagnosis. Acute hepatitis with vomiting is treated symptomatically. Management also includes watching for the ominous findings of progressive encephalopathy, ascites, and coagulopathy.

TABLE 12.16   Diagnostic Criteria for Cyclic Vomiting Syndrome

- At least 5 episodes overall or a minimum of 3 episodes noted in a 6-mo period
- Recurrent episodes of vomiting and nausea lasting 1 hr to 10 days and occurring at least 1-wk apart
- Stereotypical pattern and symptoms in the individual patient
- Vomiting during episodes occurring at least 4 times per hr for at least 1 hr
- Returning to baseline health between episodes
- Not attributable to another disorder

From Li BUK, Kovacic K. Vomiting and nausea. In: Wyllie R, Hyams JS, Kay M, eds. *Pediatric Gastrointestinal and Liver Disease.* 5th ed. Philadelphia: Elsevier; 2016:98.

Biliary Colic and Cholecystitis

Biliary obstruction produces vomiting and abdominal pain in children; the vomiting is usually less severe and occurs later than that in pancreatitis. Biliary colic is visceral pain resulting from transient obstruction of the cystic duct, usually by a stone. In occasional patients, biliary dyskinesia causes these symptoms. Biliary colic produces several hours of steady, vaguely localized pain, often in the right upper quadrant; most patients also have vomiting. Episodes of biliary colic commonly recur at unpredictable intervals, from weeks to years. Acute cholecystitis may ensue if the obstruction persists and leads to inflammation of the gallbladder. The pain may localize more clearly to the right upper quadrant and may radiate to the back or shoulder. There may be fever or mild jaundice. Serum alanine aminotransferase, aspartate aminotransferase, γ–glutamyl transpeptidase, alkaline phosphatase, and bilirubin levels may be elevated. In both biliary colic and acute cholecystitis, abdominal films and ultrasonography may disclose stones or gallbladder thickening. Common duct stones may produce concurrent elevations of liver enzymes and pancreatic enzymes. Recurrent biliary colic and cholecystitis are managed by cholecystectomy, which can be performed laparoscopically in many children. Endoscopic removal of common duct stones is also possible, although it does not prevent recurrence.

Pancreatitis

Pancreatitis is usually associated with epigastric abdominal pain, which may radiate to the back. Elevated serum amylase and lipase levels usually confirm the diagnosis.

Gynecologic and Urologic Disorders
Pyelonephritis

High fever, chills, nausea, vomiting, and, less often, diarrhea develop rapidly. There may be symptoms of cystitis with dysuria, frequency, urgency, and suprapubic pain. Costovertebral angle tenderness focuses the diagnosis on the urinary tract.

The urinalysis shows pyuria and bacteriuria, and the hemogram shows leukocytosis. Treatment is with antibiotics.

Ureteropelvic Junction Obstruction and Hydronephrosis

Ureteropelvic junction obstruction ("beer drinker's kidney," Dietl crisis) is caused by partial obstruction at the ureteropelvic junction and by the resulting hydronephrosis during fluid loading and diuresis. Congenital cases are usually diagnosed in the 1st year of life (usually on the basis of a renal hydronephrotic mass or urinary tract infection); 10-30% of affected older children present with flank or periumbilical pain, frequently accompanied by vomiting.

Typically, the symptoms commence in the evening after an increased fluid intake, although the hyperhydration history is often unclear. The child's pain and vomiting usually remit spontaneously in several hours, as dehydration gradually relieves the renal pelvic distention. Superimposed unilateral urinary tract infection may cause additional findings of fever, failure to thrive, and pyuria.

Ultrasonography at the time of an episode or after furosemide, or an intravenous pyelogram, provides the diagnosis; the treatment is surgical.

Renal Colic

Passage of a renal stone usually causes more pain than vomiting. Lateralized colicky pain, hematuria, and confirmatory radiologic studies assist the diagnosis.

Dysmenorrhea, Endometriosis, and Pelvic Inflammatory Disease

These gynecologic disorders manifest with lower abdominal pain but only occasionally manifest with vomiting. Association with menses or vaginal discharge aids the diagnosis. Motion of the cervix exacerbates the pain in pelvic inflammatory disease.

Ovarian Torsion

Torsion of a normal ovary occasionally occurs in girls of any age, probably caused by laxity of adnexal supports. Repeated attacks of crampy, lower abdominal pain culminates in a final acute episode with severe retching and vomiting, an enlarged ovarian mass, and eventual signs of peritonitis. Leukocytosis may be accompanied by fever. The location of the pain suggests the diagnosis, and the treatment is surgical.

Hyperemesis Gravidarum

Pregnant adolescents may have prolonged vomiting. In parallel to the experience with ruminating infants, esophagitis has been suggested to play a role in this disease.

Testicular Torsion

Testicular torsion is a vascular emergency. It is readily diagnosed by the site of pain; surgical treatment is required.

Respiratory Disorders
Sinusitis, Pharyngitis, and Otitis

Sinusitis may induce chronic, unexplained vomiting. The vomiting is more apt to occur in the morning and must be differentiated from serious intracranial processes. Sinus tenderness and sinus CT scans suggest the diagnosis, and a successful trial of antibiotic therapy confirms it. Less often, pharyngitis or otitis media may manifest acutely with nonspecific vomiting.

Pneumonia

Because pneumonia can also be caused by vomiting on the basis of aspiration, it is important to consider the direction of causality in children with pneumonia and vomiting. Aspiration of vomitus is particularly likely to occur in the context of obtundation or other neurologic dysfunction.

Central Nervous System Disorders
Increased Intracranial Pressure

Various causes of increased intracranial pressure (e.g., tumors) induce vomiting, typically described as projectile but without retching. This description may be an oversimplification, but the occurrence on awakening and before eating is important information.

A careful neurologic and funduscopic examination, attention to measurement of occipitofrontal head circumference, and relevant radiologic studies (CT or magnetic resonance scans) should help the examiner make the diagnosis.

Abdominal Epilepsy

The diagnosis of abdominal epilepsy is suggested by recurrent episodes of nausea or vomiting, usually accompanied by abdominal pain and by symptoms suggesting its central nervous system origin, such as headache, dizziness, confusion, or temporary blindness. Patients may sleep after an episode.

The diagnosis is aided by neurologic consultation, electroencephalography during an episode, and response to anticonvulsant therapy.

Vestibular Disorders, Motion Sickness

Motion sickness is a common experience in some situations. Vestibular disorders produce similar symptoms.

Because of the symptoms of nausea, nystagmus, vertigo, and dizziness, the diagnosis is usually obvious. Antihistamines and anticholinergics are particularly useful for motion sickness.

Ventriculoperitoneal Shunt Complications

Occlusion or infection of a shunt may produce vomiting on a neurologic basis, whereas the intraabdominal end of the shunt may provoke intestinal obstruction by volvulus, adhesions, or loculations. These possibilities must be kept in mind for the vomiting patient with a shunt.

Psychobehavioral Disorders
Psychogenic Vomiting

The syndrome of vomiting without organic cause illustrates the prominent influence that cortical and psychologic inputs may have in stimulating nausea and vomiting. Characteristic features of psychogenic vomiting include chronicity, association with stress and with meals, can be suppressed by distracting the patient, the patient's indifference toward the symptom itself, and relief by hospitalization. There may be no nausea or anorexia, and the vomiting may be self-induced.

Rumination

In the process of rumination, food is regurgitated, then mouthed or chewed and re-swallowed, apparently voluntarily and pleasurably. Adults and older children may regurgitate by contracting abdominal muscles; infants may put their fingers or fists deep in their mouths in an apparent attempt to stimulate regurgitation. Whereas such apparent self-stimulation probably has a psychogenic origin in many cases, some infants cease ruminating when esophagitis is treated, which suggests that in some cases what appears to be an attempt to stimulate the gag reflex may actually be a response to pain in the throat. Thus, diagnosis of and treatment for both psychogenic causes and esophagitis should be considered.

Two types of rumination, psychogenic and self-stimulating, have been described. The former tends to occur in normal infants with a disturbed parent-child relationship; the latter occurs in intellectually disabled individuals of any age and without regard to nurturing. Both positive reinforcement and negative reinforcement have been utilized in behavioral therapy.

Eating Disorders

Anorexia nervosa and bulimia are considered eating disorders primarily of psychogenic origin. However, symptoms of disordered upper gastrointestinal motility, including esophageal dysmotility, may manifest in a manner similar to these eating disorders, and patients with primary anorexia nervosa often manifest delayed gastric emptying, which may benefit from therapy with prokinetic agents.

Management

Psychiatric consultation and therapy are often needed for eating disorders, rumination, and psychogenic vomiting. Principles of behavior modification help to eliminate secondary gain from the vomiting. Nasogastric or nasojejunal feedings can be used to guarantee nutritional rehabilitation if voluntary oral nutrition is not readily reestablished; such tube feedings also provide the child with the incentive to return to oral nutrition. A prokinetic agent and H_2-receptor blocker therapy are often useful initially, both to treat esophagitis and to maximize forward movement of enteral nutrients through the gastrointestinal tract.

Metabolic Disorders

Metabolic diseases that cause vomiting are difficult to diagnose because they are both rare and diverse. Their diagnosis and treatment, however, are crucial because of the severe morbidity and death they can cause and their amenability to treatment. They are also important because of their relevance to genetic counseling, inasmuch as most metabolic disorders are hereditary, on an autosomal recessive basis. Situations that should prompt consideration of metabolic diseases are listed in Table 12.10.

The history and physical examination (Table 12.17) and screening studies (Table 12.18) that help distinguish among many of the specific metabolic disorders provide useful clues. Laboratory studies should be done while the child is symptomatic. Vomiting accompanied by hyperammonemia is a particular diagnostic problem, for which a schematic is presented in Fig. 12.12.

Poisonings and Drugs

Most ingested poisons, and some absorbed by inhalation, skin contact, or intravenous administration, induce vomiting, which can be seen as a physiologic protection against harmful substances. Symptoms and signs of some of the most common pediatric poisonings causing vomiting are indicated in Table 12.19. Acute known poisonings, either accidental or intentional, are a management problem rather than a diagnostic one and a Poison Control Center or other toxicology resources may be helpful.

Initial diagnostic evaluation can be directed by a careful search of the environment for poisonous items and by toxicology screens on blood, urine, vomitus, and stool; these materials should not be discarded. A few agents, such as lead, cause chronic poisoning, manifested by vomiting, among other symptoms. Because it may be particularly difficult to suspect and treat these poisonings, an index of suspicion of poisoning is important in the chronically vomiting child. Laboratory studies that are useful in addition to toxicology screenings are presented in Table 12.20.

Hematemesis

Endoscopic evaluation (and therapy) is often needed for children with hematemesis. Before such evaluation, however, it is important to know the most likely causes (see Table 12.13). The physician should also have determined that there is no underlying coagulopathy necessitating correction (see Table 12.14) and that hematemesis is a primary symptom, not a secondary one caused by a Mallory-Weiss tear.

Peptic ulcer disease, particularly duodenal ulcer, is the most common cause of hematemesis in children; in newborns, swallowed maternal blood (uterine, breast milk), esophagitis, gastritis, and duodenal ulcers are most common; in preschool children, gastric ulcers predominate; and in older children and adolescents, duodenal ulcers are most common. Esophagitis is occasionally severe enough to cause hematemesis, as is Barrett ulcer, a premalignant lesion superimposed on chronic esophagitis. Obstructive lesions such as pyloric stenosis and antral webs are occasionally associated with hematemesis.

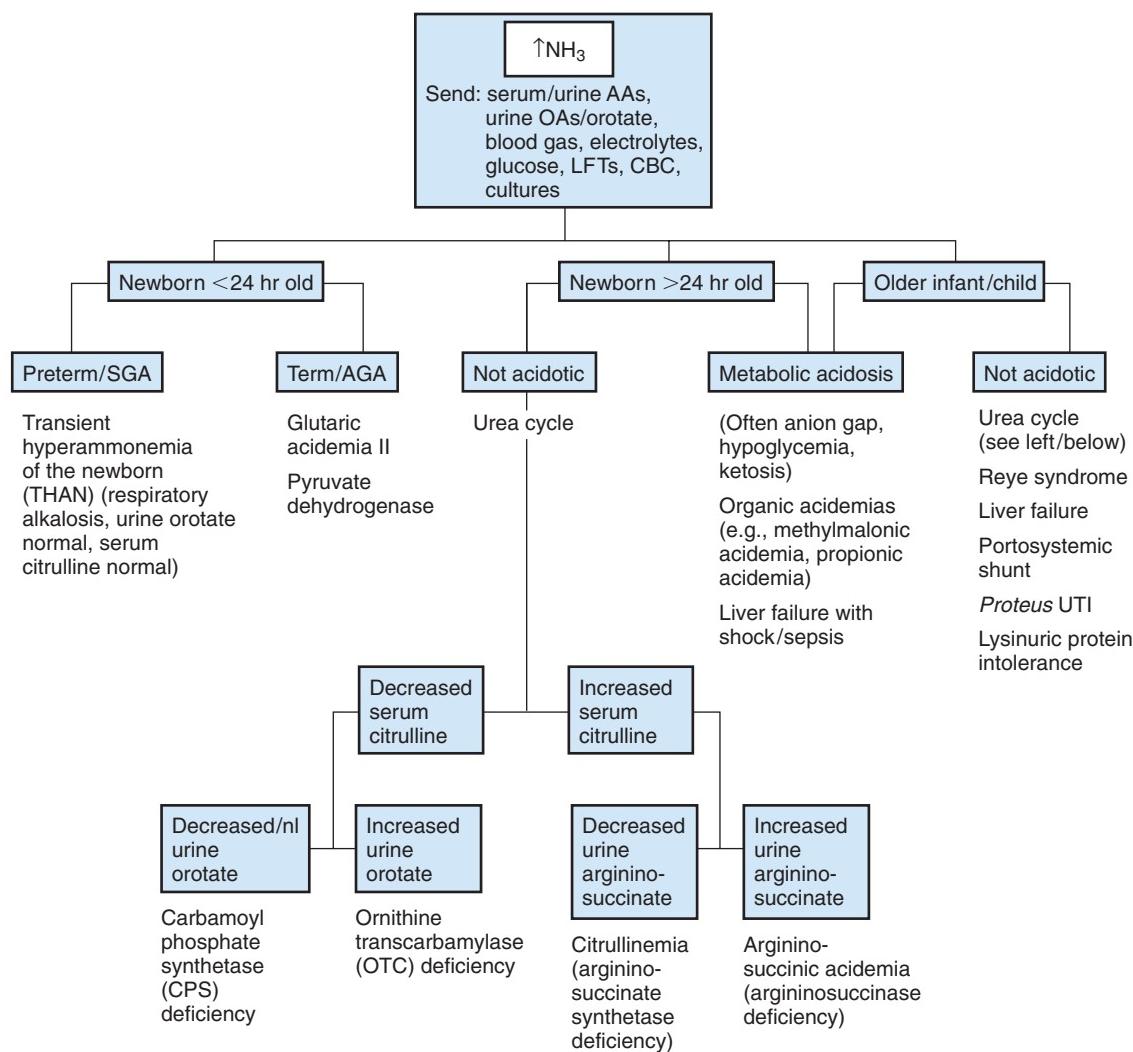
Variceal bleeding is uncommon but serious. Gastric vascular malformations are rare and serious and may be difficult to diagnose. Duplications are lined by gastric mucosa in 30% of affected patients; if they are located above the ligament of Treitz, they may cause hematemesis. The metabolic and toxic (iron, salicylates, theophylline, corrosives, isopropyl alcohol, mushroom poisoning) causes of hematemesis should be kept in mind.


FIGURE 12.12 Flow diagram for evaluation of hyperammonemia in children. AAs, amino acids; AGA, appropriate for gestational age; CBC, complete blood count; LFTs, liver function tests; NH₃, ammonia; OAs, organic acids; SGA, small for gestational age; UTI, urinary tract infection.

Therapy of hematemesis includes, as needed, correction of any abnormalities of coagulation: hemostasis, stabilization of hemodynamic status, and direct attention to the bleeding site endoscopically (e.g., heater probe, injection therapy) or surgically. Reduction of gastric acid secretion pharmacologically is useful in virtually all cases of hematemesis and carries minimal risk.

Other Causes of Vomiting
Chemotherapy
Chemotherapy causes predictable vomiting, which is usually not a diagnostic but a management problem. It may be complicated by anticipatory vomiting. Ondansetron, high-dose metoclopramide (accompanied by diphenhydramine for prophylaxis of extrapyramidal side effects), dexamethasone, and the marijuana-related nabilone have all shown some effectiveness against chemotherapy-induced vomiting. Anxiolytics may also be beneficial as a component of combination antiemetic therapy.

Radiation Therapy
Like chemotherapy, radiation therapy may cause acute vomiting, apparently by stimulating giant retrograde peristaltic waves.

Subacutely, diarrhea predominates as a complication of radiation therapy. Months to years later, vomiting may again be a result of radiation therapy, often caused by inflammatory ulcers and strictures. These lesions are difficult to treat without surgery.

Cyclic Vomiting
Cyclic vomiting syndrome (CVS) is a chronic, potentially disabling condition marked by a history of three or more bouts of intense, acute nausea and vomiting that may last hours or days, punctuated by entirely symptom-free intervals that last weeks to months (see Table 12.16). Work-up, which may ultimately include endoscopy and imaging studies of the gastrointestinal tract and brain, reveals no evidence of significant underlying primary disease. Typically, bouts begin in children 2-7 years old (range, 6 months to 18 years) and occur an average of 12 times yearly (range, 1-70). For a particular patient, episodes tend to begin at the same time of day (usually during the night or early morning hours) and have similar durations. An inciting event such as an infection or emotional excitement can be identified in 80% of episodes. Bouts are often accompanied by pallor, intolerance of noise or light, abdominal pain, or diarrhea. The pathophysiologic process of CVS remains speculative at this time but may

overlap with that of migrainous phenomena. One hypothesis purports that stress-initiated release of corticotropin-releasing hormone leads to cascading production of substances, such as adrenocorticotropic hormone, antidiuretic hormone, histamine, and catecholamines, which in turn mediate the syndrome's signs and symptoms. Some children may harbor subclinical defects in mitochondrial fatty acid oxidation metabolism or neuronal ion channel function that heighten their susceptibility to attacks when confronted by the increased cellular energy needs created by a physiologic or emotional stressor. Although CVS is now becoming better characterized, the physician should not be lulled into missing treatable, "look-alike" organic conditions. Reported cases of organic disease mislabeled "cyclic vomiting" have included intermittent intussusception or volvulus caused by enteric duplication, diverticulum, or malrotation; increased intracranial pressure in patients with shunts who have slit ventricles; and toxic or metabolic disease. Additional considerations in the differential diagnosis include brainstem glioma, obstructive uropathy, porphyria, and familial dysautonomia.

In CVS, the patient experiences nausea and pallor during the stereotypical and characteristic episodes but is symptom-free between episodes.

Medications potentially useful in CVS prophylaxis and in treatment of acute episodes are listed in Table 12.21.

Porphyria

Acute intermittent porphyria is an autosomal dominant disorder of episodic abdominal pain (85-95% of patients); 40-90% of patients have associated vomiting. The association of neurologic symptoms such as mental symptoms (50%), muscle weakness (50%), sensory loss (20%), and convulsions (15%); the onset after puberty; and the frequent association with menses or provocative drugs (phenobarbital) are suggestive. Elevated levels of porphobilinogen and δ-aminolevulinic acid in urine are suggestive, and decreased red blood cell porphobilinogen deaminase is diagnostic.

Familial Mediterranean Fever (Benign Paroxysmal Peritonitis, Periodic Peritonitis, Polyserositis)

Episodic attacks of abdominal pain with rapid development and resolution (within 48 hours) of peritoneal signs (fever, vomiting, absent bowel sounds) occurring in a child of Israeli or North African descent should suggest this autosomal recessive diagnosis. Synovitis, pleuritis, and an erysipelas-like skin lesion are also characteristic. The erythrocyte sedimentation rate is raised. Fifty percent of patients have their first attack between 1 and 10 years of age; 90%, by age 20. Amyloidosis, a possible etiologic role for C5a inhibitor deficiency, and probable response to colchicine has been described. Definitive genetic testing is now available for detection of the familial Mediterranean fever gene, which has been localized to the short arm of chromosome 16.

Familial Dysautonomia

Familial dysautonomia may manifest with episodic vomiting. It is an autosomal recessive disorder of the sensory and autonomic nervous systems affecting children of Ashkenazi Jewish descent. The gene for familial dysautonomia has been localized to the distal long arm of chromosome 9, allowing for both prenatal diagnosis and identification of carriers. Associated symptoms include disturbed swallowing, drooling, frequent pneumonias, absence of overflow tearing, erratic temperature control, skin blotching, postural hypotension, relative indifference to pain, corneal anesthesia, breath-holding spells, motor incoordination, spinal curvature, and growth retardation. Glossal fungiform papillae are also absent. The disease is diagnosed with the intradermal histamine test or the conjunctival methacholine (or pilocarpine) test. Management is complex and requires a multidisciplinary team.

Complications of Vomiting

The complications of vomiting are shown in Table 12.22. Their importance is twofold. First, these complications, particularly the metabolic, nutritional, esophagitis, and hemodynamic ones, must be treated. Second, there may be diagnostic implications. Hematemesis resulting from Mallory-Weiss tear should be distinguished from primary hematemesis caused by some other lesion. Metabolic acidosis or hyperkalemia should be recognized as atypical for vomiting illnesses and possible crucial signs of metabolic disease or severe intraabdominal disease.

Metabolic Complications

Dehydration results from the inability to ingest fluid effectively, because of anorexia or nausea, as well as from the loss of secretions in the emesis. Alkalosis resulting from loss of gastric hydrogen chloride in the vomitus is exacerbated by a shift of H^+ into cells because of potassium deficiency and by contraction of the extracellular fluid because of sodium deficiency. Potassium and sodium are lost in the vomitus and are also wasted by the kidneys when they accompany the renal excretion of bicarbonate caused by the alkalosis. In states of marked alkalosis, urine pH is 7 or 8, and urinary sodium and potassium levels are high, despite sodium and potassium depletion. Urine chloride, however, remains low, reflecting the nonrenal losses of sodium chloride and potassium chloride. If intravenous fluid therapy is required, it must be designed with an understanding of the sodium and potassium deficits. The usual metabolic alkalosis is adequately compensated by the patient's spontaneous hyperpnea and responds to fluid and electrolyte therapy.

Nutritional Complications

The nutritional deficits resulting from chronic vomiting and associated anorexia are obvious. Their correction must be included in the treatment plan for chronic vomiting. No more than a day or 2 of fluid therapy should take place without attention to nutritional needs. Frequent, small, high-carbohydrate feedings may minimize the stimulation to vomit, but continuous nasogastric feedings are sometimes needed for chronic vomiting. The presence of metabolic or allergic disease should be considered when the reintroduction of protein leads to relapse of symptoms.

Mallory-Weiss Tear

This linear mucosal laceration in the juxtaesophageal gastric mucosa usually occurs after prolonged forceful retching or vomiting, but it occasionally produces blood in the initial vomitus. Invisible radiographically, it is diagnosed endoscopically (if necessary). Mallory-Weiss tears usually necessitate no treatment, but transfusion is occasionally necessary. Intractable cases are quite rare and may be treated with vasopressin infusion, balloon tamponade, angiographic embolization, or surgery.

Peptic Esophagitis

Esophagitis, similar to that resulting from gastroesophageal reflux, may result from chronic vomiting from many causes. Diagnosed endoscopically or histologically, it should be treated. The treatment of esophagitis usually includes H_2-receptor antagonists or proton pump inhibitors; prokinetic agents may also be needed. The use of antacids should be tempered by knowledge of the acid-base status of the patient.

TABLE 12.17 Metabolic Disease: History and Physical Examination

	NEUROLOGIC			LIVER		GASTROINTESTINAL	RESPIRATORY		Precipitants/ Aversions	Other

Therapy

Therapy of vomiting starts with treatment of the cause, treatment of complications, and treatment of behavioral aspects that may perpetuate the vomiting. General supportive and more specific pharmacologic approaches to therapy are outlined in Table 12.21 and Table 12.23. The physician should be very careful about treating the vomiting symptom without diagnosing and treating its cause. In several situations, diagnostic procedures, such as diatrizoate (Gastrografin) enema for fecal obstructions in cystic fibrosis, barium enema for intussusception, and endoscopy with sclerotherapy for variceal hematemesis, are also therapeutic.

◆ Treatment of Behavioral Aspects

Treatment of psychobehavioral aspects of vomiting may also be important because of the cortical influences on emesis. Such treatment may include eliminating secondary gain for vomiting and reducing anxiety about the vomiting through a confident approach to the child.

Antiemetic Drugs

In situations of persistent vomiting, antiemetic drugs are useful to reduce the metabolic and nutritional consequences and perhaps to interrupt vicious circles in which psychogenic factors may also participate. Currently available antiemetic drugs include the prokinetic agents, metoclopramide, erythromycin, and domperidone, as well as the other medications listed in Table 12.21. These drugs function at many sites by:

- modifying central cortical input (anxiolytic agents)
- depressing the chemoreceptor trigger zone (metoclopromide, domperidone)
- reducing vestibular input
- enhancing the secretion or effects of acetylcholine from the motor neuron (cisapride, available in the United States on restricted-use protocol only)
- blocking serotonin receptors, which inhibit the function of the acetylcholine-secreting motor neuron (ondansetron)

TABLE 12.21	**Pharmacologic Therapies for Vomiting Episodes**
Disease/Condition	**Therapy–Drug Class: Specific Agent/Trade Name (Dose)**
Reflux	Dopamine antagonist: metoclopramide (Reglan) (0.1-0.2 mg/kg q.i.d. PO/IV) Peripheral dopamine antagonist: domperidone (Motilium) (0.2-0.6 mg/kg t.i.d.-q.i.d. PO)
Gastroparesis	Metoclopramide, domperidone; see above Motilin agonist: erythromycin (2-4 mg/kg t.i.d.-q.i.d. PO/IV)
Intestinal pseudoobstruction	Stimulation of intestinal migratory myoelectric complexes: octreotide (Sandostatin) (1 µg/kg b.i.d.-t.i.d. SC)
Chemotherapy	Metoclopramide; see above (0.5-1.0 mg/kg q.i.d. IV, with antihistamine prophylaxis of extrapyramidal side effects) Serotoninergic 5-HT$_3$ antagonist: ondansetron (Zofran) (0.15-0.3 mg/kg t.i.d IV/PO) Phenothiazines (extrapyramidal, hematologic side effects): prochlorperazine (Compazine) (~0.3 mg/kg b.i.d.-t.i.d. PO) chlorpromazine (Thorazine) (>6 mo of age: 0.5 mg/kg t.i.d.-q.i.d. PO/IV) Steroids: dexamethasone (Decadron) (0.1 mg/kg t.i.d. PO) Cannabinoids: nabilone (tetrahydrocannabinol) (0.05-0.1 mg/kg b.i.d.-t.i.d. PO)
Postoperative	Ondansetron, phenothiazines: see above
Motion sickness; vestibular disorders	Antihistamine: dimenhydrinate (Dramamine) (1 mg/kg t.i.d.-q.i.d. PO) Anticholinergic: scopolamine (Transderm Scoōp) (adults: 1 patch/3 days)
Adrenal crisis	Steroids: cortisol (2 mg/kg bolus IV followed by 0.2-0.4 mg/kg/hr IV [± 1 mg/kg IM])

Cyclic vomiting syndrome (CVS)*	Supportive:
	    Analgesic: meperidine (Demerol) (1-2 mg/kg q4-6h IV/IM)
	    Anxiolytic, sedative: lorazepam (Ativan) (0.05-0.1 mg/kg q6h IV)
	    Antihistamine, sedative: diphenhydramine (Benadryl) (1.25 mg/kg q6h IV)
	Abortive:
	    Serotoninergic 5-HT$_3$ antagonist:
	      Ondansetron: see above
	      Granisetron (Kytril) (10 µg/kg q4-6h IV)
	    Nonsteroidal antiinflammatory agent (GI ulceration side effect):
	      Ketorolac (Toradol) (0.5-1.0 mg/kg q6-8h IV)
	    Serotoninergic 5-HT$_{1D}$ agonist: sumatriptan (Imitrex) (>40 kg; 20 mg intranasally/25 mg PO, 1 time only)
	Prophylactic: (if >1 CVS bout/mo; taken daily)
	    Antimigraine, β-adrenergic blocker: propranolol (Inderal) (0.5-2.0 mg/kg b.i.d. PO)
	    Antimigraine, antihistamine: cyproheptadine (Periactin) (0.25-0.5 mg/kg/day ÷b.i.d.- t.i.d. PO)
	    Antimigraine, tricyclic antidepressant: amitriptyline (Elavil) (0.33-0.5 mg/kg t.i.d. PO, and titrate to maximum of
	      3.0 mg/kg/day as needed; obtain baseline ECG at start of therapy, and consider monitoring drug levels)
	    Antimigraine antiepileptic: phenobarbital (Luminal) (2-3 mg/kg q.h.s.)
	    Erythromycin: see above
	    Low-estrogen oral contraceptives: consider for catamenial CVS episodes

b.i.d., twice daily; ECG, electrocardiogram; GI, gastrointestinal; IM, intramuscularly; IV, intravenously, PO, orally; q4-6h, every 4-6 hours; q6h, every 6 hours; q6-8h, every 6-8 hours, q.h.s. each bedtime; SC, subcutaneously; t.i.d., three times daily; q.i.d., four times daily.

TABLE 12.22	**Complications of Vomiting**	
Complication	**Pathophysiology**	**History, Physical Examination, and Laboratory Studies**
Metabolic	Fluid loss in emesis	Dehydration
	HCl loss in emesis	Alkalosis*; hypochloremia
	Na, K loss in emesis	Hyponatremia; hypokalemia*
	Alkalosis → Na into cells	
	$\quad$ HCO$_3$ loss in urine	Urine pH 7-8
	$\quad\quad$ Na and K loss in urine	Urine Na ↑, K ↑
	Hypochloremia → Cl conserved by kidneys	Urine Cl ↓
Nutritional	Emesis of calories and nutrients	Malnutrition; "failure to thrive"
	Anorexia for calories and nutrients	
Mallory-Weiss tear†	Retching → tear at lesser curve of gastroesophageal junction	Forceful emesis → hematemesis
Esophagitis	Chronic vomiting → esophageal acid exposure	Heartburn; Hemoccult + stool
Aspiration	Aspiration of vomitus, especially in context of obtundation	Pneumonia; neurologic dysfunction
Shock*	Severe fluid loss in emesis or in accompanying diarrhea	Dehydration (accompanying diarrhea can explain acidosis?)
	Severe blood loss in hematemesis	Blood volume depletion

*If patient is acidotic, hyperkalemic, or in shock, see Table 12.24.
†Occasionally produces blood in the initial vomitus. Invisible radiographically, it is diagnosed endoscopically (if necessary).
Cl, chloride; HCl, hydrogen chloride; HCO$_3$, bicarbonate; K, potassium; Na, sodium.

TABLE 12.23	**Supportive and Nonpharmacologic Therapies for Vomiting Episodes***
Disease	**Therapy**
All	Treat Cause: obstruction → operate; allergy → change diet (±steroids); metabolic error → Rx defect; acid peptic disease → H$_2$RAs, PPIs, etc.
Complications	
$\quad$ Dehydration	IV fluids, electrolytes
$\quad$ Hematemesis	Transfuse, correct coagulopathy
$\quad$ Esophagitis	H$_2$RAs, PPIs
$\quad$ Malnutrition	NG or NJ drip feeding useful for many chronic conditions
Meconium ileus	Gastrografin enema
DIOS	Gastrografin enema; balanced colonic lavage solution (e.g.,GoLytely)
Intussusception	Barium enema; air reduction enema
Hematemesis	Endoscopic: injection sclerotherapy or banding of esophageal varices; injection therapy, fibrin sealant application, or heater probe electrocautery for selected upper GI tract lesions
Sigmoid volvulus	Colonoscopic decompression
Reflux	Positioning; dietary measures (infants: rice cereal, 1 TBSP/ounce of formula)
Psychogenic components	Psychotherapy; tricyclic antidepressants; anxiolytics (e.g., diazepam: 0.1 mg/kg/t.i.d.-q.i.d. PO)

*If patient is acidotic, hyperkalemic, or in shock, see Table 12.24; adrenal crisis therapy outlined in Table 12.21.
DIOS, distal intestinal obstruction syndrome; GI, gastrointestinal; H$_2$RAs, histamine$_2$-receptor antagonists; IV, intravenous; NG, nasogastric; NJ, nasojejunal; PO, orally; PPIs, proton pump inhibitors; q.i.d, four times a day; TBSP, tablespoon; t.i.d, three times a day.

- blocking dopamine's inhibitory effect at the neuromuscular junction (domperidone, metoclopramide)
- stimulating the motilin receptor on gastric smooth muscle (erythromycin)
- substituting for acetylcholine's stimulatory effect at the neuromuscular junction (bethanechol)

In some settings, the diverse sites of action account for the useful additive effects of these drugs. Optimal therapy for vomiting caused by chemotherapy, for example, may include several agents in order to provide blockade of the multiple receptor types in the chemoreceptor trigger zone and elsewhere. Metoclopramide and ondansetron have been the most widely used general antiemetic agents.

TABLE 12.24	Vomiting Emergencies*					
Drug/Symptoms	**Poison[†]**	**Metabolic[‡]**	**Surgical**	**Neurologic**	**Liver Failure**	**Laboratory Studies**
Shock	+	+	+			
Mental status change, lethargy, coma, seizure, psychosis	++	++		+++	+++	NH_3, head CT/MRI, glucose
Severe abdominal pain/distention	++	+	+++		+	Abdominal films
Acute liver dysfunction: jaundice, anicteric	++	++	+	+	+++	NH_3, PT
Respiratory: apnea, Kussmaul breathing	++	++	+	++	++	Blood gas; electrolytes; urinalysis, glucose
Other						
Bilious emesis		+	+++		+	Abdominal films
Silent abdomen			+++			
Hematemesis			+		++	Endoscopy

*An acutely ill child with vomiting needs:

Physical examination: especially vital signs, neurologic, funduscopic, abdominal (auscultation, peritoneal signs), rectal.

Laboratory tests: complete blood cell count, differential white blood cell count, platelets; sodium, potassium, chloride, carbon dioxide; glucose (Dextrostix); blood urea nitrogen, creatinine; liver function tests; amylase, lipase; blood gas; urinalysis.

If fever is present: cultures of blood, urine, cerebrospinal fluid (if mentation change), and stool (if diarrhea or hematochezia) are also needed.

If hematemesis is present: platelets, prothrombin time, and partial thromboplastin time also must be measured.

[†]See Tables 12.19 and 12.20.

[‡]See Tables 12.17 and 12.18.

CT, computed tomography; MRI, magnetic resonance imaging, NH_3, ammonia; PT, prothrombin time.

+, suggestive; ++, moderately suggestive; +++, highly suggestive.

SUMMARY AND RED FLAGS

Vomiting and regurgitation are commonly encountered symptoms in children. Most commonly they are the result of acute, self-resolving illnesses, such as acute gastroenteritis. In infants, regurgitation caused by gastroesophageal reflux must be distinguished from other more serious causes. Symptoms suggesting vomiting emergencies are listed in Table 12.14 and Table 12.24. These are generally diseases that arise after surgery, are metabolic, or are caused by poisoning; liver failure and neurologic disorders are also included.

Gastrointestinal Bleeding

Julia Fritz and Bernadette Vitola

Gastrointestinal (GI) bleeding in children can range from small amounts of blood in the stool, associated with milk protein allergy or anal fissure, to life-threatening hemorrhage, associated with portal hypertension or peptic ulcer disease. Severe bleeding is a true medical emergency and necessitates prompt diagnostic attention and appropriate management. *Hemodynamic stabilization of the patient with severe bleeding should always precede diagnostic studies.* An accurate history and thorough physical examination usually allow the physician to categorize the problem as mild or severe and to direct evaluation at the appropriate pace.

DEFINITIONS

Children with gastrointestinal bleeding generally present with hematemesis, hematochezia, or melena, although the clinical manifestation can be as subtle as evidence of occult blood loss. An **upper gastrointestinal bleed** is bleeding from the esophagus, stomach, or duodenum. Upper sources account for the majority of gastrointestinal bleeds in children. If the site of bleeding is distal to the ligament of Treitz, it is a **lower gastrointestinal bleed**. Blood passed per rectum can originate from either an upper or lower gastrointestinal source. Occult bleeding may occur from disorders at numerous sites.

Hematemesis. Vomited blood can be either red or the color of coffee grounds. Hematemesis is most commonly associated with an upper gastrointestinal bleed, although swallowed blood produces the same clinical picture. Bright red hematemesis suggests active bleeding that has not had prolonged contact with gastric secretions. When gastric secretions interact with the blood, the blood will darken in color as the iron oxidizes and leads to dark red or "coffee ground" emesis.

Hematochezia and melena. The presence of hematochezia (bright red blood) is generally associated with colonic bleeding, although it may result from a brisk upper bleed. Maroon stools from the rectum are generally associated with a lower gastrointestinal bleed. The presence of melena—passage of black, tarry stools—generally results from significant blood loss proximal to the ileocecal valve, including an upper gastrointestinal bleed. The color results from bacterial breakdown of the hemoglobin. *Up to 10-15% of upper gastrointestinal bleeds present with melena in the absence of hematemesis.* These patients are more likely to have a clinically significant bleed.

APPROACH TO GASTROINTESTINAL BLEEDING

The first step is to determine whether the problem is actually gastrointestinal bleeding. Many substances and nongastrointestinal sources may simulate gastrointestinal bleeding (Table 13.1). Stool guaiac and the modified guaiac (Gastroccult) test for emesis are used to determine the presence of blood. Recommendations from manufacturers are to avoid red meat, citrus fruits and juices, supplemental vitamin C in excess of 250 mg/day for 3 days prior to testing, and to avoid antacids for at least 60 minutes prior to testing. Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided for 1 week prior to testing and aspirin exposure should be minimized; however, it is uncertain whether these products affect the reliability of the test. In addition, although iron preparations may blacken stools, they do not lead to false-positive results. Female patients should be told not to collect test samples for 3 days after or during a menstrual period. To avoid potential false-positive or false-negative results, stool should be collected from diapers or from disposable collection devices rather than directly from toilet water. Finally, an alkali denaturation test, also known as the Apt-Downey or Apt test, should be performed when a breast fed infant vomits bright red blood or passes red bloody stools to distinguish whether it is maternal or fetal hemoglobin.

Once gastrointestinal bleeding is confirmed, the evaluation, differential diagnosis, and therapeutic interventions will depend on the age of the patient and whether the bleed is coming from the upper or the lower gastrointestinal tract (Tables 13.2, 13.3, and 13.4). A nasogastric (NG) tube may be placed in the appropriate patient when the source of bleeding is not clear. Bloody aspirate from the stomach is confirmation of upper gastrointestinal bleeding. The tube may then be used to lavage the stomach with warm saline. If aspirated saline clears after repeated lavage, the bleeding has likely stopped or is from a different source.

HEMATEMESIS AND MELENA: UPPER GASTROINTESTINAL BLEED

◆ History

Neonates who did not receive prophylactic vitamin K are at risk for hemorrhagic disease of the newborn (see Chapter 38) and additional perinatal factors may place them at risk for sepsis or other stress that could lead to gastritis. Infants who require intensive care may have trauma from an NG tube, and infants with neonatal umbilical vein catheterization or neonatal omphalitis are at risk for portal vein thrombosis and resultant later onset of esophageal varices. In older children, a recent history of vomiting, regurgitation, or abdominal pain suggests a mucosal lesion. Forceful, repeated vomiting may result in a Mallory-Weiss tear or prolapse gastropathy. Reactive gastritis can be due to medications such as NSAIDs as well as alcohol or ingestion of caustic substances. Providers must ask about recent bleeding such as epistaxis or dental procedures, which could lead to hematemesis without a gastrointestinal source of bleeding.

Information regarding chronic pulmonary disease, renal disease, bleeding disorders, and liver disease, including a history of jaundice, should be obtained in all children. Patients with cystic fibrosis are at risk not only for the development of esophageal varices caused by biliary cirrhosis but also for coagulopathies from vitamin K deficiency. They may also have hemoptysis, which can be misinterpreted as hematemesis. In patients with renal disease, uremia will cause platelet dysfunction, which may manifest as a gastrointestinal bleed. The family

	Trauma

CMV, cytomegalovirus; DIC, disseminated intravascular coagulation; NSAIDs, nonsteroidal antiinflammatory drugs.

history should address the presence of bleeding disorders, peptic ulcer disease, and possible *Helicobacter pylori* exposure.

◆ Physical Examination

Immediate attention must be given to signs of hypovolemia, anemia, or shock. An orthostatic change, such as a pulse rate increase of 20 beats/min or a drop in systolic blood pressure of more than 10 mm Hg when the patient changes from supine to standing is a sensitive index of significant volume depletion. Blood pressure may remain normal up to the point of circulatory collapse in children and a normal blood pressure should not be reassuring in the setting of other signs of hypovolemia such as tachycardia or delayed capillary refill.

In addition to close attention to changes in vital signs, a physical exam with emphasis on potential sources of bleeding is essential (Table 13.5). The oropharynx and nasal canals should be examined for lesions as the cause of bleeding. Palpation to evaluate organomegaly should begin at the iliac crests so as not to miss a hugely enlarged liver or spleen. A prominent venous pattern on the abdomen (Fig. 13.1), splenomegaly, and ascites may suggest portal hypertension. Tenderness and guarding indicate a significant inflammatory process.

In addition to assessing for pallor, cutaneous lesions may help determine the underlying cause of bleeding. Petechiae can indicate disseminated intravascular coagulation, hypersplenism, or another bleeding abnormality. Hyperpigmented lesions of the oral or anal mucosa may indicate Peutz-Jeghers disease. Cutaneous telangiectasia

TABLE 13.4   Causes of *Occult* Gastrointestinal Bleeding

Inflammatory Causes	Infectious Causes
Peptic esophagitis	Hookworm
Crohn disease	Strongyloidiasis
Ulcerative colitis	Ascariasis
Mild enterocolitis	Tuberculosis enterocolitis
Celiac disease	Amebiasis
Eosinophilic gastroenteritis	
Meckel diverticulum	**Tumors and Neoplastic Causes**
Solitary rectal ulcer	Polyps
	Lymphoma
Vascular Causes	Leiomyoma
Angiodysplasia and vascular ectasias	Lipoma
Gastroesophageal varices	Carcinoma
Congestive gastropathy	
Hemangiomas	**Artificial Causes**
	Hematuria
Drugs	Menstrual bleeding
Nonsteroidal antiinflammatory drugs	Nonspecific test positivity
Extragastrointestinal Causes	**Miscellaneous Causes**
Hemoptysis	Long-distance running
Epistaxis	Coagulopathies
Oropharyngeal bleeding	Factitious

Oral ulcers Perianal fistula Perianal skin tag Erythema nodosum Pyoderma gangrenosum	Inflammatory bowel disease

FIGURE 13.1 Prominent venous pattern on the abdomen.

◆ **Differential Diagnosis**

In infants, esophagitis, gastritis, and ulcers are the most common causes of upper gastrointestinal bleeding. Esophagitis may be associated with dysphagia, irritability, and arching with feeds (see Chapter 12). Milk protein sensitivity should be considered as well, although it more often presents with blood in stool. Trauma or infection (such as cytomegalovirus, herpes simplex, or fungal) can cause mucosal irritation presenting as hematemesis. Anatomic abnormalities including duplication cysts or vascular abnormalities may also lead to hematemesis or melena in infants.

and hemangiomas may indicate such diseases as Osler-Weber-Rendu syndrome and ataxia-telangiectasia, or they may simply suggest a predisposition for vascular malformations. Palmar erythema, spider angioma, or jaundice suggests underlying liver disease. Scleral icterus may be subtle but can be the first sign of liver disease and may be more easily appreciated than jaundice in darker-skinned individuals.

FIGURE 13.2 Endoscopic view of fundus showing area of prolapse gastropathy.

FIGURE 13.3 Skin tags and fistulas as in Crohn disease.

In older children, mucosal lesions remain common causes of bleeding. Mallory-Weiss tears are associated with repeated forceful vomiting from a variety of causes (e.g., acute gastroenteritis). The forcefulness of the vomiting causes a tear in the distal esophagus at the level of the lower esophageal sphincter. The history is generally one of frequent nonbloody vomiting that then becomes hematemesis. Prolapse gastropathy, caused by prolapse of gastric mucosa into the distal esophagus, can similarly occur after forceful vomiting and lead to hematemesis (Fig. 13.2). Reactive gastritis secondary to medication (NSAIDs) or infection (*H. pylori*) are also common causes of upper gastrointestinal bleeding. Children with known or unknown liver disease can develop esophageal varices that may lead to large-volume hematemesis and melena (or hematochezia if bleeding is brisk). Ulcers, although rare, can also lead to significant blood loss and may be related to *H. pylori* infection, stress such as surgery or burns, and foreign body ingestion, specifically button batteries, which can lead to significant bleeding.

HEMATOCHEZIA: LOWER GASTROINTESTINAL BLEED

◆ History

Chronicity of bleeding is essential to ascertain because infectious colitis may cause acute bloody diarrhea, while inflammatory bowel disease generally presents with a more prolonged history (see Chapter 11). Presence or absence of pain can also help distinguish between causes of bleeding. Severe, acute abdominal pain is often present in patients with vascular compromise, such as in intussusception, midgut volvulus, and bowel ischemia (e.g., Henoch-Schönlein purpura), while painless rectal bleeding suggests a Meckel diverticulum, polyp, or angiodysplasia. Growth failure is suggestive of inflammatory bowel disease, specifically Crohn disease; constipation points to the possibility of an anal fissure (see Chapter 16) or Hirschsprung disease with enterocolitis. Information regarding travel (either by the patient or by visitors), sick contacts, daycare exposure, camping, and antibiotic exposure may reveal potential infectious causes. Family history of polyps or colon cancer is important given the inherited polyposis syndromes, as is a family history of inflammatory bowel disease.

◆ Physical Examination

Physical exam in any patient with gastrointestinal bleeding must begin with assessment of hemodynamic status. In addition to a general exam, for patients with hematochezia, a rectal exam is important to evaluate for fissures as well as skin tags and fistulas, which may be seen in Crohn disease (Fig. 13.3). Local intense tenderness, fever, and erythema of the perianal area may suggest group A β-hemolytic streptococcus infection. Infants and toddlers may have a palpable right lower quadrant abdominal mass, which suggests intussusception. Skin examination may show purpura which, although not always present initially, is seen in Henoch-Schönlein purpura; it may also be seen in hemolytic uremic syndrome. Erythema nodosum or pyoderma gangrenosum is present in approximately 3% of children with inflammatory bowel disease and may correlate with disease severity.

◆ Differential Diagnosis

Anal fissures are probably the most frequent cause of streaks of bright red blood mixed with stool. The bleeding may be associated with hard bowel movements but may occur from straining with normal bowel movements. There is also an association with group A streptococcal perianal cellulitis and bleeding. Anal fissure may be a manifestation of milk protein allergy with resultant perianal inflammation and subsequent constipation to avoid painful defecation. More often, a milk protein allergy will present with specks of blood within the stool. There may be a history of increasing frequency and amount of blood and mucus in the stool. The infant may exhibit cramping with bowel movements and vomiting may be part of the presentation. Often there is a family history of food allergies. Milk protein allergy can be seen in infants fed cow's milk– or soy protein–based formulas, as well as in breast-fed infants. Ischemic bowel disease, including necrotizing enterocolitis and volvulus, may lead to rectal bleeding and an acutely ill, sick-appearing neonate or infant. Risk factors for necrotizing enterocolitis include prematurity, cardiac surgery, polycythemia, chronic diarrhea, and gastrointestinal malformations.

Infectious colitis is common in both infants and children and causes frequent, often watery, bloody bowel movements (see Chapter 11). There may be cramping pain before and during the bowel movement as a result of the colitis. Common pathogens include *Salmonella* and *Shigella* organisms, especially with dysentery type stools, but *E. coli* O157:H7, *Campylobacter* species, *Yersinia* species, and *Entamoeba histolytica* should also be considered. *Clostridium difficile* is a common cause of hematochezia in older children but is also found in healthy infants without causing disease due to lack of toxin receptors in the immature colon.

For young children, intussusception and Meckel diverticulum are common causes of hematochezia. The hallmark of intussusception is the presence of "currant jelly" stools associated with colicky abdominal pain, lethargy, or irritability. Meckel diverticulum occurs in 1-3% of the population and manifests by the age of 2 years in about 50% of patients. Bleeding results from mucosal ulceration secondary to secretion of gastric acid or pepsin from ectopic gastric or pancreatic tissue, respectively, in the tip of the diverticulum. It is usually brisk and painless with blood ranging from dark red to bright red.

Juvenile polyps also present with painless rectal bleeding but are uncommon in children under 1 year of age with peak incidence between ages 5 and 7 years. They are more common in boys and non-Caucasian races. Most juvenile polyps occur in the distal colon and may cause bleeding from autoamputation as they outgrow their blood supply. These polyps are generally benign but adenomatous polyps in children suggest an inherited disorder, such as familial adenomatous polyposis (FAP). Affected individuals with FAP are at significant risk for the development of colonic carcinoma and require repeated colonoscopies and, eventually, prophylactic colectomy and ileoanal pouch procedures.

In older children, inflammatory bowel disease becomes a more common cause of hematochezia. The rectal bleeding varies from occult to frank blood in the bowel movements. Blood is present in 100% of cases of ulcerative colitis but in only 30-50% of cases of Crohn disease. Inflammatory bowel disease is generally accompanied by fever, weight loss, and rectal bleeding (see Chapter 11).

Henoch-Schönlein purpura is a vasculitic syndrome that can cause bloody stools. It is often accompanied by cramping abdominal pain, purpuric rash (palpable purpura), joint swelling, scalp edema (infants and toddlers), and occasionally, nephritis (see Chapter 20).

OCCULT BLOOD LOSS

Occult blood loss most often presents as iron-deficiency anemia or may be detected during evaluation for abdominal pain, vomiting, diarrhea, or weight loss (see Table 13.4).

◆ Laboratory Evaluation

Initial laboratory evaluation should include a complete blood count with differential and platelet count, coagulation profile, and a comprehensive metabolic profile with total and direct bilirubin (Table 13.6). Patients with clinical signs of significant blood loss should have a blood typing with cross match sent. Guaiac testing can be performed on stool or emesis to confirm presence of blood. In patients with lower gastrointestinal bleeding, stool should be sent for analysis of infectious causes. Urinalysis may be useful in patients with hematochezia with suspicion for hemolytic uremic syndrome.

◆ Imaging
Radiographs

Abdominal radiographs should be obtained in all infants with acute hematochezia to look for pneumoperitoneum, pneumatosis intestinalis, or hepatic portal vein gas suggesting necrotizing enterocolitis. Flat plate films may also identify intussusception, volvulus, abdominal masses, or foreign bodies (Fig. 13.4). Upper gastrointestinal contrast studies can discern anatomic lesions, such as strictures, stenosis,

TABLE 13.6 Laboratory Findings Suggestive of a Diagnosis

Lab Finding	Significance
Hgb/HCT	Normal hemoglobin or hematocrit does not rule out significant bleed as it may take time to equilibrate
Low MCV	Chronic blood loss
Low platelets	HUS, hypersplenism (secondary to portal hypertension), ITP, DIC
Elevated prothrombin time	Liver disease, coagulation disorder, DIC
Increased BUN/Normal Cr	UGI bleed more likely
Increased BUN/Elevated Cr	HUS or HSP
Decreased albumin	IBD or liver disease
Elevated ESR/CRP	IBD
Elevated AST/ALT	Liver disease
Elevated bilirubin	Liver disease

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; Cr, creatinine; DIC, disseminated intravascular coagulation; ESR, erythrocyte sedimentation rate; Hgb/HCT, hemoglobin/hematocrit; HSP, Henoch-Schönlein purpura; HUS, hemolytic uremic syndrome; IBD, inflammatory bowel disease; MCV, mean corpuscular volume; UGI, upper gastrointestinal.

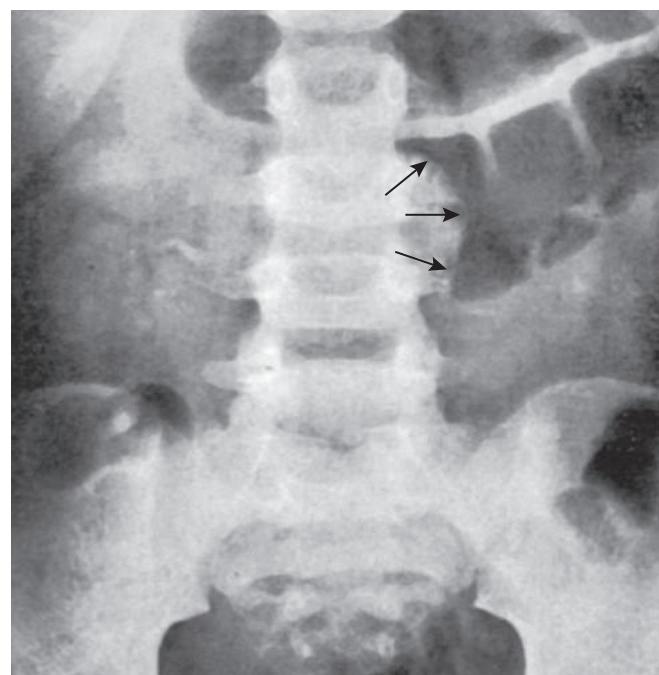

FIGURE 13.4 Flat plate film.
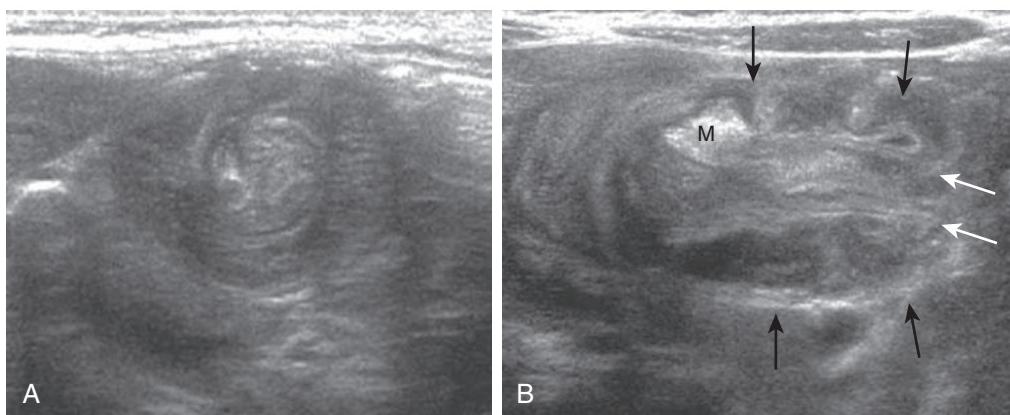

FIGURE 13.5 Abdominal ultrasound illustrating intussusception. *A*, Transverse plane shows target-like appearance of bowel. *B*, Longitudinal plane shows inner bowel loops *(white arrows)* telescoping through outer bowel loops *(black arrows)*. Edema of affected bowel causes hyperechoic mucosa *(M)*.

atresias, malrotation, large ulcerations, and masses. Small bowel follow-through examination allows evaluation of the small bowel from the ligament of Treitz to the ileocecal valve. Areas of ulceration, mucosal thickening, and narrowing may be appreciated. An air or water soluble enema should be performed in infants and children in whom there is a concern of distal intestinal obstruction, such as intussusception (see Chapter 10). In cases of intussusception, the enema not only aids in diagnosis but may also be therapeutic. Crohn disease and ulcerative colitis may be suggested by results of this test, but endoscopy is necessary for histologic confirmation of these diagnoses.

Abdominal Ultrasound

An ultrasound may be useful in patients with suspected liver disease to evaluate for portal hypertension. It may also be used in potential cases of intussusception or suspected large vascular malformations (Fig. 13.5).

Computed Tomography

CT scans may be useful in evaluating possible anatomic anomalies and may reveal signs of inflammation related to infectious or inflammatory colitis. CT enterography can localize an *active* lower gastrointestinal bleed. Given the radiation exposure, the value of a CT over other diagnostic modalities must be considered.

Magnetic Resonance Enterography

MRE can be useful in cases of occult bleeding or in suspected and known inflammatory bowel disease to evaluate for areas of inflammation in the small bowel that may be causing blood loss. Patients must be awake and able to stay still through the prolonged study, which limits its utility in younger patients.

Angiography

Angiography may help identify the source of bleeding but is only sensitive for an active bleed at a rate of at least 0.5 mL/min. Nevertheless, angiography can identify extravasation of contrast in a Meckel diverticulum or the presence of vascular malformations of the bowel, which may be acquired or congenital. Therapeutic angiography can also be used to control gastrointestinal bleeding.

Nuclear Imaging

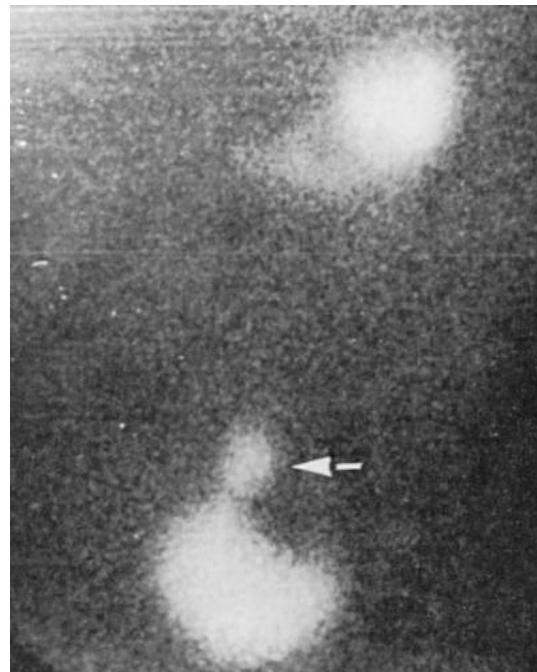
Nuclear medicine may determine the site of bleeding with minimal complications; it is associated with minimal radiation exposure and requires minimal sedation. Technetium 99m (99mTc) pertechnetate is


FIGURE 13.6 Positive Meckel scan. *Arrow* indicates abnormal area of increased uptake in lower abdomen above bladder, consistent with gastric mucosa containing Meckel diverticulum.

rapidly taken up by gastric mucosa and it is useful in identifying sites of bleeding secondary to ectopic gastric mucosa. Gastric mucosa is found in 90% of bleeding Meckel diverticula, and in these patients the Meckel scan has a sensitivity of 94% and a specificity of 97% in the pediatric population (Fig. 13.6). False-negative results have been reported frequently because of insufficient gastric tissue mass, downstream washout of isotope, impaired blood supply, or suboptimal techniques. Positive identification may be improved by the administration of ranitidine to prevent excretion of pertechnetate from gastric tissue.

Bleeding scans are performed by intravenously injecting technetium sulfur colloid. The agent is distributed quickly and is rapidly taken up by the reticuloendothelial system. It can detect a rate of bleeding of 0.1 mL/min. However, because the technetium is taken up by the reticuloendothelial system, this may hinder the search for bleeding sites behind the liver or spleen. Finally, the clearance is very rapid, with a half-life of 2 minutes, which means that bleeding has to be occurring at the time of the scan.

The 99mTc pertechnetate–labeled red blood cell scan is a sensitive and accurate test for the localization of active bleeding. In cases of intermittent bleeding, a single injection of labeled cells allows repeated scans for up to 24 hours. It can detect as little blood as 0.5 mL/min.

◆ Imaging

Esophagogastroduodenoscopy (EGD) is the procedure of choice in identifying the site of upper gastrointestinal bleeding. EGD can also allow direct intervention at the bleeding site, as in the case of esophageal varices or a visible vessel in an ulcer crater. Endoscopic visualization of the stomach and duodenum should be performed even if the bleeding is thought to originate from esophageal varices. Of patients with proven esophageal varices, 50% may manifest bleeding from gastritis or peptic ulcer disease rather than the varices. Endoscopy, however, should not be performed until the patient is as hemodynamically stable as possible. Gastric lavage may be useful prior to upper endoscopy to remove any blood present in the stomach to allow for better views as well as to determine whether there is still active bleeding. Erythromycin can be given prior to endoscopy to accelerate gastric emptying and removal of blood from the stomach.

Lower gastrointestinal tract bleeding can also be evaluated endoscopically. Procedures frequently used in children include proctosigmoidoscopy and flexible colonoscopy. With the patient under appropriate sedation, lower gastrointestinal endoscopy allows for full exploration of the colon; identifies the presence of multiple lesions; allows for therapeutic intervention to bleeding lesions through electrocoagulation, laser therapy, or thermocoagulation; and allows for removal of bleeding lesions, such as polyps. Colonoscopy is indicated when there is melena or severe bleeding with no evidence of upper gastrointestinal lesions, when stools are guaiac-positive over a long time, and when examination of the terminal ileum is indicated to determine whether inflammatory bowel disease is present. One disadvantage is that large amounts of luminal blood obscure visualization of a lesion. Before lower gastrointestinal colonoscopy, intestinal lavage with oral administration of polyethylene glycol should be used to remove as much of the luminal blood and stool as possible.

Small bowel enteroscopy, or evaluation of the jejunum or proximal ileum, can be useful in the evaluation of occult bleeding. While its diagnostic yield varies by study, it allows for direct intervention if the source of bleeding is found. In addition, it has been employed intraoperatively to help identify lesions and guide surgical intervention.

Capsule Endoscopy

Wireless capsule endoscopy may be useful in patients with occult or apparent bleeding when other work-up, including an upper and lower endoscopy, have been negative. The patient swallows or has the capsule placed endoscopically and images are taken as the capsule passes through the small and large intestines, which can identify vascular malformations and other sources of bleeding (Fig. 13.7). The main risk is capsule retention and so children must be of a certain size and be evaluated for possible stricture prior to the study.

◆ Treatment
Resuscitation

The severity of bleeding determines the general guidelines for treatment. For severe bleeding, initial management reestablishes and maintains the intravascular volume. Subsequently, the site of blood loss must be determined and attempts made to stop the hemorrhage. Severe anemia also necessitates packed red blood cell transfusions after the intravascular volume deficit is corrected (Table 13.7).

Although parents tend to overestimate the amount of blood lost by their child, a major error in the management of gastrointestinal bleeding is underestimating blood loss. The hematocrit may remain unchanged initially, despite significant blood loss, and therefore is not a good indicator of significant bleeding. If orthostatic blood pressure changes or tachycardia are present, the initial goal of treatment should be to hemodynamically stabilize the patient, maintain the intravascular volume, and provide adequate oxygen delivery to the tissues. A second potential error is the failure to establish adequate intravenous (IV) access. The largest possible IV catheter must be rapidly placed in a child

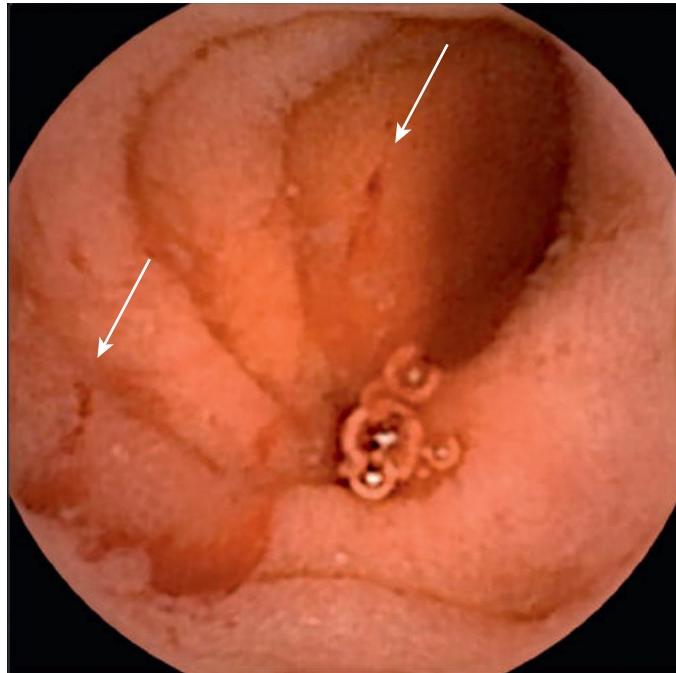

FIGURE 13.7 Capsule endoscopy image revealing jejunal bleeding from a vascular malformation in a patient who presented with anemia refractory to iron supplementation.

TABLE 13.7 Initial Management of Patients with Hypovolemia Secondary to Gastrointestinal Hemorrhage

1. Establish adequate intravenous (IV) access by placing 2 IV catheters.
   - Recommended catheter size:
     - Infant: 20 gauge
     - Child: 18 gauge
     - Adolescent: 16 gauge
2. Rapidly infuse saline or lactated Ringer solution, use smaller boluses and frequent monitoring in patients with suspected varices to avoid rapid increase in venous pressure and worsening of variceal bleed.
3. Carefully monitor pulse, blood pressure, and central venous pressure to avoid fluid overload.
4. Monitor urine output, skin perfusion, and orthostatic changes in pulse and blood pressure for early recognition of shock.
5. Transfuse with packed red blood cells to return oxygen-carrying capacity to normal.
6. Carefully record all fluids transfused, and estimate and record all recognized fluids lost.

Modified from Olson AD, Hillemeier AC. Gastrointestinal hemorrhage. In: Wyllie R, Hyams JS, eds. *Pediatric Gastrointestinal Disease.* Philadelphia: WB Saunders; 1993:253.

TABLE 13.8	**Pharmacotherapy in Pediatric Gastrointestinal Bleeding***	
Medication	**Mechanism of Action/Indication**	**Dosage**
Ranitidine	H$_2$-receptor antagonist, acid reducer	*IV:* ≤16 yr: 2-4 mg/kg/day divided every 6-8 hr (max dose: 50 mg/dose) >16 yr: 50 mg every 6-8 hr *Oral:* ≤16 yr: 4-8 mg/kg/day divided twice daily (max dose: 300 mg/day) >16 yr: 150 mg twice daily
Famotidine	H$_2$-receptor antagonist, acid reducer	*IV or PO:* ≤16 yr: 0.5 mg/kg/day nightly or divided twice daily (max dose 40 mg/day) >16 yr: 40 mg/day nightly or divided twice daily (max dose 40 mg/day)
Pantoprazole[†]	Proton pump inhibitor, acid reducer	*IV:* ≥2 yr: 0.8 or 1.6 mg/kg once daily (max dose: 80 mg/dose) *Oral:* <5 yr: 1.2 mg/kg/day once daily >5 yr: 20 or 40 mg once daily
Omeprazole[†]	Proton pump inhibitor, acid reducer	*Oral:* 5 kg to <10 kg: 5 mg once daily 10 kg to <20 kg: 10 mg once daily ≥20 kg: 20 mg once daily
Lasoprazole[†]	Proton pump inhibitor, acid reducer	*Oral:* ≤30 kg: 15 mg once daily >30 kg: 30 mg once daily
Sucralfate	Coats mucosal injury and binds bile acids to prevent further injury, inhibits pepsin in the presence of acid[‡]	*Oral:* 40-80 mg/kg/day divided every 6 hr (max dose 1000 mg/dose)
Octreotide	Somatostatin analog, selectively decreases splanchnic blood flow	*IV:* 1-2 µg/kg initial bolus followed by 1-2 µg/kg/hr continuous infusion (doses up to 4 µg/kg/hr have been used) Following endoscopic intervention may taper dose by 50% every 12 hr and discontinue when dose is 25% of initial dose

*Dosages listed are from *Pediatric Lexi-Comp* online formulary and do not apply to infants aged <3 mo. Evidence-based dosing of these medications is not well established.

[†]Proton pump inhibitors (PPIs) should not be administered in infants aged <1 yr without endoscopic evidence of acid-induced disease.

[‡]Use in conjunction with PPI may limit efficacy.

with active bleeding. Blood loss should be replaced immediately with a crystalloid solution, such as normal saline or lactated Ringer solution. Initially, a fluid push of 20 mL/kg should be given, although resuscitation should be performed cautiously in patients who may have portal hypertension as overly aggressive resuscitation raises the venous pressure and could worsen bleeding from varices. In these patients, small, repeated fluid boluses with close monitoring are preferred to large volume boluses. If blood loss continues and the patient appears to be at risk for hypovolemic shock, infusion of normal saline or colloid solutions (5% albumin) can be continued until blood is available. Plasma is indicated if coagulation factors are depleted. Once bleeding has stopped, transfusions of packed red blood cells should continue, to slowly raise the hematocrit to 30% (10 g/dL hemoglobin) (for patients with variceal bleeding the goal is instead hemoglobin of 8-9 g/dL). If continued blood loss necessitates multiple transfusions, fresh-frozen plasma and calcium should be given to replace coagulation factors and correct the hypocalcemia caused by the citrate in blood products. The platelet count in such patients must be monitored because thrombocytopenia may develop.

If a nasogastric tube is inserted, the tube size is determined by the child's age and size. A 12-French tube is used in infants and preschool children; a 14- or 16-French tube is appropriate for children of elementary school age or older. Gastric lavage should be undertaken with room-temperature normal saline. The color of the gastric lavage fluid gives the physician an indication of the rate of bleeding. Lavage returns that are bright red indicate significant ongoing bleeding; pink-tinged or brown flecks in the solution indicate less significant or minimal bleeding.

Maintaining a gastric pH of more than 4 is considered standard therapy for upper gastrointestinal mucosal bleeding. This can be accomplished with either H$_2$-receptor antagonists or proton pump inhibitors.

Vasoactive Agents

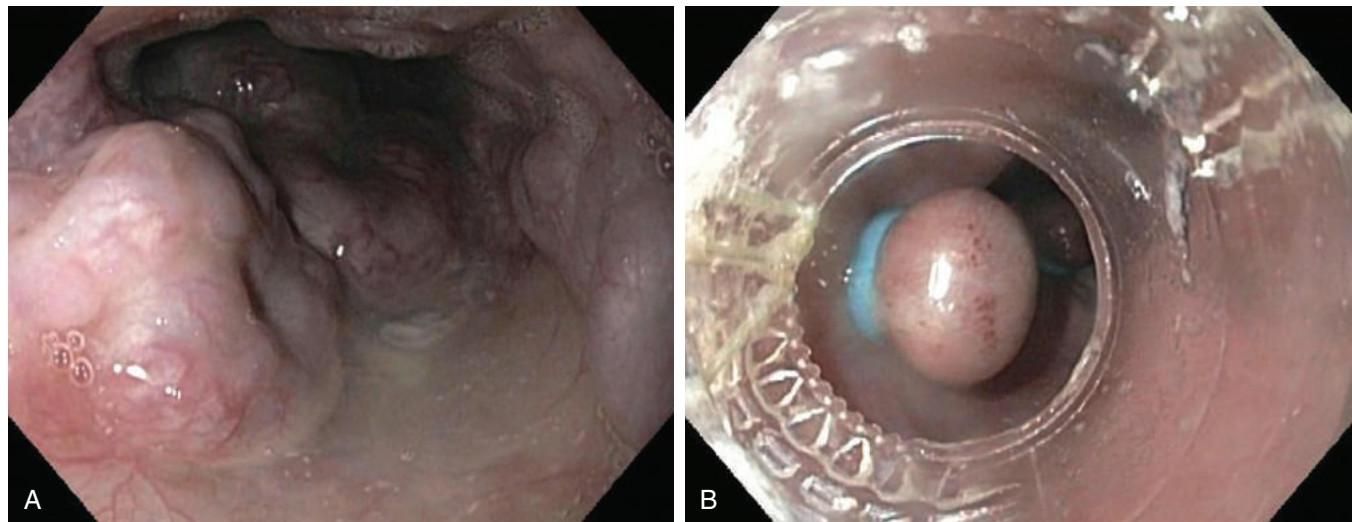
In patients with suspected variceal bleeding, a continuous infusion of octreotide may be started. This agent reduces splanchnic blood flow with minimal disturbance to other organs. It is safer than vasopressin but has not been shown to have benefit in nonvariceal bleeding. Customarily, a bolus of octreotide (1-2 µg/kg) is given over 5-10 minutes, and this is followed by a continuous infusion of 1 µg/kg/hr, although higher doses may be required. The infusion may help control the bleeding until definitive therapy (banding or sclerotherapy) is performed. After endoscopic intervention, octreotide infusions may be weaned slowly (every 12 hours) with close monitoring of the patient to ensure varices do not re-bleed. See Table 13.8 for additional pharmacotherapy.


FIGURE 13.8 Variceal banding is the preferred method for treating esophageal varices. *A,* Grade 3 esophageal varices in patient with cirrhosis. *B,* View of varices after band application.

Endoscopic Modalities

Most patients with gastrointestinal bleeding will undergo upper and/or lower endoscopy for definitive diagnosis and treatment. For patients with mucosal lesions, such as ulcers or bleeding polyps, there are multiple therapeutic interventions available. Injection with a diluted epinephrine solution, thermal coagulation, laser photocoagulation, and endoscopic clips can be used to stop active bleeding. Vascular lesions may also be treated endoscopically. For patients with colitis, colonoscopy is used primarily to confirm diagnosis and extent of disease.

Variceal banding is the preferred method for treating bleeding esophageal varices (Fig. 13.8 *A* and *B*). Ideally, the banding takes place after good control of acute bleeding, affording the endoscopist an unobstructed view of the varices. Side effects of this therapy are minimal, and the procedure is repeated weekly to monthly until the varices are obliterated. Sclerotherapy is also effective in controlling the acute bleeding from esophageal varices and may be performed weekly to monthly until the varices resolve. In young children whose upper esophageal sphincter is too small for the endoscopic banding device to pass, sclerotherapy may be the only option. Complications include esophageal ulceration and esophageal stricture. A number of sclerosing agents (e.g., ethanolamine, sodium morrhuate, ethanol, tetradecyl sulfate) are efficacious in treating varices.

Surgical intervention is a definitive treatment for many of the anatomic anomalies causing gastrointestinal bleeding and may be performed in conjunction with endoscopy to identify the lesion. Vessel ligation may also be a necessary step in bleeding ulcers that cannot be controlled endoscopically.

Interventional Radiology

Selective embolization during angiography can be used to treat vascular malformations and to control bleeding from ulcers. The rate of complications from angiography is 2%, whether the procedure is diagnostic or therapeutic. In patients with intrahepatic portal hypertension with bleeding from gastrointestinal sites inaccessible to sclerotherapy or banding, coiling of varices or transjugular intrahepatic portosystemic shunting may be beneficial.

SUMMARY AND RED FLAGS

Gastrointestinal bleeding may occur anywhere along the gastrointestinal tract and can range from occult blood loss to massive hemorrhage. Approach to gastrointestinal bleeding begins with ensuring hemodynamic stability of the patient while obtaining a thorough history and physical exam to help determine upper versus lower source of bleeding. Red flags include hemodynamic instability that necessitates immediate attention. Laboratory, radiologic, and endoscopic evaluation are used for confirmation of diagnosis and potentially treatment.

Hepatomegaly

Grzegorz W. Telega

Hepatomegaly occurs commonly in children as a feature of primary liver disease or as a result of systemic disorders involving the liver and other organs (Table 14.1). Because of congenital anomalies, inborn errors of metabolism, and perinatal infections, there may be a greater number of disorders manifesting with hepatomegaly during infancy than during any other time of life (Table 14.1). Common symptoms of hepatic dysfunction, such as fatigue, fever of unknown origin, pruritus, failure to thrive, confusion, change in mental status, and diarrhea are nonspecific. Hepatomegaly and jaundice are frequently the findings that lead to an evaluation for liver disease. Causes of hepatomegaly associated with jaundice are discussed in Chapter 15.

ASSESSMENT OF THE LIVER

An accurate assessment of liver size is an important initial step in evaluating a patient with possible liver disease. Considerable patience may be necessary to obtain the required information. The patient should lie down in a supine position with the knees flexed. The abdominal muscles should be relaxed as much as possible. The provider should become familiar with the sensation of pressure over the abdominal wall in the lower abdomen in order to detect the difference while transitioning over the liver edge. The examiner should also be sure that the lower border of a massively enlarged liver is not missed by failure to palpate below the umbilicus. The lower edge of the liver should be determined by palpation just lateral to the right rectus muscle. Careful palpation of the liver edge along the lower border is important as enlargement of the liver can be asymmetrical in chronic cirrhosis, in Budd-Chiari syndrome, and with liver tumors.

The lower edge of the liver is usually palpable in normal subjects with deep inspiration when it moves downward 1-3 cm. In the newborn, the liver edge may be palpable 2-3 cm below the right costal margin, but that distance is usually less than 2 cm by 4-6 months of age. In older children, the liver edge is usually not more than 1 cm below the right costal margin except on deep inspiration. The liver may be normally palpable in the midline several centimeters below the xiphoid.

Palpation should always be combined with percussion of the upper and lower boundaries of the liver. The upper edge of the liver is determined through percussion passing downward from the nipple line. The examiner may also define the lower edge through light percussion, moving upward from the umbilicus toward the costal margin. The anterior span of the liver is the difference between the highest and lowest points of hepatic dullness in the right midclavicular line.

In the scratch test the stethoscope is placed over the right lower costal area. The examiner then scratches the skin of the abdomen and uses auscultation to detect the lower liver edge by using the difference in sound transmission over solid liver and hollow intestine.

It is important to remember that physical examination has limitations. It may be difficult to detect the borders of the liver in patients with morbid obesity, ascites, pleural effusion, or extensive surgical scars. Physical examination determines only the external borders of the

liver and does not truly measure liver volume. A downward, tongue-like projection of the right lobe—the Riedel lobe—is a normal anatomic variant that is more commonly found in girls. It is a common error to express liver size and to define hepatomegaly on the basis of only the liver edge felt below the right costal margin. The liver may be displaced downward in patients with pulmonary disease, particularly with hyperaeration of the lungs. It may be difficult in some cases to distinguish masses arising from the right kidney or adrenal gland from an enlarged liver.

Liver size changes with age in proportion to the body size (Table 14.2). At birth, the liver constitutes approximately 4% of body weight and normally occupies a larger portion of the abdominal cavity than it does later in life. Liver weight increases twofold by the end of the first year of life, triples by the age of 3 years, and is increased sixfold by the age of 9 years. In the adult, liver weight is approximately 12 times that in the neonate.

The consistency and surface of the liver should be noted, including whether the liver edge is sharp or rounded and whether the liver surface is soft, hard, or irregular. The liver edge is normally soft, fairly sharp, and nontender. Livers enlarged because of congestive heart failure or because of acute infiltration by inflammatory cells or tumor are firm, have a somewhat rounded edge, and have smooth surfaces. In cirrhosis, the liver is hard and may have an irregular surface and edge. Tenderness generally suggests an acute process, as rapid distention of the liver capsule causes pain.

Hepatomegaly may resolve rapidly when congestive heart failure is controlled, biliary obstruction is relieved, diabetes is better controlled, or when massive liver cell necrosis leads to collapse of the liver tissue.

◆ History and Physical Examination

Once the presence of hepatomegaly is established, the provider should focus on the aspects of the history and physical examination that will direct the diagnostic evaluation. Review of systems should focus on growth, achievement of developmental milestones, changes in mental status, vomiting, diarrhea, fevers, pruritus, easy bruising, bleeding, urine output, and abdominal distention. Obtaining a detailed family and travel history is important, as many conditions leading to hepatomegaly are genetic in nature or are a result of infections. The possibility of intentional or accidental drug intake should always be entertained. On physical examination, it is important to determine the presence or absence of jaundice, splenomegaly, ascites, change in mental status, tremors, neurologic abnormalities, fever, signs of malnutrition, prominent vascular patterns on the anterior abdominal wall (caput medusae, spider angiomas), arterial hypertension, hypotension, bruising, petechiae, hemangiomas, pallor, obesity, renal enlargement, masses outside of the liver, lymphadenopathy, muscle weakness, cyanosis, heart murmurs, tachypnea, tachycardia, abnormal eye exam (cataracts, Kayser-Fleischer ring), bone and joint abnormalities, and dysmorphic features. A pelvic exam in sexually active females may detect signs of

a sexually transmitted infection, which can lead to Fitz-Hugh–Curtis syndrome.

◆ Pathophysiology

The pathophysiologic mechanisms underlying the enlargement of the liver are complex and heterogeneous. Hepatomegaly may reflect proliferation or enlargement or malfunction of one or more component structures of the liver, including liver parenchyma (hepatocytes), bile ducts (cholangiocytes, cysts), the reticuloendothelial system (Kupffer cells), interstitial tissue (stellate cells, collagen), blood (including hematopoietic cells), and blood vessels (endothelial cells). The liver also increases in size as a result of hepatic tumors, benign cysts, and infiltration of inflammatory or malignant cells.

The liver is particularly susceptible to injury not only from drugs and other exogenous toxins, but also from endotoxins that arise after the activation of inflammatory cells and the production of cytokines. Inborn errors of metabolism can be responsible for disturbances of liver structure and function and can produce hepatomegaly. The liver can be enlarged because of storage of glycogen, lipid, or glycolipids within the hepatocyte. In glycogen storage disease, the cytoplasm of enlarged hepatocytes is filled with dense pools of glycogen particles that displace other organelles. Steatosis is a frequent finding in diabetic or obese patients and is characterized ultrastructurally by large lipid inclusions, which may almost entirely fill the cytoplasm of hepatocytes. In lysosomal storage disorders such as Gaucher disease and Niemann-Pick disease, there is marked involvement of Kupffer cells with lysosomal inclusions characteristic of each disorder. Inclusions may also be present within hepatocytes; they contribute to hepatomegaly.

In many cases of biliary obstruction, such as biliary atresia, there may be significant hepatic enlargement, related in part to fibrosis and portal tract edema. As part of the liver's response to biliary obstruction, there may also be marked proliferation of small bile ductules that contribute to liver mass. Other conditions in which this could occur include choledochal cysts and common bile duct strictures.

The liver is the largest reticuloendothelial organ, and Kupffer cells, which are intensely phagocytic cells that line the sinusoids, constitute 15% of all the cells in the liver. In septicemia, hepatitis, and a number of other inflammatory conditions, hepatomegaly may result from proliferation and hyperplasia of Kupffer cells. Kupffer cells are involved in the cellular response to hepatocellular destruction. Kupffer cells also contribute to hepatomegaly in lysosomal storage disorders.

Resident stellate cells produce collagen, leading to fibrosis and eventually cirrhosis in response to injury of the liver from numerous causes, including infection, drug toxicity, and biliary obstruction. Hepatocellular injury can result in activation of stellate cells, which leads to the production of collagen and fibrosis. Fibrosis is a long-standing process, which may evolve over time to complete disruption of hepatic architecture and cirrhosis. Although an end-stage cirrhotic liver is often small, it may be significantly enlarged during the early stages of evolution. Congenital hepatic fibrosis is an inherited malformation of the liver characterized by the presence of broad bands of fibrous tissue and numerous distorted bile ducts and vascular structures. All of these abnormal components contribute to marked enlargement and hardening of the liver.

About 15% of the liver is occupied by sinusoidal and vascular structures. The liver is capable of rapid and massive enlargement in association with increased venous pressure. Distention of hepatic sinusoids can be present in congestive heart failure, constrictive pericarditis, or obstruction of hepatic venous outflow as a result of thrombosis or endothelial damage from drug toxicity (venoocclusive disease).

Since the liver serves as a secondary site of hematopoiesis, hepatomegaly can be caused by extramedullary hematopoiesis, particularly in young infants. Hepatomegaly can be the result of chronic inflammation, hemolysis, hemophagocytic lymphohistiocytosis (HLH), or bone marrow failure.

Hepatomegaly can occur as a result of cellular infiltration by inflammatory cells. Lymphocytic infiltrate is present in various forms of acute and chronic viral hepatitis, as well as in autoimmune hepatitis. Plasma cells may also be a prominent part of the infiltrate in autoimmune disease. Macrophages may also be observed, particularly in reaction to liver cell necrosis. The increase in liver size resulting from cellular infiltration may be balanced by loss of liver cell mass from liver cell necrosis or apoptosis.

Cellular infiltration of the liver may also occur in malignant disorders such as leukemia. A number of intraabdominal malignancies such as neuroblastoma may metastasize to the liver, producing hepatomegaly.

A variety of space-occupying lesions can lead to hepatomegaly. Cysts, either isolated or communicating with the biliary tract, tumors intrinsic to the liver, and hepatic abscesses can all be associated with hepatomegaly. Each must be differentiated by clinical features and defined more precisely by imaging studies.

EVALUATION OF THE CHILD WITH HEPATOMEGALY

Important historical or physical examination findings are noted in Tables 14.3 and 14.4.

◆ Laboratory Studies

Laboratory assessment of liver function in children with hepatomegaly is essential. Because of the large functional reserve of the liver, hepatomegaly may be the only indication of liver disease. The onset of symptoms such as jaundice and bleeding may be delayed long after laboratory evidence of disturbed liver function is evident. Patients with progressive liver disease, including those with chronic viral hepatitis, Wilson disease, or α_1-antitrypsin deficiency, may be asymptomatic for years or even decades. The pattern of liver test abnormalities may be helpful in suggesting whether the patient's liver disease is primarily hepatocellular or biliary in nature. Moreover, some laboratory studies, particularly when followed sequentially, may provide information about the synthetic, exocrine, metabolic (glucose, amino acids, lipids, detoxification) and endocrine (hyperaldosteronemia, vitamin D activation) liver function. Laboratory data provide input into several prognostic models used in assessment of the mortality risk and in evaluation for liver transplant.

All patients with hepatomegaly should have a complete metabolic panel (sodium, potassium, chloride, bicarbonate, creatinine, blood urea nitrogen (BUN), AST, ALT, albumin, glucose, lactate dehydrogenase (LDH), alkaline phosphatase, total bilirubin, total protein), fractionated bilirubin (conjugated and unconjugated bilirubin), complete blood count, urinalysis, prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen. D-dimers should also be tested in patients with suspected sepsis or thrombosis.

TABLE 14.3 Historical Features in the Diagnostic Evaluation of Hepatomegaly or Hepatosplenomegaly

Symptom	Diagnosis
Failure to thrive	Glycogen storage disease (infancy) types I, III, IV, IX, X Hereditary fructose intolerance Organic acidemias Wolman disease Cystic fibrosis Hemophagocytic lymphohistiocytosis Cholestatic liver disease
Fever	Acute and chronic hepatitis Systemic illness Hepatic abscess Hemophagocytic lymphohistiocytosis Viral infection
Diarrhea	Wolman disease Cholestatic liver disease
Peculiar odor	Organic acidemias Hepatic failure
Neurologic/psychiatric symptoms in older child	Wilson disease Porphyria Hyperammonemia (urea cycle disorders, organic acidemias) Drug intoxication/toxicity Hypoglycemia (glycogen storage disease, organic acidemias, β-oxidation defects)

Hepatocellular Injury

The concentrations of serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are frequently studied to assess hepatocellular injury. The aminotransferases may be elevated as a result of hepatocyte necrosis induced by a number of infectious, inflammatory, or metabolic disorders or by drug toxicity. ALT is present in much lower concentration in most tissues other than the liver. AST is less specific, as it is present not only in liver but also in muscle and brain. Some patients with a systemic viral illness such as influenza may have acute rhabdomyolysis, which leads to a very marked increase in serum AST. Hemolysis may also lead to an elevation of this enzyme. Although in most cases of liver disease there is some elevation of aminotransferase values, significant liver disease (hepatic steatosis, hepatitis C infection, and many metabolic disorders) may be present even when these test results are normal. Aminotransferases do not reflect liver function and have little correlation with the specific diagnosis or prognosis.

Biliary Injury

Alkaline phosphatase and γ-glutamyltransferase (GGT) are expressed in the bile collecting system. Their elevation can occur in both intrahepatic and extrahepatic cholestasis. Alkaline phosphatase is found in several other tissues, including bone, small intestine, placenta, and kidney. Because children have a significant proportion of serum alkaline phosphatase activity originating from bone, this test may be of less value in the assessment of pediatric liver disease. Even minor bone trauma or vitamin D deficiency can lead to elevation of alkaline phosphatase. The tissue origin of alkaline phosphatase can be determined by fractionation of alkaline phosphatase isoenzymes. The normal newborn may have very high levels of GGT, up to 10 times the upper limit of normal for adults. Values of GGT for premature babies may be higher than those for term infants during the first weeks after birth. In comparison with other standard serum assays, that of GGT may be the most sensitive indicator of hepatobiliary disease, but it is not of value in determining a specific diagnosis. Nonetheless, the highest levels of GGT are found in biliary obstruction. GGT levels may be paradoxically normal or low in progressive familial intrahepatic cholestasis type 1 and 2 and in some inborn errors of bile acid metabolism.

Exocrine Function

Because bilirubin requires conjugation with glucuronic acid in the hepatocyte, excretion across the canalicular membrane, and unobstructed passage through the biliary tree, the serum concentration of conjugated bilirubin represents a test of exocrine liver function. It is important to remember that the pathophysiologic effects of cholestasis are more directly related to bile acid excretion. Insufficient bile acid levels in the intestinal lumen lead to fat malabsorption, fat-soluble vitamin deficiencies, and steatorrhea. Analysis of serum bile acid levels, vitamin A, 25-hydroxy vitamin D, vitamin E, PT/international normalized ratio (INR), and measurement of fecal fat may further define the extent of exocrine dysfunction (see Chapter 15).

Synthetic Function

Albumin is the principal serum protein synthesized by the liver and has a half-life in serum of approximately 20 days. A decrease in serum albumin concentration may result from decreased production by the liver caused by severe impairment of liver function or significant loss of liver parenchyma. Serum albumin may also be low because of loss into the urine or the gastrointestinal tract.

The liver plays a central role in the production of coagulation factors. The PT and PTT are reasonable tests of liver synthetic capacity once vitamin K deficiency has been excluded. All of the clotting factors except factor VIII are exclusively made by the hepatocyte. The half-life of several clotting factors is short (factor VII has a half-life of 3-5 hours), and so the PT rapidly reflects changes in hepatic synthetic function and serves as a prognostic indicator in patients with fulminant hepatic failure. Caution should be used in interpreting a prolonged PT or PTT as sepsis with disseminated intravascular coagulation may cause abnormalities.

Metabolic Function

Many tissues can break down glycogen or produce glucose-6-phosphate via the gluconeogenesis pathway for local energy production inside the cell. The liver is the only organ that is able to release glucose into circulation. Patients with hepatic failure, glycogen storage diseases, mitochondrial diseases, fatty acid β-oxidation defects, pyruvate metabolism defects, Krebs cycle and gluconeogenesis defects, organic acidurias, or hereditary fructose intolerance may be hypoglycemic. Blood glucose level determination is essential in the evaluation of hepatomegaly, particularly in patients with alterations in their mental status. In the majority of conditions, hypoglycemia is associated with ketosis and lactic acidosis. Hypoglycemia in the absence of or with low levels of ketones in the urine strongly suggests a fatty acid β-oxidation defect or a mitochondrial disorder. Blood gas (and anion gap), serum amino and urinary organic acids, lactate, pyruvate, acylcarnitines, acylglycines, cortisol, insulin, thyroid function, and adrenocorticotropic hormone (ACTH) as well as the ratios of total and esterified to free serum carnitine concentrations, should be determined in follow-up studies.

The urea cycle is a series of enzymatic reactions converting highly toxic ammonia into less toxic urea. Ammonia is a ubiquitous by-product of amino acid metabolism. The urea cycle takes place exclusively in the liver. In liver disease, impairment of the urea cycle can be caused by destruction of hepatocytes, metabolic block at the level of the urea cycle, organic acid catabolism defects, or

TABLE 14.4   **Physical Signs in the Differential Diagnosis of Hepatomegaly**

Sign	Differential Diagnosis	Sign	Differential Diagnosis
Asymmetric hepatomegaly	Tumor, cyst, abscess	Skin findings	
Abdominal mass	Congenital hepatic fibrosis/polycystic kidneys Extrahepatic tumors (neuroblastoma, Wilms tumor) Choledochal cysts Adenoma Hepatoblastoma Hepatocellular carcinoma	Papular acrodermatitis Eczematoid rash	Hepatitis B Histiocytosis
		Neurodegeneration	Mucopolysaccharidoses (types IH, II, III) Gaucher disease types II and III GM_2 gangliosidosis Niemann-Pick disease types A, B, C Glycoproteinoses Mucolipidoses Disorders of protein glycosylation Peroxisomal disorders (Zellweger syndrome) Mitochondrial disorders
Hepatic bruit	Hemangioendothelioma		
Splenomegaly	Congenital infection Systemic infection (viral, bacterial, fungal) Cirrhosis Portal hypertension Lysosomal storage disease Lymphoma		
		Hypotonia	Glycogen storage disease type II Peroxisomal disorders (Zellweger syndrome) Mitochondrial disorders Mucolipidoses
Cutaneous hemangioma or telangiectasia	Hemangioendothelioma Hereditary hemorrhagic telangiectasia Cirrhosis (vascular spiders)	Malnutrition	Cystic fibrosis Steatosis
		Virilization	Hepatoblastoma Nonalcoholic fatty liver (female)
Coarse/dysmorphic facial features	Mucopolysaccharidosis GM_1 gangliosidosis Glycoproteinoses (sialidosis, mucolipidosis II) Disorders of protein glycosylation Glycogen storage disease type I Alagille syndrome Zellweger syndrome	Eye findings	
		Cataracts Kayser-Fleischer rings Telangiectasias Iritis	Galactosemia Wilson disease Hereditary hemorrhagic telangiectasia Primary sclerosing cholangitis
Episodic acute encephalopathy/coma	Disorders of fatty acid β-oxidation Hyperammonemia (urea cycle disorders, organic acidemias) Mitochondrial disorders Some urea cycle disorders (arginosuccinate lyase deficiency) Drug toxicity	Cherry red spot	Glycoproteinoses GM_2 gangliosidosis Niemann-Pick disease type B
		Posterior embryotoxon	Acute hepatitis (viral, toxic, autoimmune) Congestion (heart failure, hepatic vein obstruction) Trauma (subcapsular hematoma, fracture, laceration) Abscess (hepatic, subphrenic) Cholangitis
Skeletal deformities	Sialidosis (dysostosis multiplex) Mucopolysaccharidoses (dysostosis multiplex) Gaucher disease (marrow infiltration, deformities, fractures) Mucolipidosis II (restricted joint mobility)		

mitochondrial electron transport defects. Shunting of portal blood in cirrhosis or in congenital portosystemic shunts permits large amounts of ammonia and other toxins to bypass the liver and reach the systemic circulation directly.

Hepatomegaly with an acute change in mental status should raise the possibility of a serious metabolic condition. Since both hypoglycemia and hyperammonemia can lead to severe and irreversible brain damage, correction of these abnormalities should be considered an emergency.

The liver is the main site of biosynthesis and processing of cholesterol, lipids, and lipoproteins. Liver disease may profoundly affect serum lipid and lipoprotein concentrations. In cholestatic liver disease there may be extreme elevations of free cholesterol and phospholipids. These abnormalities are accompanied by the presence of an abnormal low-density lipoprotein fraction called lipoprotein X. In end-stage liver disease and acute liver failure, serum cholesterol may be low.

Enzymatic analysis of cultured lymphocytes or hepatic tissue may aid in the diagnosis. Genetic diagnosis is possible in a number of these disorders.

Extrahepatic Involvement

High levels of unconjugated bilirubin suggest the possibility of a concurrent hemolytic disorder or may reflect inborn errors of conjugation (see Chapter 15).

Neutropenia can be associated with splenomegaly/hypersplenism from portal hypertension, glycogen storage disease type Ib, Shwachman-Diamond syndrome, hemophagocytic lymphohistiocytosis (HLH), sepsis, leukemia, and neuroblastoma.

Renal involvement can be reflected by elevated creatinine, inability to concentrate urine, or by Fanconi syndrome. This could raise suspicion for autosomal recessive polycystic kidney disease, tyrosinemia, glycogen storage disease type Ib, Wilson disease, hereditary fructose intolerance, or galactosemia.

◆ Imaging Studies

A plain film of the abdomen may initially suggest the possibility of hepatomegaly. Air may be seen within the portal venous system, a late finding in bowel infarction and necrosis, intraabdominal sepsis, and associated inflammatory bowel disease. Air may also be present within the biliary tree, especially in patients who have undergone recent biliary tract surgery or who have an enterobiliary fistula. Coarse calcifications may be found in hepatoblastoma and laminated calcifications in hepatocellular carcinoma. Subacute abscesses and echinococcal cysts may also contain calcium.

Ultrasonography is often the most useful initial imaging modality. It can assess gallbladder size, detect gallstones and sludge in the bile ducts and gallbladder, demonstrate ascites, and define cystic or obstructive dilatation of the biliary tree. Extrahepatic anomalies may also be detected. Mass lesions in the liver, including tumors, cysts, abscesses, vascular malformations, and hematomas, can be defined. Abnormal echogenicity may suggest diffuse parenchymal liver disease including fatty infiltration or fibrosis. Doppler studies may be used to differentiate between vascular and nonvascular structures. The study may be particularly useful for assessing portal hypertension, in which portal venous flow may be decreased or reversed.

Computed tomography (CT) with contrast provides useful information in differentiation of liver masses. CT angiograms and/or venograms are useful in defining the anatomy of vascular anomalies. Disadvantages of CT scans are the frequent need for sedation, potential renal toxicity of contrast, and risks from ionizing radiation.

Magnetic resonance imaging (MRI) provides additional information about liver anatomy. Magnetic resonance angiography (MRA) may be of value in assessing the vascularity of masses within the liver. Magnetic resonance cholangiography is commonly used to assess the biliary tract with visualization of details previously possible only with transhepatic or endoscopic retrograde cholangiography.

Hepatic scintigraphy can be useful for assessing the liver parenchyma and biliary tree. The most frequently performed study is hepatobiliary scintigraphy performed with a technetium 99m (^{99m}Tc)–labeled iminodiacetic acid derivative. Biliary imaging with this technique provides information about patency of the biliary tract and gallbladder. ^{99m}Tc–sulfur colloid scanning may be used in assessing a patient with a mass. ^{99m}Tc–sulfur colloid accumulates in Kupffer cells. Most malignant tumors, hemangiomas, abscesses, and cysts lack Kupffer cells and appear as "cold" spots on these scans. In contrast, a nodule taking up the isotope suggests a benign lesion containing Kupffer cells, such as a regenerative nodule of cirrhosis, fatty change, or focal nodular hyperplasia.

Liver Biopsy

Percutaneous, transjugular, or open-liver biopsy is one of the most important diagnostic tests in evaluating a child with hepatomegaly. Liver biopsy is essential in establishing a diagnosis and possibly prognosis in patients with chronic viral hepatitis, drug-induced liver disease, autoimmune hepatitis, and various metabolic disorders. Abnormal storage of material in hepatocytes or Kupffer cells and viral inclusions may also be found. Electron microscopy and immunohistochemical methods may aid in identification and localization of these abnormalities. Liver tissue may also be frozen for later biochemical or molecular analysis.

SPECIFIC ISSUES IN THE DIAGNOSIS AND TREATMENT OF HEPATOMEGALY

The clinical challenge in the evaluation of hepatomegaly is that there is a very broad differential with many relatively rare conditions. Tables

TABLE 14.5 Helpful Laboratory Abnormalities in the Evaluation of Hepatomegaly	
Vacuolated white blood cells in peripheral smear	Wolman disease GM$_1$ gangliosidosis
Neutropenia	Glycogen storage disease type I Organic acidurias Shwachman-Diamond syndrome Hemophagocytic lymphohistiocytosis Sepsis Leukemia Neuroblastoma Portal hypertension (hypersplenism)
Hemolytic anemia	Wilson disease Autoimmune hepatitis Hemoglobinopathy (with extramedularry hematopoeisis)
Hypophosphatemia	Glycogen storage disease type I Hereditary fructose intolerance
Hypertriglyceridemia	Glycogen storage disease type I Hemophagocytic lymphohistiocytosis Nonalcoholic fatty liver
Elevated creatinine	Disorders of fatty acid β-oxidation Reye syndrome Congenital hepatic fibrosis/autosomal recessive polycystic kidney disease
Renal tubular dysfunction	Tyrosinemia Glycogen storage disease type I Hereditary fructose intolerance Wilson disease Galactosemia

14.4 and 14.5 list some of the physical signs and laboratory abnormalities that may be associated with hepatomegaly. Table 14.6 lists a stepwise approach for devising the differential diagnosis and directing the investigation. The first goal is to identify potentially life-threatening conditions, to focus on emergency measures to manage immediate threats to life, and to prevent irreversible end-organ damage. The second goal is to identify potentially treatable disorders requiring timely interventions. Ultimately, the clinician should focus on other chronic conditions in order to establish the diagnosis and prognosis. Some disorders may be corrected by liver transplantation; such patients should be promptly referred to a transplant center for evaluation.

Hepatomegaly in the Infant

Hepatomegaly in the neonate is commonly associated with liver dysfunction and jaundice (see Chapter 15). In infants, jaundice is a frequent presenting feature of liver disease rather than a later manifestation of advanced liver disease, as in the older child or adult. The majority of infants with cholestatic liver disease manifest the disease during the first month of life.

Changes in mental status, such as irritability or lethargy, poor feeding, and vomiting, are frequent symptoms in metabolic disorders. Urea cycle defects lead to hyperammonemia and acute encephalopathy associated with astrocyte swelling without axonal damage. Patients present with a change in mental status or ataxia. Severe or prolonged hyperammonemia ultimately leads to progressive irreversible changes in the brain characterized by cortical and brainstem gliosis and

neuronal atrophy. Symptomatology of galactosemia and tyrosinemia depends on the presence of nutritional substrates; thus irritability, lethargy, hepatomegaly, ascites, edema, and coagulopathy may manifest soon after feedings are initiated and evolve over the first weeks of life.

A profound impairment of hepatic synthetic function, often in excess of that expected for the degree of cholestasis, may be an early indication of metabolic liver disease. Hepatic failure may be present in mitochondrial disorders, including both mitochondrial DNA mutations and mitochondrial DNA depletion syndromes. Multiple organs (brain, heart, skeletal muscle) may be involved in addition to the liver. Affected patients often have lactic acidosis, hypoglycemia, hypertriglyceridemia, and an abnormal acylcarnitine profile.

Neonatal hemochromatosis may manifest with hepatic failure at birth. Patients with neonatal hemochromatosis may benefit from treatment with plasmapheresis and may require liver transplantation. Diagnosis of hemochromatosis also bears significance for future pregnancies. Hemochromatosis will develop in up to 80% of infants of mothers with a child diagnosed with hemochromatosis. As hemochromatosis is likely caused by maternal alloantibodies crossing the placenta and damaging the liver, the severity of hemochromatosis can be alleviated by prenatal administration of intravenous immunglobulin (IVIG).

A number of clinical features may provide clues about the cause of neonatal cholestasis. An enlarged liver with a firm or hard consistency is more commonly found in infants with extrahepatic bile duct obstruction or neonatal hemochromatosis. Congenital infection may be associated with low birthweight, hepatomegaly, microcephaly, purpura, and chorioretinitis. Dysmorphic facial features may be seen in association with chromosomal abnormalities and with Alagille syndrome. Congenital malformations, including cardiac anomalies, polysplenia, intestinal malrotation, and situs inversus, may be found in the syndromic form of biliary atresia. In the **polysplenia syndrome**, a midline liver may be palpable in the hypogastrium. The spleen may also be enlarged with infection or as a result of portal hypertension. Hepatomegaly, as well as a mass in the right upper quadrant, may be felt in infants with a choledochal cyst. Infants may present with hepatomegaly, cholestasis, and sometimes hepatic failure related to infection. Cytomegalovirus, herpes simplex virus, enteroviruses, echovirus, coxsackievirus and parvovirus B19 are sometimes isolated from infants with cholestasis and hepatomegaly. Hepatomegaly and cholestasis can also be associated with bacterial sepsis, syphilis, tuberculosis, and toxoplasmosis. α_1-Antitrypsin deficiency can present as hepatomegaly associated with cholestasis in infants.

Infants with **storage diseases** can present with isolated hepatomegaly or hepatosplenomegaly and few other symptoms in the early stages. Hepatomegaly is a feature of these disorders because of a pathologic accumulation of undegraded or partially degraded macromolecules. The mucopolysaccharidoses, the lipid storage diseases, the mucolipidoses, and glycoprotein storage disease are examples of these disorders. The clinical features of lysosomal storage diseases are determined by where the deficient enzyme is expressed and the rate of accumulation of the abnormal material. Hepatomegaly in the neonate can occur in Gaucher disease, Niemann-Pick disease type A, and Wolman disease. Neonatal hepatosplenomegaly and jaundice may occur in Niemann-Pick disease type C. Progressive neurologic dysfunction may occur later. Hepatosplenomegaly accompanied by coarse facial features and skeletal abnormalities is present in infants with the GM_2 gangliosidoses and mucopolysaccharidoses. Significant liver disease may occur in some of these disorders, leading to chronic liver failure and cirrhosis. On the basis of clinical features and manifestations, specific enzymatic activities may be determined in peripheral white blood cell culture or in cultured skin fibroblasts to establish a precise diagnosis. Treatment options are limited for most of these disorders.

Enzyme replacement with recombinant β-glucocerebrosidase is effective in treating patients with Gaucher disease without neurologic involvement. Although of limited efficacy, bone marrow transplantation has been used in patients with several of these disorders, including the mucopolysaccharidoses and Gaucher disease.

Hepatomegaly is one of the most common findings in glycogen storage disorders. A common feature of **glycogen storage disorders (GSD)** is inefficient release of glucose from glycogen stores; this can lead to hypoglycemia when fasting. Since brain energy metabolism heavily depends on the availability of glucose, severe hypoglycemia can lead to metabolic strokes, irreversible brain damage, and death.

Hepatomegaly in the Child and Adolescent

Hepatomegaly in the child or adolescent may be an isolated finding on a routine physical examination or may be associated with many other clinical features related to systemic disease or impaired liver function.

Steatohepatitis

Fatty liver disease in the child and adolescent is associated with childhood obesity. An increase in serum ALT value is found in 6% of overweight children and 10% of obese children. A large number of U.S. adolescents may have fatty infiltration of the liver (**nonalcoholic steatohepatitis**). Nonalcoholic steatohepatitis should be suspected in any obese child with hepatomegaly and/or abnormal liver test results. Nonalcoholic steatohepatitis is more prevalent in Hispanic patients. Many of these children have features of metabolic syndrome, such as insulin resistance, arterial hypertension, and elevated serum cholesterol and triglyceride levels. In overweight children presenting with hepatomegaly and liver dysfunction, nonalcoholic steatohepatitis should be the primary diagnostic consideration, but other disorders, such as autoimmune hepatitis and chronic viral hepatitis, must be ruled out. Imaging studies, including ultrasonography, MRI, and CT, may suggest altered composition of the liver consistent with steatosis. Liver biopsy is the definitive diagnostic test and should be considered in patients with persistently abnormal aminotransferases. The purpose of the biopsy is to establish the diagnosis of nonalcoholic steatohepatitis, rule out other conditions and evaluate the degree of steatosis, inflammation, and fibrosis. Steatohepatitis can progress to cirrhosis and chronic liver failure. Steatohepatitis is associated with increased mortality from cardiovascular disease and liver cancer. Obese patients with steatohepatitis should be enrolled in a weight-management program. Medications such as vitamin E and metformin could be considered.

Viral Hepatitis

Acute viral hepatitis should be considered in the child with hepatomegaly and liver dysfunction. The patient may be acutely ill with sudden onset of fever, anorexia, nausea, and vomiting. Jaundice may occur, but many children with acute viral hepatitis are anicteric. On physical examination, varying degrees of tender hepatomegaly may be defined. Hepatitis is confirmed by an elevation in serum aminotransferase levels. Hepatitis may be caused by hepatotropic viruses (hepatitis A, B, C, D, or E) or by other viral infections that can involve the liver, such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), adenovirus, enterovirus, and echovirus. Serodiagnosis of all of these infections is possible. The evaluation for various forms of hepatitis should include anti–hepatitis A virus immunoglobulin M (IgM), hepatitis B surface antigen, anti–hepatitis B core antibody, anti–hepatitis C antibody, CMV IgM or CMV polymerase chain reaction (PCR), and EBV serologic profile or EBV PCR. Therapy is available for hepatitis B, hepatitis C, and CMV hepatitis. Hepatitis B or C have the potential to evolve to cirrhosis over many years. Table 14.7 presents the main causes of chronic hepatitis in children. Chronic hepatitis B infection is defined

TABLE 14.7   **Causes of Chronic Liver Disease in Children**

Drugs

by persistently elevated serum levels of hepatitis B DNA. Hepatitis C is an indolent infection with the potential to evolve to cirrhosis over several decades. However, some children, particularly when co-infected with human immunodeficiency virus, may have more rapidly progressive liver disease. Chronic hepatitis C infection is defined by the persistent presence of hepatitis C RNA in serum. As new antiviral agents are becoming available, eradication of hepatitis C is possible in the majority of adult patients though there are no clinically tested pediatric protocols currently.

Toxins

All patients presenting with hepatomegaly and liver dysfunction should be questioned about recent exposure to medications or environmental toxins. Acute and chronic hepatitis can be caused by a number of different medications such as isoniazid and methyldopa. Treatment of drug- or toxin-related liver injury is mainly supportive. Contact with the offending agent should be avoided. Corticosteroids may have a role in immune-related injury, as may occur with phenytoin. *N*-acetylcysteine therapy, by stimulating glutathione synthesis, is effective in preventing hepatotoxicity when administered within 16 hours after an overdose of acetaminophen and appears to improve survival in patients with severe liver injury even 36 hours after toxin ingestion. Liver injury in most cases is completely reversible when the hepatotoxic drug is withdrawn. With continued use of certain drugs, such as methotrexate, the effects of hepatotoxicity may proceed insidiously to cirrhosis.

Alpha-1-Antitrypsin Deficiency

Children and adolescents with α_1-antitrypsin deficiency may present with manifestations of chronic liver disease or cirrhosis with evidence of portal hypertension. Liver biopsy may show a chronic hepatitis with varying degrees of fibrosis. The diagnosis is established by determination of the α_1-antitrypsin phenotype (phenotypes ZZ and SZ cause liver disease) and may be confirmed by liver biopsy. Periportal hepatocytes demonstrate periodic acid–Schiff–positive diastase-resistant intracytoplasmic globules. Immunocytochemical studies confirm that this material is the abnormal α_1-antitrypsin. There is no specific treatment other than to manage the complications of cirrhosis, cholestasis, and portal hypertension. Patients with α_1-antitrypsin deficiency are at increased risk of hepatocellular carcinoma. Liver transplantation is curative, though the majority of the patients with α_1-antitrypsin deficiency do not require liver transplantation.

Wilson Disease

Wilson disease is a metabolic disorder that may manifest with hepatic disease in childhood, ranging from asymptomatic hepatomegaly (with or without splenomegaly) to subacute or chronic hepatitis or fulminant hepatic failure. Initial manifestations of Wilson disease may include portal hypertension, ascites, edema, and esophageal hemorrhage. Wilson disease can also present with extrahepatic symptoms, such as hemolytic anemia, movement disorders, or mood disorders. Wilson disease is due to mutations in a copper-transporting P-type adenosine triphosphatase, which leads to a failure of biliary copper excretion and a progressive accumulation of copper in the liver and other organs. Lipid peroxidation, particularly of mitochondrial membranes, results from copper overload leading to the functional alterations in the liver and the brain. A low serum ceruloplasmin level suggests the diagnosis of Wilson disease. Serum copper levels may also be elevated, and urinary copper excretion is high, often up to 1000 μg or more per day. The diagnosis is confirmed with a quantitative determination of copper in a liver-biopsy specimen. Treatment of Wilson disease involves chelation and urinary excretion of the excess copper. The most frequently employed agents are penicillamine and trientin. In response to chelation therapy, urinary copper excretion increases markedly, and this is associated with a gradual clinical improvement. Liver transplantation may be required for treatment of fulminant Wilson disease or in patients with decompensated cirrhosis.

Autoimmune Liver Disease

Several forms of autoimmune liver disease may also manifest with hepatomegaly during childhood and adolescence. Autoimmune hepatitis is defined as a continuing inflammatory process manifested by elevated aminotransferase concentrations and a number of circulating autoantibodies. The severity at presentation is highly variable; affected children may have only biochemical evidence of liver disease, may have stigmata of chronic liver disease, or may present in hepatic failure. In 25-30% of patients with autoimmune hepatitis, particularly children, the illness may mimic acute viral hepatitis; however, in most patients, the onset is insidious. The patient may be asymptomatic or have fatigue, malaise, behavioral changes, anorexia, and amenorrhea. Months or even years may pass before a liver problem is recognized with onset of jaundice or bleeding. There is a high association with extrahepatic disorders, including arthritis, vasculitis, nephritis, thyroiditis, celiac disease, inflammatory bowel disease and Coombs-positive anemia.

Laboratory studies in autoimmune hepatitis reveal a moderate elevation, usually less than 1000 IU/L, of serum aminotransferase activities. Serum bilirubin levels are commonly 2-10 mg/dL. Serum alkaline phosphatase activity is normal or only slightly increased. A diagnosis of autoimmune hepatitis may initially be suggested by marked polyclonal elevations of serum gamma globulin levels. Characteristic patterns of serum autoantibodies may be present. The most common is formation of non–organ-specific antibodies such as anti-actin (smooth muscle), and antinuclear antibodies (**type 1 autoimmune hepatitis**). In this variant of autoimmune hepatitis, most patients present between 10 and 20 years of age. High titers of a liver-kidney microsomal antibody can be detected in **type 2 autoimmune hepatitis** that usually affects children between the ages of 2 and 14 years. Liver biopsy is useful in confirming the diagnosis and assessing the degree of liver damage. Cirrhosis may be present at the time of diagnosis in children.

Immunosuppressive medications are necessary to treat autoimmune hepatitis. Corticosteroid therapy, with or without low doses of azathioprine, improves the clinical, biochemical, and histologic features in most patients and prolongs transplant-free survival in most patients with severe disease.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis is an autoimmune disorder with the focus of injury being the biliary tract. The disorder may be difficult to

(See *Nelson Textbook of Pediatrics,* p. 1961.)

distinguish from autoimmune hepatitis, and some patients have an overlap syndrome with features of both disorders. Hepatomegaly is frequently present. Patients may be asymptomatic or have jaundice, pruritus, or abdominal pain. Although serum aminotransferase levels are elevated, there is more striking elevation of serum alkaline phosphatase, 5'-nucleotidase, and GGT activities. **Inflammatory bowel disease** occurs in 50-75% of patients and may manifest at any time in the course of the liver disease. MR cholangiography reveals beading and irregularity of the intrahepatic and extrahepatic bile ducts. There is no definitive treatment. The course of the disorder is slowly progressive and eventually necessitates liver transplantation.

Acquired Immunodeficiency Syndrome

Hepatobiliary manifestations are common in patients with acquired immunodeficiency syndrome (AIDS). Hepatomegaly may be present, caused by a heterogeneous group of issues that includes viral hepatitis, opportunistic infections, medication-induced hepatic injury, malnutrition, peliosis hepatis, AIDS cholangiopathy, and neoplasms. Pathologic features that are most typical of pediatric AIDS include giant cell transformation and diffuse parenchymal lymphoplasmacytic infiltrates, the latter being associated with lymphoid interstitial pneumonitis.

Other Infections

Hepatosplenomegaly and anicteric hepatitis have been reported with cat-scratch disease, typhoid, brucellosis, tularemia, syphilis, Lyme disease, leptospirosis, Rocky Mountain spotted fever, Q fever, tuberculosis, and actinomycosis.

Fitz-Hugh–Curtis Syndrome

Fitz-Hugh–Curtis syndrome is a perihepatitis associated with acute salpingitis. Symptoms and signs include acute onset of severe right upper quadrant abdominal pain, friction rub over the anterior liver surface, and physical signs of pelvic inflammatory disease on pelvic examination (see Chapter 18).

Hepatic Abscess

A pyogenic, fungal, or parasitic hepatic abscess is an unusual infection in children. Common clinical findings are fever, abdominal pain, and hepatomegaly, with or without tenderness.

Pyogenic abscesses occur most frequently in infants who have had sepsis or umbilical infections. Cases in older children are usually associated with underlying host-defense defects, particularly human immunodeficiency virus, chronic granulomatous disease, and leukemia, or with occurrence of previous blunt trauma to the liver. Pyogenic abscess may follow an episode of appendicitis. Liver abscess may also occur in previously healthy children. *Staphylococcus aureus* and enteric and anaerobic bacteria are common etiologic agents. Liver function test results are commonly normal. Ultrasonography or CT scan confirms the presence and number of lesions. Echogenic debris or gas may be seen.

Amebiasis occurs in clusters in the southern United States, with person-to-person transmission in association with poor sanitation and crowding. Amebic abscess follows portal invasion by the parasite. The diagnosis is established by demonstrating a positive result on enzyme-linked immunosorbent assay for antibody to *Entamoeba histolytica* or by finding trophozoites or cysts in the stool. Toxocariasis and echinococcosis are caused by abortive infection of the liver in humans with the natural parasite of dogs or cats. The diagnosis is confirmed by specific serologic profiles.

Endocrine Disorders

Hepatomegaly and mild elevations of aminotransferase levels and bilirubin are common in hypothyroidism and are occasionally observed in hyperthyroidism. An enlarged liver is often found in patients with diabetes mellitus, particularly those with severe or poorly controlled diabetes, mainly as a result of excessive glycogen deposition. An extreme, rare case of this process is represented by **Mauriac syndrome**, which is characterized by dwarfism, obesity, moon facies, hypercholesterolemia, and marked hepatomegaly. Patients with acromegaly can also have mild to severe hepatomegaly as part of a generalized visceromegaly associated with the disease.

Liver Tumors

Liver tumors are the third most common solid abdominal tumors, after neuroblastoma and Wilms tumor (see Chapter 17). Hepatic metastatic disease can also occur with many childhood neoplasms, most frequently neuroblastoma, leukemia, and lymphoma. The primary tumor location is usually known.

Benign liver tumors account for 33% of cases of primary hepatic tumors. Benign liver tumors include hemangioendotheliomas, mesenchymal hamartomas, focal nodular hyperplasia, and adenomas. Malignant tumors include hepatoblastoma, hepatocellular carcinoma, and undifferentiated embryonal cell sarcoma. Of all hepatic neoplasms, hepatoblastoma, hepatocellular carcinoma, and infantile hemangioendothelioma are the 3 most common, accounting for 65% of cases. Most hepatic tumors are asymptomatic or may manifest with abdominal distention, abdominal pain, weight loss, vomiting, or diarrhea. Any hepatic mass can present with acute abdominal pain caused by hemorrhage into the tumor or peritoneal cavity.

Hemangioendotheliomas are the most common benign hepatic tumors. Nearly 95% of all hemangioendotheliomas manifest in the first year of life. Congestive heart failure due to hyperdynamic circulation may be present in 10-15% of cases. In addition to hepatomegaly, anemia and hemangiomas of the skin, lungs, lymph nodes, pancreas, retroperitoneum, intestine, or bone may be seen with hepatic hemangioendothelioma. Liver ultrasound shows a hyperechogenic mass frequently associated with increased vascular flow on Doppler evaluation. MRI or CT with intravenous contrast can be useful to further define the mass if sonographic evaluation is not conclusive.

Typically, a mesenchymal hamartoma, which consists of multiple cysts filled with serous fluid separated by myxomatous stroma, has no capsule. Of mesenchymal hamartomas, 70% manifest in the first 2 years of life. Hepatic adenoma is a rare benign tumor of the liver. Oral contraceptives, diabetes mellitus, glycogen storage disease, portosystemic shunts, and androgen therapy for Fanconi anemia increase the risk of adenoma.

Focal nodular hyperplasia (FNH) is caused by nodular regeneration of the liver around a focal scar of the liver parenchyma. FNH is seen predominantly in females and may occur at all ages. FNH is more common in patients who have congenital portosystemic shunts (Abernethy anomaly).

The majority of patients with **hepatoblastoma** present before 2 years of age and 90% by the age of 4. **Hepatocellular carcinoma,** and less commonly, undifferentiated embryonal sarcoma occur primarily in older children. Hepatocellular carcinoma is associated with hereditary tyrosinemia, ataxia-telangiectasia, glycogen storage disease type I, chronic hepatitis B or hepatitis C, α_1-antitrypsin deficiency, autoimmune hepatitis, and familial cholestatic cirrhosis. Serial screening with periodic liver sonograms is indicated for patients with these diseases. If nodules are identified, the nature of the mass can be clarified with CT with contrast (triphasic CT) or MRI with contrast.

Serum α-fetoprotein (AFP) is the most useful marker of malignant liver tumors; 80-90% of hepatoblastomas and 60-90% of hepatocellular carcinomas are positive. The serum AFP level is normal in mesenchymal hamartoma, focal nodular hyperplasia, and adenoma. The diagnosis is confirmed by needle biopsy, usually with CT guidance.

(See *Nelson Textbook of Pediatrics,* p. 2479.)

TABLE 14.8 **Red Flags Suggesting Serious Liver Disease in a Patient with Hepatomegaly**	
History History of prolonged hyperbilirubinemia in infancy History of neurologic or psychiatric disease Previous blood transfusion, intravenous drug use Past history of hepatitis Delayed puberty Gastrointestinal bleeding Family history of chronic liver or kidney disease **Physical Examination** Hard or nodular liver Splenomegaly Ascites Prominent abdominal venous pattern Growth retardation	Muscle wasting Digital clubbing Palmar erythema Spider angiomata Arthritis Papular acrodermatitis Kayser-Fleischer rings Mental status changes Asterixis **Laboratory Test Results** Prolonged prothrombin time Hypoglycemia Decreased serum albumin

Hepatic Cysts

The origin of solitary cysts is unknown. They are probably the sequelae of intrahepatic hemorrhage. **Peliosis hepatis**, characterized by multiple blood-filled spaces of varying sizes within the liver parenchyma, can be a complication of long-term treatment with anabolic steroids. Hepatomegaly, often with tenderness, may be present before any evidence of liver biochemical abnormality is evident.

Choledochal cysts are defined as congenital dilation or outpouching of large bile ducts. Though the majority of choledochal cysts are diagnosed in the first year of life, later presentation is possible. Choledochal cysts are associated with an increased risk of ascending cholangitis and cholangiocarcinoma; thus they should be surgically removed.

Congenital hepatic fibrosis is almost universally associated with autosomal recessive polycystic kidney disease (ARPKD). Approximately 40% of patients with congenital hepatic fibrosis have involvement of large bile ducts, which can be visualized by MR cholangiogram as multiple cystic dilations of the intrahepatic bile ducts (Caroli disease). **Caroli disease** is associated with an increased risk of ascending cholangitis and sepsis, particularly in patients who underwent kidney transplantation for ARPKD. Recurrent cholangitis in patients with ARPKD can be an indication for combined liver/kidney transplantation.

Hepatic Venous Outflow Obstruction

Hepatic venous outflow obstruction is classified into 3 categories on the basis of the level of obstruction. Obstruction can occur at the level of hepatic venules (venoocclusive disease), hepatic veins (Budd-Chiari syndrome), or suprahepatic vena cava. Hepatic venous outflow obstruction manifests with acute ascites and tender hepatomegaly. Abdominal pain, distention, and splenic enlargement may be prominent. Elevation of the aminotransferases or serum bilirubin level are present in the acute stage.

The pathologic hallmark of **venoocclusive disease** is occlusion of central and sublobular hepatic veins by intimal edema and fibrosis. The illness classically follows ingestion of plants that contain a toxic pyrrolizidine alkaloid, which can be present in bush teas and herbal medicines. Venoocclusive disease may also occur as a hepatic response to irradiation and induction for bone marrow transplantation. A familial form of venoocclusive disease associated with immunodeficiency has also been reported. The clinical diagnosis is based on either the McDonald (modified Seattle) or Jones (Baltimore) criteria. The McDonald criteria require the presence of 2 features from hepatomegaly with right-upper quadrant pain, total bilirubin of 34.2 µmol/L or more (normal range <20 µmol/L), and ascites or unexplained weight gain >2% of baseline. The Jones criteria require a total bilirubin of 34.2 µmol/L or more and presence of at least 2 of the following: hepatomegaly, ascites, and weight gain >5% of baseline.

Budd-Chiari syndrome develops in a variety of conditions that predispose to thrombosis, including intake of oral contraceptives, pregnancy, previous trauma, tumor invasion, cirrhosis, inflammatory bowel disease, collagen vascular disease, protein C deficiency, sickle cell anemia, polycythemia vera, and lymphoproliferative disorders. Membranous obstruction of the suprahepatic vena cava is the most common cause of suprahepatic outflow obstruction. However, thrombosis of the suprahepatic vena cava can occur in any condition that may precipitate Budd-Chiari syndrome. Diagnostic evaluation begins with pulsed Doppler sonography of the hepatic vessels. CT angiogram can further define the anatomy of the outflow obstruction. Liver biopsy in hepatic outflow obstruction reveals a characteristic pattern of sinusoidal dilation with centrilobular congestion. Cirrhosis is a poor prognostic sign.

SUMMARY AND RED FLAGS

Hepatomegaly that is persistent suggests a chronic illness, which with time may produce serious morbidity or mortality, despite an initial well appearance of the patient. It is important to determine whether the hepatomegaly is a result of a specific liver disease or whether it is part of a generalized systemic illness. Red flags include signs of acute hepatic failure (coma, hemorrhage), developmental delay, failure to thrive, and those noted in Table 14.8.

Jaundice

Grzegorz W. Telega

Jaundice, the yellow discoloration of skin and sclerae, results when the serum level of bilirubin, a pigmented compound, is elevated. Jaundice is not evident until the total serum bilirubin is at least 2-2.5 mg/dL in children out of the neonatal period.

Bilirubin is formed from the degradation of heme-containing compounds, particularly hemoglobin (Fig. 15.1). Microsomal heme oxygenase, located principally in the reticuloendothelial system, catabolizes heme to biliverdin, which is then reduced to bilirubin by biliverdin reductase. This unconjugated bilirubin (UCB) is lipophilic and cannot be eliminated via the kidney because of its insolubility in water. It can easily cross cell membranes and the blood-brain barrier. UCB is transported bound primarily to albumin. A receptor on the hepatocyte surface facilitates bilirubin uptake. Bilirubin is then conjugated with glucuronic acid by bilirubin uridine diphosphate glucuronosyltransferase (UDPGT). UDPGT can be induced by a variety of drugs (e.g., narcotics, anticonvulsants, and contraceptive steroids) and by bilirubin itself. Enzyme activity is decreased by restriction of calorie and protein intake.

Conjugated bilirubin (CB) is a polar, water-soluble compound. It is excreted from the hepatocyte to the canaliculi, through the biliary tree, and into the duodenum. Once CB reaches the colon, bacterial hydrolysis converts CB to urobilinogen. A small amount of urobilinogen is reabsorbed and returned to the liver via enterohepatic circulation or excreted by the kidneys. The remainder is converted to stercobilin and excreted in feces. In neonates, β-glucuronidase in the intestinal lumen hydrolyzes CB to UCB, which is then reabsorbed and returned to the liver via the enterohepatic circulation.

Hyperbilirubinemia can result from alteration of any step in this process. Hyperbilirubinemia can be classified as conjugated (direct) or unconjugated (indirect), depending on the concentration of CB in the serum. Conjugated and unconjugated are more accurate terms, because "direct" and "indirect" refer to the van den Bergh reaction, used for measuring bilirubin. In this assay, the unconjugated fraction is determined by subtracting the direct fraction from the total and, therefore, is an indirect measurement. The direct fraction includes both conjugated bilirubin and Δ-bilirubin, an albumin-bound fraction. Conjugated hyperbilirubinemia exists when more than 20% of the total bilirubin or more than 2 mg/dL is conjugated. If neither criterion is met, the hyperbilirubinemia is classified as unconjugated.

Unconjugated hyperbilirubinemia can be caused by any process that results in increased production, decreased delivery to the liver, decreased hepatic uptake, decreased conjugation, or increased enterohepatic circulation of bilirubin. The primary concern in patients with high levels of unconjugated bilirubin is kernicterus, resulting from the neurotoxicity of UCB across the blood-brain barrier mostly in the basal ganglia, pons, or cerebellum. This is a concern primarily in neonates.

Conjugated hyperbilirubinemia can occur due to hepatocellular dysfunction, biliary obstruction, and abnormal excretion of bile acids or bilirubin.

DIAGNOSTIC STRATEGIES

The causes of jaundice in the neonate and older infant are not the same as the causes of jaundice in the older child or adolescent (Figs. 15.2 and 15.3). The approach to the problem varies with age.

Bilirubin

In any patient with jaundice, the total serum bilirubin should be fractionated, as the differential diagnosis of unconjugated hyperbilirubinemia is distinct from that of conjugated hyperbilirubinemia (see Figs. 15.2 and 15.3). On occasion, hemolysis interferes with some assays and may result in a falsely elevated conjugated fraction. This can be problematic with specimens obtained by heelstick or fingerstick. If the clinical picture is consistent with unconjugated hyperbilirubinemia, the assay should be repeated with a venous sample.

Aminotransferases

Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are frequently used as markers of hepatocellular injury. AST is expressed in mitochondria of the liver and cytosol of red blood cells and muscles; thus it is not specific for liver injury. Since ALT is less abundant outside of the liver, an increased ALT level is more suggestive of liver disease. Levels of both are markedly elevated (>5- to 10-fold normal) with hepatocellular injury caused by hepatitis, hepatotoxicity, ischemia, genetic or metabolic liver disorders. Elevation of AST in excess of ALT suggests extrahepatic source of injury. With acute biliary obstruction, there are initial sharp increases in ALT and AST levels and a rapid decline in 12-72 hours as obstruction is relieved. In chronic cholestasis, aminotransferases are usually only mildly elevated. With hepatocellular injury, ALT and AST levels tend to remain more significantly elevated longer. In acute liver failure a rapid decline in ALT and AST levels with worsening coagulopathy is a poor prognostic factor.

It is important to remember that aminotransferases reflect cell injury, not liver function. *There is no correlation between the severity of the liver dysfunction and the degree of elevation of ALT and AST levels.* Temporal trends in serum aminotransferase levels are useful in monitoring disease activity in chronic viral and autoimmune hepatitis.

Alkaline Phosphatase

Alkaline phosphatase is an enzyme found in bile ducts, bone, intestine, placenta, and tumors. Elevations in the serum alkaline phosphatase level occur with hepatobiliary disease but also normal growth, healing

Jaundice in Neonate or Young Infant

Unremarkable history
Normal physical examination
Onset after 24 hr of age
Bilirubin <13 mg/dL (<15 mg/dL if breast-fed)
Not persisting beyond 14 days of age (1 mo
    if breast-fed)

No — Fractionation of bilirubin

Yes — Physiologic jaundice
or
Breast-feeding/breast milk jaundice

Conjugated <20% of total
<2 mg/dL

Conjugated >20% of total
>2 mg/dL

Diagnosis = UNCONJUGATED HYPERBILIRUBINEMIA

Diagnosis = CONJUGATED HYPERBILIRUBINEMIA

Hematocrit

High (>65%) — Polycythemia

Low or normal
Reticulocyte count
Blood type
Coombs test
Platelets
PT/PTT
Evaluate smear

Normal reticulocyte count

Look for evidence of:
1. Infection—blood culture
    urine culture
2. Obstruction of GI tract
3. Enclosed hemorrhage
4. Congestive heart failure
5. Hypoxia or acidosis
6. Hypopituitarism or
    hypothyroidism—T_4, TSH
7. Drugs or toxins

None found

Familial disorders:
    Gilbert syndrome
    Crigler-Najjar syndromes
    Lucey-Driscoll syndrome

Elevated reticulocyte count

Consider:
1. Isoimmunization—Coombs positive
2. Erythrocyte membrane defect—
    characteristic smear
3. Erythrocyte enzyme defect
4. DIC—decreased platelets
        prolonged PT/PTT

PT-if elevated, administer vitamin K
Glucose-if low, give glucose enterally or parenterally
AST, ALT, GGT, alkaline phosphatase, CBC

Evaluate for treatable causes:
1. Infection - blood culture
        urine culture
        VDRL
2. Metabolic disorders -
    urine-reducing substances
    serum amino acids
    urine amino acids
    urine organic acids
    serum bile acids
    urine FAB-MS
    T_4, TSH

Abnormal findings

No

Evaluate for other identifiable causes:
1. α_1-Antitrypsin deficiency—phenotype
2. Cystic fibrosis—sweat chloride
3. Congenital viral infection—
    selected viral PCR testing based
    on index of suspicion
4. Neonatal iron storage disease*
5. Familial hemophagocytic syndromes
6. Biliary atresia
7. Alagille syndrome

Abnormal findings

No

Evaluate for anatomic abnormalities
and intrahepatic cholestasis:
1. Stool color
2. Ultrasonography
3. Hepatobiliary scintigraphy
4. Liver biopsy

Yes

Specific confirmatory
studies
Specific treatment

Yes

Supportive therapy

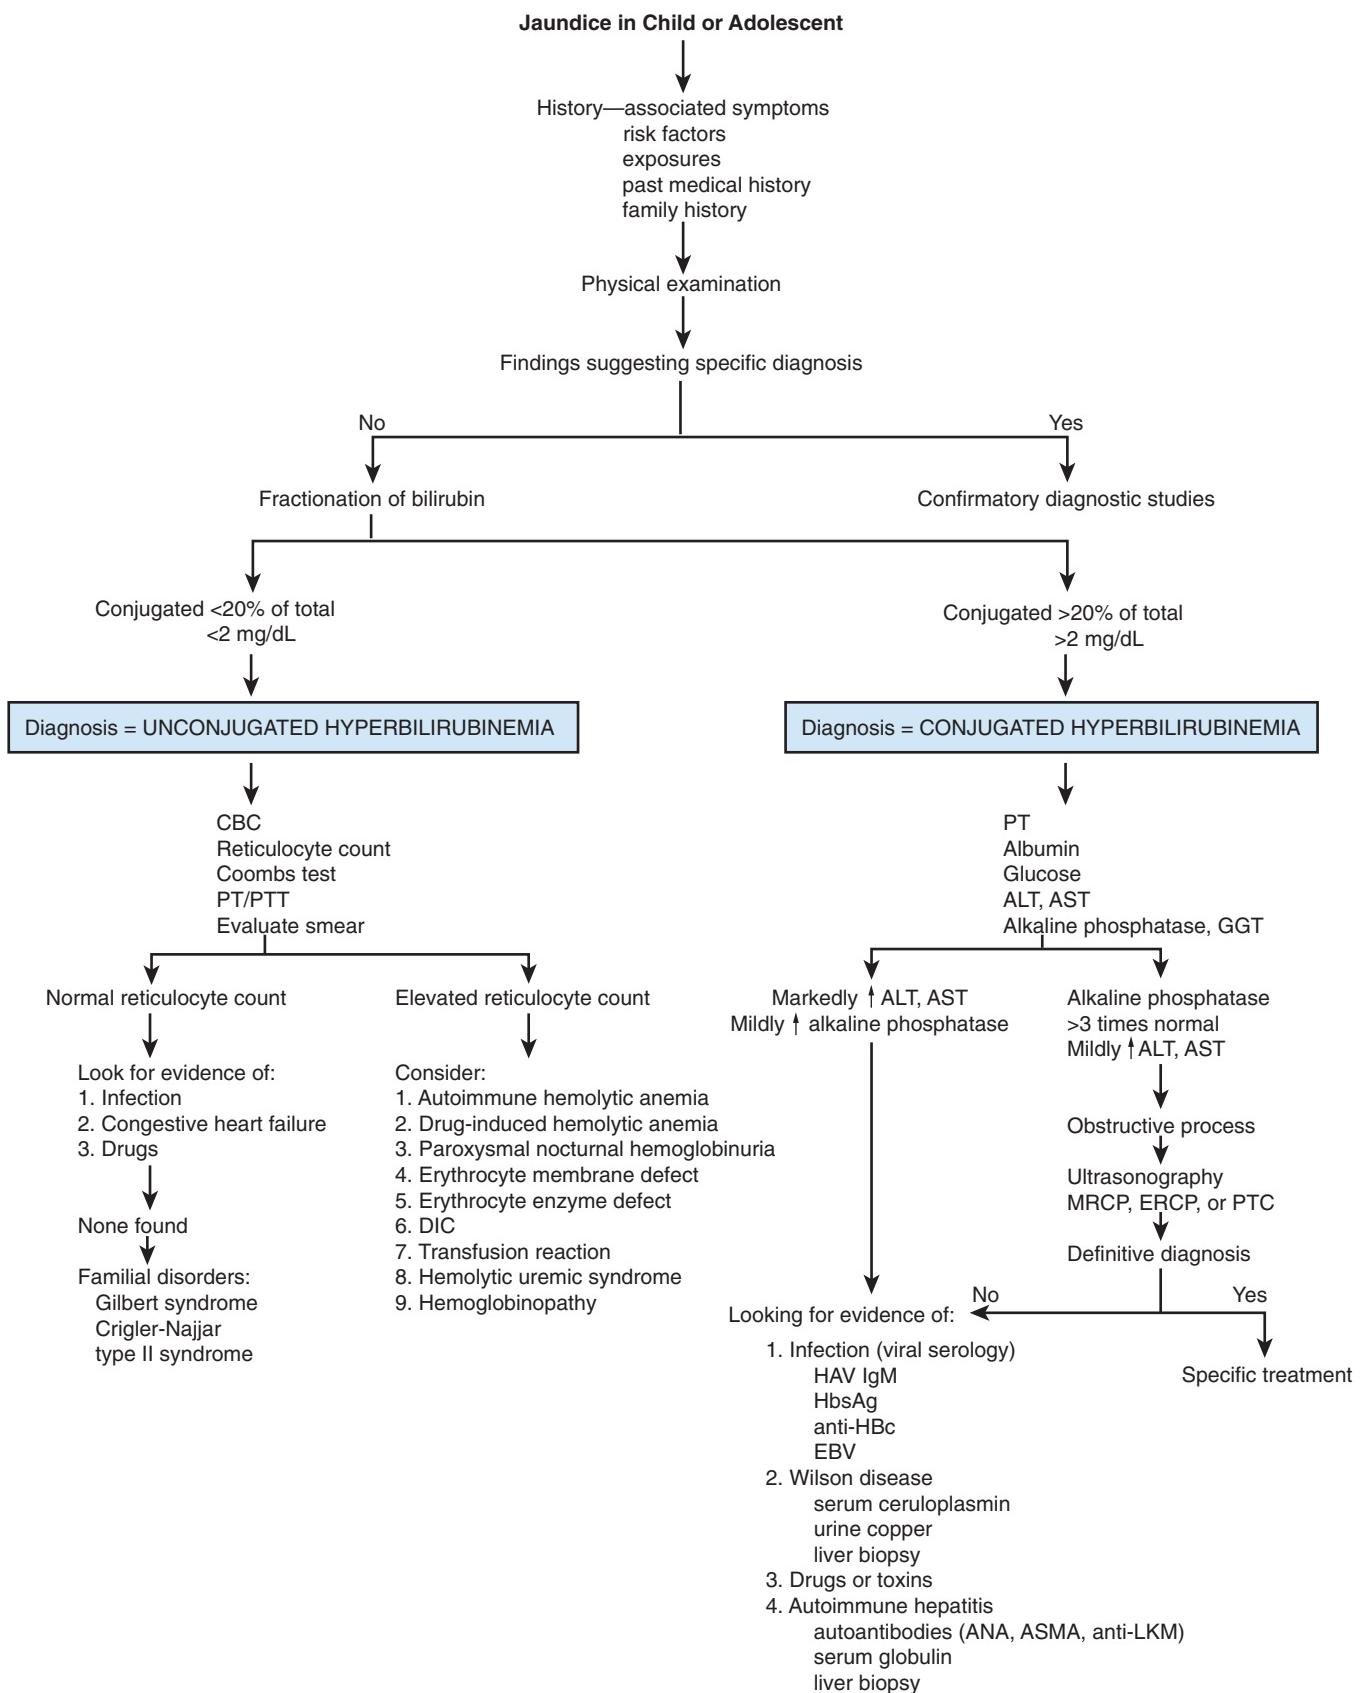
FIGURE 15.2 Diagnostic approach to the neonate or infant with hyperbilirubinemia. *Also called congenital alloimmune hepatitis or neonatal hemachromatosis. ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; DIC, disseminated intravascular coagulation; FAB-MS, fast atom bombardment mass spectrometry; GGT, γ-glutamyltransferase; GI, gastrointestinal; PT, prothrombin time; PTT, partial thromboplastin time; T_4, thyroxine; TSH, thyroid-stimulating hormone; VDRL, Venereal Disease Research Laboratory.


FIGURE 15.3 Diagnostic approach to the child or adolescent with hyperbilirubinemia. ALT, alanine amino-transferase; ANA, antinuclear antibody; ASMA, anti–smooth muscle antibody; AST, aspartate transaminase; CBC, complete blood count; DIC, disseminated intravascular coagulation; EBV, Epstein-Barr virus; ERCP, endoscopic retrograde cholangiopancreatography; GGT, γ-glutamyltransferase; HAV, hepatitis A virus; HBc, hepatitis B core; HBsAg, hepatitis B surface antigen; IgM, immunoglobulin M; LKM, liver-kidney microsomal; MRCP, magnetic resonance cholangiopancreatography; PT, prothrombin time; PTC, percutaneous transhepatic cholangiography; PTT, partial thromboplastin time.

fractures, vitamin D deficiency, bone disease, pregnancy, and malignancy. Fractionation of the alkaline phosphatase isoenzymes can help to determine its site of origin. A mild increase can be seen transiently in normal individuals. In the evaluation of conjugated hyperbilirubinemia, an alkaline phosphatase level of greater than 3 times normal indicates cholestasis; a milder elevation is more consistent with hepatocellular disease.

γ-Glutamyltransferase

The γ-glutamyltransferase (GGT) level is more specific for biliary tract disease than are ALT and AST levels. GGT elevations are inducible by alcohol and certain drugs, including phenytoin and phenobarbital. GGT is found in a variety of tissues and can be elevated in chronic pulmonary disease, renal failure, and diabetes mellitus. The GGT concentration is most helpful in confirming that an elevated alkaline phosphatase level is a result of liver disease rather than bone disease and in differentiating familial cholestatic syndromes.

Bile Acids

Serum bile acids are a very sensitive measure of cholestatic disease. Bile acid levels may be elevated before an increase in bilirubin. Levels are generally very high in primary cholestasis and biliary obstruction but only mildly increased (more than twice normal) in hepatocellular disease. Bile acids should be measured while fasting.

Albumin

Albumin is produced in the liver, and levels can reflect hepatic synthetic function. Serum albumin levels can be useful in monitoring progression of chronic liver disease and in discriminating an acute illness from a previously unrecognized chronic disorder. Hypoalbuminemia can also be secondary to nephrotic syndrome or a protein-losing enteropathy. Due to a long half-life (20 days), albumin is of limited use in assessing synthetic dysfunction in acute liver failure.

Prothrombin Time

Prothrombin time (PT) is the best marker of hepatic synthetic function, as most clotting factors are produced in the liver. It is important not only to measure the PT but also to document the response to parenteral administration of vitamin K because vitamin K deficiency may be an alternative explanation of the elevation of the PT. With severe hepatocellular injury, there is little improvement in the PT. Disseminated intravascular coagulation and thrombosis of a major blood vessel should not be overlooked as the cause of a prolonged PT.

Ultrasonography

Ultrasound studies are useful, noninvasive, relatively inexpensive diagnostic tools for the evaluation of liver disease. Ultrasonography provides information on the size and consistency of the liver and spleen and anatomic abnormalities of the biliary tree, gallstones, and hepatic masses such as cysts, tumors, or abscesses. Dilated intrahepatic ducts may indicate extrahepatic obstruction; however, the absence of dilation on ultrasonography cannot exclude obstruction, and further studies are required for definitive diagnosis. The utility of ultrasonography is limited in obese patients and in patients with excessive bowel gas. Doppler ultrasonography also demonstrates dynamic flow in hepatic blood vessels and the portal vein; it can identify vascular anomalies of the liver and suggest presence of portal hypertension.

Scintigraphy

Hepatobiliary scintigraphy can aid in the diagnosis of biliary atresia. In a healthy individual, hepatic uptake and excretion of the radionuclide via the biliary system are prompt. When there is an injury to the hepatocyte, the uptake of radionuclide by the liver is diminished; however, the tracer should eventually be visualized in the intestinal tract. With obstructive processes, such as biliary atresia, uptake should be relatively normal unless the problem has been present long enough to have caused hepatocellular injury; however, there is no excretion into the intestinal tract. Administration of phenobarbital (5 mg/kg/day) for 5 days before the study may increase bile flow and thus can increase the diagnostic accuracy. Unfortunately, a significant percentage of patients with intrahepatic cholestasis and neonatal hepatitis do not demonstrate biliary excretion, and further evaluation is needed; thus final diagnosis is delayed. In patients with high level of suspicion for biliary atresia (acholic stools, high GGT), liver biopsy and percutaneous cholangiogram provide a faster and more direct way to reach the diagnosis.

Computed Tomography

Computed tomography (CT) is useful for identifying mass lesions within the liver and when there are technical problems with ultrasonography. CT with contrast can be used to define nature of liver tumors. CT angiography can define the anatomy of portal and hepatic circulation. CT has limited value in the evaluation of biliary anatomy.

Magnetic Resonance

MR studies provide valuable information regarding the anatomy of the liver. Since many imaging protocols can be used depending on the purpose of the study, contacting a radiologist prior to ordering the study is recommended. Cost and frequent need for sedation make MR evaluation the tool for secondary evaluation after screening imaging with ultrasound leaves diagnostic questions. MR imaging can demonstrate storage of heavy metals, such as iron in neonatal iron storage disease. MR with contrast can define the nature of liver tumors. MR angiography is useful in studying the vascular system, including the vascular supply of tumors. MR cholangiopancreatography (MRCP) visualizes abnormalities of the intrahepatic and extrahepatic biliary tree and is also quite useful in evaluating the pancreatic duct system. At this point resolution of MRCP is inadequate to diagnose biliary atresia. Unlike endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC), MRCP is noninvasive.

Endoscopic Retrograde Cholangiopancreatography

ERCP is performed for the evaluation of biliary anatomy. Unlike MRCP, ERCP is both diagnostic and potentially therapeutic for common duct stones and for strictures. Complications of the procedure include cholangitis and pancreatitis. ERCP is recommended for evaluation of biliary tree when therapeutic intervention is likely.

Percutaneous Transhepatic Cholangiography

PTC can be used as an alternative to ERCP as a diagnostic and therapeutic tool in evaluating the biliary tree. Under ultrasound guidance, a needle is passed through the liver and into the biliary tree, and contrast material is injected. If obstruction is identified, biliary drainage, if required, can be performed at the same time. PTC is contraindicated if there is marked ascites or irreversible coagulopathy. The complications of PTC include bleeding, pneumothorax, infection, and bile leakage.

Liver Biopsy

Percutaneous liver biopsy is often necessary to determine the cause of conjugated hyperbilirubinemia. In some instances, a specific pattern of injury, such as paucity of bile ducts or bile duct proliferation, may be evident. In other cases, specific markers of disease may be identified (the distinctive inclusions in α_1-antitrypsin deficiency) or measured

(metabolic enzyme activity). Ultrasound-guided biopsy is useful when a specific lesion needs to be evaluated or if there is abnormal anatomy of the liver. An open biopsy may be necessary when a large sample of tissue is needed or when there are contraindications to the percutaneous approach, such as ascites or coagulopathy. Transjugular liver biopsy can reduce the risk of bleeding in patients with coagulopathy. The complications of liver biopsy are the same as those for PTC.

JAUNDICE IN THE NEONATE AND INFANT

◆ History

Evaluation of the infant with jaundice starts with a thorough history, including age at onset and duration of jaundice (see Fig. 15.2). In the neonate, the causes of jaundice range from a benign, self-limited process associated with immaturity of bilirubin excretion (physiologic jaundice) to life-threatening biliary atresia or metabolic disorders (galactosemia, fructosemia, tyrosinemia). In older infants, there are fewer benign explanations for jaundice. For example, physiologic jaundice generally resolves by 1-2 weeks of age, and jaundice associated with breast milk usually resolves by the time the infant is 1 month old.

Acholic stools usually indicate obstruction of the biliary tree; however, nonpigmented stools can be seen with severe hepatocellular injury. The clinician should document the presence or absence of acholic stool in every infant evaluated for jaundice. The center of the stool should be examined because the outside may be lightly pigmented from sloughed jaundiced cells of the intestinal tract. Delayed passage of meconium may be secondary to cystic fibrosis or Hirschsprung disease. Delayed passage of stools, by itself, can lead to increased enterohepatic circulation of bilirubin.

Clues to the diagnosis of hyperbilirubinemia are often found in the prenatal and perinatal history (Table 15.1). Maternal infections that can be transmitted to the fetus or neonate, such as syphilis, toxoplasmosis, cytomegalovirus (CMV), hepatitis B, enterovirus, herpes simplex, and human immunodeficiency virus, are rare causes of cholestatic liver disease in the neonate. Prenatal growth pattern should be carefully evaluated. Perinatal infections such as CMV, rubella, and toxoplasmosis can present with intrauterine growth restriction. Premature infants are prone to higher bilirubin levels and more prolonged hyperbilirubinemia; they are also more likely to have risk factors for hyperbilirubinemia, such as delayed enteral feedings, require parenteral nutrition, and have perinatal insults with hypoxia and acidosis.

Delay of feeding can contribute to both conjugated and unconjugated hyperbilirubinemia; this effect is usually transient and should not be overinterpreted. Breast-feeding is associated with higher levels of unconjugated bilirubin and a longer duration of jaundice than in formula-feeding. Even when diagnosis of breast milk jaundice is likely, conjugated bilirubin should be checked because it provides an easy screening tool for liver disorders, including biliary atresia. Galactosemia does not manifest in the infant who receives a lactose-free formula. Hereditary fructose intolerance is not clinically apparent until the infant ingests fluids or solids containing fructose or sucrose. Infants with metabolic disorders often present with a history of vomiting, lethargy, and poor feeding. Vomiting may also be a symptom of intestinal obstruction including malrotation/volvulus.

The family history can often provide direction to the evaluation, particularly with some of the less common hereditary disorders. This can include most of the metabolic disorders, hemolytic diseases, and disorders associated with intrahepatic cholestasis (Tables 15.2 and 15.3).

TABLE 15.1   Diagnostic Clues in the Evaluation of Infants with Jaundice

Symptom	Possible Diagnosis
Prenatal/Perinatal Findings	
Polyhydramnios	Intestinal atresia
In utero growth restriction	Cytomegalovirus; rubella; toxoplasmosis
Vomiting/poor feeding	Metabolic disorders
Delayed passage of meconium	Cystic fibrosis; Hirschsprung disease
Constipation, hypotonia, hypothermia	Hypothyroidism
Maternal preeclampsia	HELLP: fatty acid oxidation disorders
Microphallus	Hypopituitarism associated with SOD
Intrahepatic cholestasis of pregnancy	PFIC type 2 and 3
Repeated affected neonates	Alloimmune hepatitis
Characteristic Facies	
Narrow cranium, prominent forehead, hypertelorism, epicanthal folds, large fontanel	Zellweger syndrome
Triangular face with broad forehead, hypertelorism, deep-set eyes, long nose, pointed mandible	Alagille syndrome
Microcephaly	Congenital viral infections
Ophthalmologic Findings	
Cataracts	Galactosemia; rubella
Chorioretinitis	Congenital infections
Nystagmus with hypoplasia of optic nerve	Hypopituitarism with septo-optic dysplasia (SOD)
Posterior embryotoxon	Alagille syndrome
Perinatal Infections	
Syphilis	Syphilis
Toxoplasmosis	Toxoplasmosis
Cytomegalovirus	Cytomegalovirus
Hepatitis B	Hepatitis B
Herpes simplex	Herpes simplex
Enterovirus	Enterovirus
Human immunodeficiency virus	HIV infection
Renal Disease	
RTA	Tyrosinemia
RTA	Galactosemia
Congenital hepatic fibrosis	ARPKD
Alagille syndrome	Alagille syndrome
Arthrogyposis	RTA–cholestasis syndrome

HELLP, hemolysis, elevated liver enzymes, low platelets; PFIC, progressive familial intrahepatic cholestasis; ARPKD, autosomal recessive polycystic kidney disease; RTA, renal tubular acidosis.

TABLE 15.2 **Differential Diagnosis of Unconjugated Hyperbilirubinemia in Neonates and Infants**	
Physiologic Jaundice	Sepsis
Breast-Feeding/Breast Milk Jaundice	Hemangioma
Polycythemia	Congenital erythropoietic porphyria
Diabetic mother	
Fetal transfusion (maternal, twin)	**Infection**
Intrauterine hypoxemia	**Intestinal Obstruction**
Delayed cord clamping	Pyloric stenosis
Congenital adrenal hyperplasia	Intestinal atresia
Neonatal thyrotoxicosis	Hirschsprung disease
	Cystic fibrosis
Hemolysis	**Enclosed Hematoma (Cephalohematoma, Ecchymoses)**
Isoimmune	**Congestive Heart Failure**
Rh incompatibility	**Hypoxia**
ABO incompatibility	**Acidosis**
Other (M, S, Kidd, Kell, Duffy)	**Hypothyroidism or Hypopituitarism**
Erythrocyte membrane defects	**Drugs/Toxins**
Hereditary spherocytosis	Maternal oxytocin
Hereditary elliptocytosis	Vitamin K
Infantile pyknocytosis	Antibiotics
Erythrocyte enzyme defects	Phenol disinfectants
Glucose-6-phosphate dehydrogenase	Herbs
Pyruvate kinase	**Familial Disorders of Bilirubin Metabolism**
Hexokinase	Gilbert syndrome
Other	Crigler-Najjar syndrome types I and II
Hemoglobinopathy	Lucey-Driscoll syndrome
Thalassemia	

Modified from Balistreri WF. Liver disease in infancy and childhood. In: Schiff ER, Sorrell MF, Maddrey WC, eds. *Schiff's Diseases of the Liver.* 8th ed. Philadelphia: Lippincott-Raven; 1999:1364.

◆ **Physical Examination**

With increasing levels of bilirubin, neonatal icterus becomes more extensive, spreading in a cephalopedal direction. **Pallor** may indicate hemolytic disease. **Petechiae** alert the clinician to thrombocytopenia, possible sepsis, congenital infections, or severe hemolytic disease.

Dysmorphic face can be present in Zellweger syndrome or Alagille syndrome (see Table 15.1). The characteristic facies of Alagille syndrome may not be recognizable until later in childhood. Microcephaly that accompanies jaundice is associated with congenital viral infections.

An **ophthalmologic examination** can demonstrate a variety of abnormalities. Cataracts are seen in galactosemia and rubella. Chorioretinitis accompanies congenital infections (toxoplasmosis, syphilis, rubella, CMV, herpes simplex virus). Nystagmus with hypoplasia of the optic nerve suggests hypopituitarism associated with septo-optic dysplasia. Posterior embryotoxon is found in Alagille syndrome.

A **heart murmur** may be caused by an underlying congenital heart disease, which may be associated with Alagille syndrome, one of the trisomies, and syndromic forms of biliary atresia (polysplenia syndrome). Heart disease that results in hepatic ischemia or congestion can be a cause of conjugated or unconjugated hyperbilirubinemia.

Hepatomegaly, splenomegaly, and ascites may be caused by both hepatic and nonhepatic etiologies, but they always require evaluation as they are not associated with physiologic or breast milk jaundice.

Microphallus can be associated with septo-optic dysplasia and hypopituitarism.

◆ **Differential Diagnosis**

When a neonate has jaundice, a thorough history, including the obstetric history, and physical examination should provide most of the information necessary to determine whether the condition represents physiologic jaundice (see Fig. 15.2). A total and fractionated bilirubin measurement should be performed if there is any question about the diagnosis of physiologic jaundice.

Physiologic and Breast Milk Jaundice

In neonates, increased bilirubin production is caused by the normally increased neonatal red blood cell mass and the decreased life span of the red blood cells (80 vs 120 days). Albumin binding is decreased because of lower albumin concentrations and diminished binding capacity, which results in decreased transport of UCB to the liver with increased deposition in tissues. Uptake of bilirubin by the hepatocytes during the 1st weeks of life is defective. Low levels of glutathione S-transferase B decrease intracellular binding, which may impede the transport of UCB to the endoplasmic reticulum. Conjugation is impaired by decreased activity of UDPGT. Secretion into the canaliculi is impaired. There is increased enterohepatic circulation of unconjugated bilirubin as a result of increased concentrations of β-glucuronidase in the intestinal lumen and as a result of decreased intestinal bacterial flora, leading to diminished urobilinogen formation (see Fig. 15.1).

These features contribute in varying degrees to **physiologic jaundice**, characterized by a peak bilirubin level of less than 13 mg/dL on

TABLE 15.3   Differential Diagnosis of Conjugated Hyperbilirubinemia in Infants

Obstructive/Anatomic Disorders
Biliary atresia
Choledochal cyst
Caroli disease (cystic dilatation of intrahepatic ducts)
Congenital hepatic fibrosis
Neonatal sclerosing cholangitis
Bile duct stenosis
Spontaneous bile duct perforation
Anomalous choledochopancreaticoductal junction
Cholelithiasis
Inspissated bile or mucous
Mass or neoplasia

Infections
Bacterial (gram negative) sepsis
Urinary tract infection
Listeriosis
Syphilis
Toxoplasmosis
Tuberculosis
Cytomegalovirus
Herpesvirus (herpes simplex, herpes zoster, human herpesvirus 6)
Rubella virus
Hepatitis B virus
Human immunodeficiency virus (HIV)
Coxsackievirus
Echovirus
Parvovirus B19
Adenovirus
Measles

Metabolic Disorders
α_1-Antitrypsin deficiency
Cystic fibrosis
Citrin deficiency
Neonatal hemochromatosis (neonatal iron storage disease)

Endocrine Disorders
Panhypopituitarism
Hypothyroidism

Disorders of Carbohydrate Metabolism
Galactosemia
Hereditary fructose intolerance (fructosemia)
Glycogen storage disease type IV

Disorders of Amino Acid Metabolism
Tyrosinemia
Hypermethioninemia

Disorders of Lipid Metabolism
Wolman disease
Cholesterol ester storage disease

Farber disease
Niemann-Pick disease
Beta-oxidation defects
Gaucher disease

Disorders of Bile Acid Synthesis and Metabolism
Primary Enzyme Deficiencies
3β-Hydroxy-Δ^5-C_{27}-steroid dehydrogenase/isomerase
Δ^4-3-Oxosteroid 5β-reductase
Oxysterol 7α-hydroxylase

Secondary
Zellweger syndrome (cerebrohepatorenal syndrome)
Infantile Refsum disease
Smith-Lemli-Opitz syndrome
Other enzymopathies
Mitochondrial disorders (respiratory chain)

Intrahepatic Cholestasis
Alagille syndrome (arteriohepatic dysplasia)
Nonsyndromic paucity of intrahepatic bile ducts
Progressive familial intrahepatic cholestasis (PFIC)
    Type 1: Byler disease
    Type 2: Defect in the bile salt export pump
    Type 3: Defect in canalicular phospholipid transporter
Benign recurrent intrahepatic cholestasis
Greenland familial cholestasis (Nielsen syndrome)
North American Indian cirrhosis
Hereditary cholestasis with lymphedema (Aagenaes syndrome)

Toxin- or Drug-Related
Cholestasis associated with total parenteral nutrition
Chloral hydrate
Home remedies/herbal medicines
Venoocclusive disease

Miscellaneous
Idiopathic neonatal hepatitis
Autoimmune hemolytic anemia with giant cell hepatitis
Shock or hypoperfusion (including cardiac disease)
Intestinal obstruction
Langerhans cell histiocytosis
Neonatal lupus erythematosus
Dubin-Johnson syndrome
North American Indian childhood cirrhosis
Trisomies (18, 21)
Congenital disorders of glycosylation
Kabuki syndrome
Donahue syndrome (leprechaunism)
Arthrogryposis, cholestatic pigmentary disease, renal dysfunction syndrome
Familial hemophagocytic lymphohistiocytosis

Modified from Balistreri WF. Liver disease in infancy and childhood. In: Schiff ER, Sorrell MF, Maddrey WC, eds. *Schiff's Diseases of the Liver*. 8th ed. Philadelphia: Lippincott-Raven; 1999:1370; Suchy FJ. Approach to the infant with cholestasis. In: Suchy FJ, Sokol RJ, Balistreri WF, eds. *Liver Disease in Children*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001:188.

postnatal days 3-5, a decrease to normal by 2 weeks of age, and a conjugated fraction of less than 20%. In premature, breast-fed infants of diabetic mothers and in Asian and Native American infants, the peak is higher and lasts longer. Conjugated bilirubin should be checked if there is any question of the nature of jaundice.

Breast-feeding has been associated with an increased incidence of unconjugated hyperbilirubinemia outside the expected range (>13 mg/dL). Jaundice of this level may occur in 10-25% of breast-fed infants, in contrast to 4-7% of formula-fed infants. It can occur within the 1st 5 days of life and is referred to as "early" or "breast-feeding" jaundice. Breast-feeding jaundice is seen in infants who are not feeding adequately and may be dehydrated or malnourished. In a second group of breast-fed infants, the jaundice develops slowly, occurring after the 1st week of life, and peaks between the 2nd and 3rd weeks of life at 10-20 mg/dL. This is referred to as "late" or "breast milk" jaundice. The precise cause of increased bilirubin levels in this latter setting has not been established; alternative theories include inhibition of glucuronosyltransferase activity and increased enterohepatic circulation of UCB. Kernicterus appears to be very rare but has been reported in association with breast-feeding. No treatment is necessary for physiologic jaundice. Practices that support breast-feeding, such as rooming-in on the maternity ward and frequent feedings, decrease the risk for breast-feeding jaundice. If the bilirubin exceeds 20 mg/dL in the breast-fed infant, discontinuing breast-feeding for 24 hours results in a decreased bilirubin level. Phototherapy or exchange transfusion may also be needed.

If there are any **red flags,** uncertainty about the diagnosis (Table 15.4), or if treatment is being considered, the hyperbilirubinemia should be investigated further, including fractionation of the bilirubin. Any abnormality identified by history or physical examination is a matter of concern.

Unconjugated Hyperbilirubinemia

The differential diagnosis of unconjugated hyperbilirubinemia in the neonate and infant is presented in Table 15.2. Unless abnormalities in the history and physical examination direct the evaluation more specifically, hematologic evaluation, which may identify causes of increased bilirubin production, should be performed. This includes a complete blood count with examination of the smear, a reticulocyte count, a direct Coombs test, and blood typing (mother and infant).

Polycythemia. Neonatal polycythemia, defined as a hematocrit greater than 65% by venipuncture, can be caused by maternal diabetes, maternal-fetal or twin-twin transfusion, intrauterine hypoxemia, endocrine disorders, and delayed cord clamping (see Table 15.2). Polycythemia results in increased bilirubin production because of the increased red blood cell mass.

TABLE 15.4 **Red Flags in the Evaluation of Infants with Jaundice**	
Onset	**Stools**
<24 hr of age	Acholic
>2 wk of age	Delayed passage of meconium
Bilirubin	**Family History**
Conjugated	Jaundice
>20% of total or >2 mg/dL	Anemia
	Liver disease
Total	Splenectomy
>13 mg/dL formula-fed	Cholecystectomy
>14-15 mg/dL breast-fed	
	Physical Examination
Course	Ill-appearing
Increases by >5 mg/dL/day	Pallor
Persists beyond 14 days of age	Petechiae
	Hematoma or ecchymoses
Prenatal History	Chromosomal stigmata
Maternal infection	Abnormal facies
Maternal diabetes mellitus	Microcephaly
Maternal drug use	Cataracts
Polyhydramnios	Chorioretinitis
Intrauterine growth restriction	Nystagmus
	Optic nerve hypoplasia
Delivery	Posterior embryotoxon
Prematurity	Heart murmur
Perinatal asphyxia	Hepatosplenomegaly (or isolated hepatomegaly or splenomegaly)
Small for gestational age	Ascites
	Acholic stools
Feeding	Dark urine
Delayed enteral feeding	Microphallus
Vomiting	
Poor feeding	
Associated with change in formula	

Hemolytic disorders. Reticulocytosis, unconjugated hyperbilirubinemia, and an increased nucleated red blood cell count, with either a low or normal hematocrit, suggest hemolysis. This can result from isoimmunization; erythrocyte membrane, hemoglobin or enzyme defects; or sepsis with disseminated intravascular coagulation. Some causes of isoimmunization have low reticulocyte counts because the antibody binds to these precursor cells. Rarer causes of hemolysis include hemangiomas and congenital erythropoietic porphyria.

Isoimmune hemolytic disease. In this group of disorders, maternal antibodies (immunoglobulin G) to the infant's erythrocytes cross the placenta, resulting in red blood cell destruction. The administration of anti-D gamma globulin ($Rh_O[D]$ immune globulin [RhoGAM]) after delivery to women who are Rh-negative has reduced the incidence of Rh sensitization and erythroblastosis fetalis. If a woman has been sensitized, the fetus can be monitored with serial amniocenteses. If necessary, intrauterine transfusion can then be performed to prevent the sequelae of severe hemolysis, which include fetal and neonatal anemia, edema, hepatosplenomegaly, and circulatory collapse or stillbirth of an infant with hydrops fetalis. If the problem has not been recognized prenatally, the infant with Rh incompatibility presents with pallor, hepatosplenomegaly, and rapidly developing jaundice.

The diagnosis is confirmed by demonstrating that the infant is Rh-positive, that the direct Coombs test result is positive, and that maternal antibody is coating the infant's red blood cells. These test results are modified with in utero transfusions with Rh-negative cells. Depending on the degree of hemolysis, postnatal phototherapy, and/or exchange transfusion may be required.

ABO blood type incompatibility causes a less severe form of isoimmune hemolytic disease with a less rapid development of jaundice. It is more common in infants with blood type A or B who are born to mothers with blood type O. Hemolysis develops in 50% of sensitized infants; of these infants, 50% have a bilirubin level greater than 10 mg/dL. In addition to showing anemia, reticulocytosis, and spherocytes on the smear, the direct Coombs test result is weakly positive, and the indirect Coombs test result is positive. In rare cases, other minor blood group antibodies can also cause hemolysis.

Erythrocyte membrane defects. Red blood cell membrane defects are relatively uncommon causes of unconjugated hyperbilirubinemia. There is often a family history of hemolysis, transfusions, cholecystectomy for bilirubin stones, or splenectomy. Hemolysis results from fragility of the red blood cell membrane. When the defect is present in infancy, there are anemia, jaundice, and splenomegaly, and the smear is often characteristic (e.g., spherocytosis or elliptocytosis). Spherocytes are also seen with ABO incompatibility. All membrane defects yield negative results of the Coombs tests.

Erythrocyte enzyme defects (see Chapter 37). Glucose-6-phosphate dehydrogenase (G6PD) deficiency is common. Jaundice is seen more frequently in persons with a Mediterranean or Far Eastern ancestry who have a complete absence of the enzyme. In these individuals, hemolysis can occur without a precipitant. In African-American patients, the disease is generally less severe, and hemolysis is rare without exposure to a drug, toxin, or infection that causes an oxidant stress. G6PD deficiency can manifest as neonatal jaundice on day 2 or 3 after birth; alternatively, it may not manifest until later in childhood, when jaundice is associated with an acute hemolytic crisis. The diagnosis of G6PD deficiency is confirmed by documenting deficiency of the enzyme in red blood cells.

Numerous deficiencies of enzymes in the glycolytic pathway have been identified. Pyruvate kinase deficiency is the most common of these rare disorders. Most of these disorders are thought to have an autosomal recessive mode of transmission and have been identified in only a small number of individuals. They all result in hemolysis. The time of manifestation depends on the degree of hemolysis.

Other considerations. If the hematocrit is normal and there is no evidence of hemolysis or a consumptive process, other explanations for unconjugated hyperbilirubinemia should be sought. Blood and urine cultures rarely identify infectious etiologic agents if the patient is otherwise clinically normal. Vomiting, abdominal distention, and delayed passage of meconium suggest obstruction of the gastrointestinal tract and should be further investigated by imaging. Clinical examination should also identify cephalohematoma, ecchymoses, heart failure, hypoxia, and acidosis. Thyroxine and thyroid-stimulating hormone levels should be obtained or checked from the state neonatal screening program to look for evidence of hypothyroidism or hypopituitarism.

Drugs, administered to either mother or neonate, and toxins should be identified by careful record review. Examples include oxytocin, excess vitamin K in premature infants, some antibiotics, and phenol disinfectants used in nurseries. Use of herbal remedies should also be investigated.

In the evaluation process, it is important to remember that the division of causes into hemolytic and nonhemolytic is an arbitrary one. For example, drugs, infection, and G6PD deficiency can contribute to both hemolytic and nonhemolytic neonatal jaundice. In addition, the cause of jaundice can be multifactorial.

Familial disorders of bilirubin metabolism

Gilbert syndrome. Gilbert syndrome is a benign condition that occurs in up to 8% of the population. A familial incidence is reported in 15-40% of cases. Gilbert syndrome is a heterogeneous group of disorders that have in common at least a 50% decrease in UDPGT activity as a result of a defect in the gene responsible for this enzyme. In 20-30% of individuals with Gilbert syndrome, there is also a decrease in hepatocyte bilirubin uptake. Affected individuals are generally asymptomatic and may not present with jaundice until the 2nd or 3rd decade of life. Gilbert syndrome may be responsible for some cases of neonatal jaundice. Mild jaundice with a bilirubin level up to 7 mg/dL can occur transiently with fatigue, exercise, fasting, febrile illness, and alcohol ingestion in older patients. Except for showing an increased indirect bilirubin level, all laboratory studies are normal. The diagnosis is generally a clinical one but can be confirmed by documenting a twofold to threefold rise in unconjugated bilirubin during a 24-hour fast.

Crigler-Najjar syndrome. Crigler-Najjar syndrome types I and II (also known as Arias syndrome) are rare autosomal recessive conditions caused by mutations (different alleles from those of Gilbert syndrome) in the gene coding for UDPGT. Crigler-Najjar syndrome type I is characterized by marked hyperbilirubinemia (20-40 mg/dL) in the neonatal period in an otherwise healthy infant. Among untreated infants, kernicterus is universal, and affected individuals usually die with severe neurologic problems. Because UDPGT is undetectable, there is no conjugated bilirubin in the bile or serum, and the bile is colorless. There is no decrease in serum UCB levels during phenobarbital administration. The only therapies are exchange transfusion, intensive phototherapy, and liver transplantation.

The onset of Crigler-Najjar syndrome type II is usually at birth, although it can be in late childhood. There is less than 5% of the normal UDPGT activity. Bile contains bilirubin monoglucuronides. Bilirubin levels, generally 8-25 mg/dL, respond to phenobarbital administration with a significant decrease. Neurologic disease is rare.

Lucey-Driscoll syndrome. Lucey-Driscoll syndrome is a transient familial neonatal hyperbilirubinemia that appears in the 1st few days of life and resolves by 2-3 weeks of age. This results from inhibition of

UDPGT by a substance that has been found in both maternal and infant serum. The bilirubin level can rise to greater than 60 mg/dL in untreated infants, resulting in severe neurotoxicity. The condition is treated with exchange transfusion.

Therapy. Treatment of unconjugated hyperbilirubinemia depends on the degree of elevation of bilirubin. Considerable controversy exists over which level is toxic and when treatment should be initiated. Because it is lipid soluble, unconjugated bilirubin can diffuse into the central nervous system, which results in neurologic toxicity. Most authorities agree that kernicterus does not occur below a bilirubin level of 20-30 mg/dL in the healthy, full-term infant without evidence of hemolysis. Kernicterus may occur at lower bilirubin levels in premature or sick neonates.

Treatment options include phototherapy and exchange transfusion. Phototherapy produces a reduction of bilirubin by 1-2 mg/dL in 4-6 hours by causing the photoisomerization and photodegradation of unconjugated bilirubin to more water-soluble forms that are more readily excreted in bile and urine. Potential complications include retinal damage, diarrhea, and dehydration. Phototherapy is begun at levels below that for exchange transfusion (~5 mg/dL less) or during preparations for an exchange transfusion.

Exchange transfusion with blood cross-matched against that of the mother is indicated for severe hyperbilirubinemia. This decision must be based not only on the bilirubin level but also, as important, on the infant's age and clinical condition. In full- or near-term infants (>2000 g in weight) with evidence of hemolysis, exchange transfusion is indicated if the serum unconjugated bilirubin level is higher than 25-30 mg/dL or if the bilirubin level does not rapidly respond to phototherapy. Signs of kernicterus (i.e., a high-pitched cry, gaze paralysis, fever, lethargy, and opisthotonic posture) warrant exchange transfusion, no matter what the bilirubin level.

Neonatal Conjugated Hyperbilirubinemia

Potential causes of conjugated hyperbilirubinemia in the neonate and infant are extensive (see Table 15.3). It is important to first evaluate the infant for potentially treatable problems (Table 15.5) and institute specific therapy that prevents significant morbidity and may be life-saving. Fig. 15.2 outlines a diagnostic approach when the clinical presentation has not suggested a likely diagnosis.

Common to all of these conditions is the potential for **hypoprothrombinemia**. If the PT is prolonged, the infant should be treated with intravenous vitamin K to avoid spontaneous hemorrhage, particularly intracranial. Depending on the degree of hepatocellular damage, vitamin K may not correct the PT. This is worrisome and mandates prompt evaluation for the underlying cause of neonatal liver failure or extrahepatic causes of coagulopathy. Interpretation of PT should be based on neonatal norms, as normal PT is higher in newborns, particularly in premature newborns versus older infants. Even with a normal PT at the outset, infants with conjugated hyperbilirubinemia should be on oral fat-soluble vitamin supplementation until their cholestasis resolves.

Hypoglycemia is another danger that is associated with diseases that cause severe hepatic dysfunction, metabolic disorders as well as with hypopituitarism. The infant may be relatively asymptomatic despite significant hypoglycemia. The serum glucose level can be measured before a feeding. If hypoglycemia is present, the infant should receive frequent feedings, continuous feedings, or intravenous dextrose infusions. Glucose level should always be the part of the evaluation of conjugated hyperbilirubinemia.

Hyperammonemia can be present in severe liver dysfunction and metabolic liver disorders. Ammonia should be checked on infants with lethargy or with a change in mental status.

TABLE 15.5 Conditions Not to Miss in Infants with Conjugated Hyperbilirubinemia

Intestinal obstruction
Familial hemophagocytic syndromes
Heart disease
Toxins

Serum levels of aminotransferases, GGT, and alkaline phosphatase, in addition to a complete blood count, should be included in the initial evaluation.

Obstructive/anatomic abnormalities, idiopathic cholestasis, and idiopathic neonatal hepatitis

Biliary atresia. Untreated biliary atresia is lethal, and only prompt diagnosis and surgical treatment can prevent mortality. Biliary atresia accounts for approximately 30% of cases of neonatal cholestasis seen at major referral centers. It occurs in 1 in 8000-15,000 live births. It is the result of a progressive inflammatory process leading to obliteration of the lumen of the extrahepatic duct. It is the leading indication for liver transplantation in the pediatric population. Infants are less often icteric from birth and more often develop jaundice at 2-6 weeks of age. Infants are usually full term and initially appear healthy except for jaundice, dark urine, and acholic stools. The family history usually is negative for liver disease. There appear to be 2 forms of biliary atresia:

1. In the "embryonic" or "fetal form," which occurs in 15-30% of cases, there is no jaundice-free period. There are often associated defects, including cardiac defects, polysplenia, malrotation, and situs inversus.
2. In the "perinatal form," there may be a jaundice-free interval after resolution of the normal physiologic jaundice, and there are no associated anomalies.

At the time of presentation, infants with biliary atresia may have an enlarged, firm liver. Pruritus, splenomegaly, and ascites can

develop with advanced disease. The work-up should be performed expeditiously; it is important to identify biliary atresia early because the success of surgical establishment of drainage is correlated with early age at surgery. Surgery performed before the infant is 2 months old carries an approximately 80% rate of success in terms of obtaining some bile flow. This rate decreases to about 20% for surgery performed in patients older than 3 months. Diagnostic work-up includes evaluation of other identifiable causes of neonatal cholestasis including CMV infection, α_1-antitrypsin deficiency, hypothyroidism, and other anatomic abnormalities of the biliary tree. Combination of conjugated hyperbilirubinemia, acholic stools, and elevated GGT should trigger prompt evaluation for biliary atresia. An ultrasound study helps exclude other treatable anatomic abnormalities, such as a choledochal cyst. The gallbladder is usually absent or collapsed in infants with biliary atresia. Liver biopsy and percutaneous cholangiogram should follow if no alternative cause of jaundice is identified. Characteristic findings on liver biopsy are periportal edema and fibrosis, bile duct proliferation, and bile duct plugs. Some centers utilize hepatobiliary scintigraphy, which demonstrates uptake of tracer but no excretion into the duodenum if biliary atresia is present. However this study can lead to delay in diagnosis (requires pretreatment with phenobarbital) and can be inconclusive in hepatic dysfunction due to poor uptake of the tracer.

The diagnosis is confirmed by intraoperative cholangiography at the time of surgery. The surgical procedure, a portoenterostomy, is that initially described by Kasai. The porta hepatis is transected, and a loop of intestine is brought up to drain the bile ducts. In a small percentage of patients (5-15%), a discrete distal lesion is identified, and the surgery is curative. Those in whom bile drainage is not established require early liver transplantation. In the majority of patients, surgery is palliative, allowing time before liver transplantation is needed; overall and post-transplant mortality are significantly reduced with timely Kasai procedure.

The important, potentially life-threatening complication of the Kasai procedure is **bacterial ascending cholangitis**. Febrile patients with biliary atresia need to be promptly evaluated for causes of fever. If no alternative source of fever is identified, they should be evaluated for cholangitis.

Most of the patients with biliary atresia remain cholestatic despite the Kasai procedure; thus they require supplementation with MCT oil (or MCT-enriched formulas) and fat-soluble vitamins. Portal hypertension with splenomegaly, esophageal varices, and ascites can develop over time in many patients with biliary atresia. Due to significant risk of complications and frequent need for liver transplant, patients with biliary atresia should be followed in centers with pediatric transplant/hepatology expertise.

Alagille syndrome. Alagille syndrome is characterized by the abnormal development of multiple organs related to defective JAG-1/NOTCH-2 signaling. The most important clinical feature is a marked reduction in the number of interlobular bile ducts. Jaundice may have its onset in the neonatal period or may not appear until later in childhood. Additionally, patients with Alagille syndrome can have unusual facies (a triangular face with broad forehead, widely spaced and deep-set eyes, a long nose, and a pointed mandible), vertebral arch defects (butterfly vertebrae, hemivertebrae, decreased interpedicular distance), posterior embryotoxon (ocular), and cardiac anomalies (ranging from peripheral pulmonic stenosis to complex congenital heart disease). Renal anomalies, pancreatic insufficiency, and growth retardation, are present in some patients (Table 15.6). This appears to be a progressive phenomenon and may not be readily recognizable in neonates. By the age of 4-6 months, pruritus develops and can be severe. Xanthomas appear in association with a markedly elevated cholesterol level.

From Mieli-Vergani G, Hadzic N. Biliary atresia and neonatal disorders of the bile ducts. In: Wyllie R, Hyams JS, Kay M, eds. *Pediatric Gastrointestinal and Liver Disease*. 4th ed. Piladelphia: Elsevier/Saunders; 2011:749.

Alagille syndrome has an autosomal dominant transmission with highly variable expression. Often other family members are recognized as being affected when an infant is brought to medical attention. There is a high proportion of sporadic cases (up to 70%) with de novo mutations in the *JAG-1* gene responsible for this syndrome. Mutations of the NOTCH-2 receptor can result in a similar clinical picture though they are less common than *JAG-1* mutations. The diagnosis is confirmed by liver biopsy. Symptoms often improve over time. There is a 20-25% rate of mortality from serious cardiac or liver disease.

There is a nonsyndromic form of bile duct paucity with cholestasis caused by bile duct paucity but not associated with clinical or genetic mutations characteristic of Alagille syndrome. The prognosis for this form is less favorable.

Choledochal cysts. Manifestations include conjugated hyperbilirubinemia with jaundice, vomiting, acholic stools, and hepatomegaly

in the neonate. Alternatively, choledochal cysts can manifest with jaundice, abdominal pain, and a right upper quadrant mass in the older child. There are five anatomic types of cystic dilatations of the extrahepatic or intrahepatic bile ducts. The diagnosis is made by ultrasound studies and confirmed by MR cholangiography or intraoperative cholangiography. Treatment involves surgical excision. Cholangitis may occur postoperatively. If the cyst is not fully excised, carcinoma can develop in the residual cyst tissue.

Treatable infections

Bacterial infection. An infant may, in rare cases, appear clinically well, with jaundice as the only sign of a bacterial infection. Blood and urine cultures should be obtained in infants with unexplained conjugated hyperbilirubinemia. Infection is less likely to be missed in the symptomatic infant who presents with poor feeding, lethargy, vomiting, temperature instability, apnea, bradycardia, or shock. *Escherichia coli* is the most common organism identified in either sepsis or urinary tract infection (often with bacteremia) when jaundice is present. The hyperbilirubinemia may be caused by endotoxin-mediated canalicular dysfunction. Less often, other gram-negative bacilli or *Listeria*, *Staphylococcus*, or *Streptococcus* species may be identified as the causative agent. Although sepsis accounts for only a small percent of the cases of neonatal cholestasis, it is easily diagnosed and treated.

Herpes simplex. Herpes simplex causes a severe neonatal infection that usually manifests at 7-14 days of age with lethargy, poor feeding, a vesicular rash (in 60-70% of patients), jaundice, hepatomegaly, temperature instability, encephalitis, and coagulopathy. The diagnosis is made by identification of the virus in skin lesions through direct fluorescent antibody staining or polymerase chain reaction of herpes simplex DNA in blood and cerebrospinal fluid. Treatment is with intravenous acyclovir. Among infants with disseminated infection, the mortality rate is 15-35%.

Enteroviruses. Maternal infection at the time of delivery may result in severe enteroviral disease in the infant within 1-7 days of birth. Manifestations are similar to that of herpes simplex virus except a macular rash. Severe hepatitis, carditis, or encephalitis or a sepsis picture may develop. Diagnosis is made through polymerase chain reaction or viral culture. Treatment strategies include intravenous immunoglobulin (IVIG) and pleconaril.

Cytomegalovirus infection. CMV infection is common, but 90% of affected infants are asymptomatic at birth. In the severely affected infant with vertical transmission, CMV can manifest within the 1st 24 hours after birth with intrauterine growth restriction, conjugated hyperbilirubinemia, hemolytic anemia, thrombocytopenic purpura, and hepatosplenomegaly. Often an infant with low birthweight presents with microcephaly, periventricular calcifications, and chorioretinitis. The diagnosis can be made by obtaining urine specimens for culture.

Treatment includes the use of ganciclovir and possibly CMV immunoglobulin. The liver disease resolves in most patients, but neurologic sequelae are common. Postnatal acquisition from CMV-positive blood transfusion may produce a sepsis syndrome and hepatitis.

The findings of CMV in a cholestatic infant without other features of congenital CMV infection should not stop the search for other causes of cholestasis, particularly biliary atresia.

Hepatitis B. Hepatitis B infection manifests with jaundice in fewer than 5% of perinatal infections. Perinatal transmission is high when mothers are chronic carriers who are seropositive for hepatitis B e antigen or when they acquire acute infection in the last trimester. Most infants are asymptomatic, but there is a high incidence of subsequent chronic infection. Perinatal infection can be prevented with hepatitis B immune globulin and vaccination. It is important to identify mothers who are seropositive for hepatitis B surface antigen (HBsAg); identification requires universal screening.

Syphilis. Congenital syphilis remains a problem despite maternal screening. With severe infection, the infant has fever, a diffuse macular-papular rash, hepatosplenomegaly, edema, anemia, and periostitis, in addition to jaundice. Nontreponemal serologic tests (Venereal Disease Research Laboratory) may be routinely performed on cord blood. If the result is positive, the diagnosis should be confirmed on serum from the infant. Confirmation requires a positive specific test for syphilis such as the immunoglobulin M (IgM) or immunoglobulin G fluorescent treponemal antibody. Treatment is with intravenous penicillin for 10-14 days.

Toxoplasmosis. If toxoplasmosis is suspected on clinical grounds, IgM titers should be obtained, or the placenta should be examined histologically. Most infected infants are asymptomatic. Infants with severe congenital infection may have hydrocephaly or microcephaly, intracranial calcifications, chorioretinitis, aseptic meningitis, jaundice, purpura, and hepatomegaly. Postnatal treatment consists of pyrimethamine and sulfadiazine; folinic acid is added to prevent folate deficiency.

Treatable metabolic disorders.

Many metabolic disorders are part of the universal newborn screening program in developed countries. The clinician needs to be aware of which disorders are and which are not screened for in a particular country or state. Even in the presence of universal neonatal screening for metabolic disorders, the test may be falsely negative, particularly if the newborn was tested too early, was premature or underwent transfusions before the test was performed. In countries with robust neonatal screening programs, repeating newborn screen may be an easy and cost-effective 1st step in evaluation for possible metabolic disease. Other useful screening modalities include: urine-reducing substances (galactosemia), serum amino acids, ammonia level, urine organic acids, quantitative serum bile acids, qualitative analysis of urinary bile acids by fast atom bombardment mass spectrometry (FAB-MS), the thyroxine level, and the thyroid-stimulating hormone level, succinyl-acetone (thyrosinemia), triglycerides, lactate, pyruvate, and acyl carnitines (mitochondrial disorders).

Galactosemia. Galactosemia, a life-threatening disorder, can easily be detected. It is an autosomal recessive disorder with deficiency of galactose-1-phosphate uridyltransferase, which is required for conversion of galactose to glucose. As a result, galactose-1-phosphate accumulates; this compound is thought to be hepatotoxic. Once lactose (glucose-galactose) is introduced into the infant's diet, vomiting, diarrhea, jaundice, hepatomegaly, and cataracts develop. Affected infants often present with *E. coli* sepsis in the 1st weeks of life.

Laboratory evaluation may demonstrate elevations of aminotransferase levels, a prolonged PT, hemolytic anemia, and aminoaciduria. The urine yields positive findings for reducing substances (galactose) if the infant is receiving a lactose-containing formula or breast milk. The diagnosis can be confirmed by documenting deficiency of the enzyme in erythrocytes or leukocytes. Transfusions may cause false-negative results. Treatment consists of eliminating galactose from the diet.

Hereditary fructose intolerance (fructosemia) is an uncommon disorder; it can manifest with hepatic failure in an infant exposed to fructose or sucrose in formula, juice, fruit, or medications. A thorough diet history in relation to the onset of jaundice is often the key to this diagnosis. Prompt removal of fructose, sucrose, and sorbitol from the diet is essential.

Tyrosinemia is diagnosed from serum amino acid levels and urine organic acid levels. Elevated urinary succinylacetone is pathognomonic. Treatment involves the dietary restriction of phenylalanine,

(See *Nelson Textbook of Pediatrics,* p. 1723.)

(See *Nelson Textbook of Pediatrics,* p. 1590.)

methionine, and tyrosine and the use of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione) to prevent the formation of toxic metabolites. Liver transplantation may still be required.

Disorders of bile acid metabolism typically are suggested by conjugated hyperbilirubinemia with low or normal GGT and low or normal total bile acid levels. They can be detected by bile acid FAB-MS analysis of urine. Treatment of some forms of bile acid synthetic disorder is possible with oral cholic acid supplementation.

Other identifiable infectious and metabolic causes of cholestasis

α_1-**Antitrypsin deficiency.** An α_1-antitrypsin protein immuno-electrophoresis can detect an α_1-antitrypsin deficiency, which is the most common inherited cause of neonatal cholestasis. Deficiency occurs in 1 in 1600-2000 live births. α_1-Antitrypsin is a protease inhibitor that is synthesized in the liver and inactivates neutrophil proteases. The normal α_1-antitrypsin phenotype, MM, is found in 80-90% of the population. There are numerous allelic variants. Liver disease is associated with the ZZ phenotype and sporadically with other variants. The exact mechanism of liver injury is unclear, and there is variability in expression so that clinically significant liver disease develops in only 10-15% of individuals with the ZZ phenotype. There is also great variability in manifestation. Commonly, the disorder manifests in early infancy with prolonged conjugated hyperbilirubinemia, failure to thrive, acholic stools, hepatomegaly, and possibly ascites. However, it may not manifest until later childhood or even adulthood. Manifestations in older individuals include jaundice, hepatosplenomegaly, ascites, portal hypertension with varices, chronic hepatitis, cryptogenic cirrhosis, or, rarely, hepatocellular carcinoma. The diagnosis is established by serum phenotyping (ZZ). Treatment is supportive. Some individuals do very well with minimal liver dysfunction. Others have progressive liver disease, requiring transplantation. α_1-Antitrypsin deficiency can enhance hepatotoxicity of hepatotoxic drugs. All indi-

viduals with α_1-antitrypsin deficiency should be aware of the potential for lung disease when they are older.

Cystic fibrosis. As many as one third of infants with cystic fibrosis may have evidence of liver involvement, frequently cholestasis. The incidence is increased among infants with meconium ileus. The diagnosis can be confirmed with a sweat chloride test or by detecting the abnormal gene. Although the cholestasis resolves, the infant with cystic fibrosis can develop problems including focal biliary cirrhosis, multilobular cirrhosis, fatty liver, obstruction of the common duct, cholelithiasis, sclerosing cholangitis, and, rarely, cholangiocarcinoma.

Hypothyroidism and hypopituitarism. Jaundice can be a manifestation of both hypothyroidism and hypopituitarism. Hypopituitarism may manifest with hypoglycemia, microphallus, and signs of hypothyroidism in addition to jaundice. Wandering nystagmus is present when hypopituitarism is associated with septo-optic dysplasia. Treatment of the underlying endocrinopathy leads to resolution of the liver disease.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is a group of disorders related to defective transport of bile acids (Table 15.7). PFIC is clinically suggested by presence of cholestasis in absence of physical damage to the bile ducts. GGT is normal except for PFIC type 3. The molecular defects for 3 PFIC types involve molecules expressed on the canalicular membrane of the hepatocyte. All types of PFIC are inherited in an autosomal recessive manner. PFIC results in progressive cholestasis and pruritus, leading to cirrhosis and end-stage liver disease. PFIC type 1 has low or normal serum γ-glutamyltransferase (GGT) and high serum concentrations of bile acids. The defect of the *FIC-1* gene, which encodes a P-type adenosine triphosphatase (ATP8B1), is involved in phospholipid translocation in the enterocytes and

---

TABLE 15.7 Progressive Familial Intrahepatic Cholestasis

	PFIC 1	PFIC 2	PFIC 3
Transmission	Autosomal recessive	Autosomal recessive	Autosomal recessive
Chromosome	18q21-22	2q24	7q21
Gene	*ATP8B1/F1C1*	*ABCB11/BSEP*	*ABCB4/MDR3*
Protein	FIC1	BSEP	MDR3
Location	Hepatocyte, colon, intestine, pancreas; on apical membranes	Hepatocyte canalicular membrane	Hepatocyte canalicular membrane
Function	ATP-dependent aminophospholipid flippase; unknown effects on intracellular signaling	ATP-dependent bile acid transport	ATP-dependent phosphatidylcholine translocation
Phenotype	Progressive cholestasis, diarrhea, steatorrhea, growth failure, severe pruritus	Rapidly progressive cholestatic giant cell hepatitis, growth failure, pruritus	Later-onset cholestasis, portal hypertension, minimal pruritus, intraductal and gallbladder lithiasis
Histology	Initial bland cholestatic; coarse, granular canalicular bile on EM	Neonatal giant cell hepatitis, amorphous canalicular bile on EM	Proliferation of bile ductules, periportal fibrosis, eventually biliary cirrhosis
Biochemical features	Normal serum GGT; high serum, low biliary bile acid concentrations	Normal serum GGT; high serum, low biliary bile acid concentrations	Elevated serum GGT; low to absent biliary PC; absent serum LPX; normal biliary bile acid concentrations
Treatment	Biliary diversion, ileal exclusion, liver transplantation, but post-OLT diarrhea, steatorrhea, fatty liver	Biliary diversion, liver transplantation	UDCA if residual PC secretion; liver transplantation

ATP, adenosine triphosphate; BSEP, bile salt export pump; EM, electron microscopy; GGT, γ-glutamyltransferase; LPX, lipoprotein X; OLT, orthotopic liver transplantation; PC, phosphatidylcholine; PFIC, progressive familial intrahepatic cholestasis; UDCA, ursodeoxycholic acid.
From Suchy FJ, Sokol RJ, Balistreri WF, eds. *Liver Disease in Children.* 3rd ed. New York: Cambridge University Press; 2007.

canalicular membrane of the hepatocyte. In addition to cholestasis, patients have chronic secretory diarrhea. PFIC 1 can also be associated with sensorineural hearing loss and pancreatitis.

Patients with PFIC type 2 also exhibit cholestasis, normal serum GGT, and high levels of serum bile acids. A PFIC 2 disorder is caused by defective function of the bile salt export pump (BSEP) protein, encoded by the *ABCB11* gene. Since BSEP is expressed only in hepatocytes, symptoms are limited to cholestatic liver disease.

Patients with PFIC type 3 have high serum GGT and cholesterol levels. They demonstrate symptoms later in life and reach end-stage liver disease at a later age. PFIC type 3 is caused by a defect in the *ABCB4* gene, which encodes a phospholipid transporter (MDR3) in the canalicular membrane and results in low biliary phospholipid levels.

Except in cases necessitating liver transplantation, chronic biliary diversion and ursodeoxycholic acid therapy may reduce pruritus and improve liver function. In **benign recurrent intrahepatic cholestasis (BRIC)**, homozygous or compound heterozygous mutations of respective genes *(ATP8B1, ABCB11, ABCB4)* develop a milder form of cholestatic liver disease, which generally does not progress to end-stage liver disease. In patients with BRIC jaundice, pruritus or fat malabsorption symptoms can be triggered by pregnancy, toxins, and medications.

Idiopathic neonatal hepatitis. Idiopathic neonatal hepatitis is a descriptive term rather than a specific disease entity. The diagnosis is made by exclusion of other causes of cholestasis, particularly biliary atresia. The infant with neonatal hepatitis is more likely to be premature or small for gestational age. Acholic stools are uncommon but can occur when the hepatitis is severe. In 5-15% of cases, there is a familial incidence. Hepatobiliary scintigraphy demonstrates delayed uptake, but there is usually excretion into the duodenum unless the hepatitis is severe. In this case, intraoperative cholangiography may be required. Biopsy findings include panlobular disarray indicative of severe hepatocellular disease, inflammatory infiltrate in the portal areas, focal hepatocellular necrosis, multinucleated giant cells, and increased extramedullary hematopoiesis.

Treatment is supportive. The outcome is variable and is better for infants with sporadic (nonfamilial) cases; of such infants, approximately 60% recover, 10% have chronic liver disease, and 30% die without liver transplantation. The percentages for recovery and death are reversed (30% and 60%, respectively) in familial cases.

Treatment of cholestasis. Some interventions are essential for all infants with cholestasis. Malabsorption of fats and fat-soluble vitamins occurs as a result of a decreased concentration of bile salts in the intestinal lumen. Affected infants should be given a formula containing medium-chain triglycerides (MCTs), which are better digested and absorbed in the absence of bile acids. Even with MCT supplementation, many patients will require caloric intake in excess of 150 kcal/kg/day to maintain growth. Due to organomegaly and ascites, weight alone may overestimate nutritional status. Proper monitoring of growth requires a routine anthropometric evaluation of skinfold and mid-arm circumference. Some affected infants require supplemental nasogastric feedings. Supplemental vitamins A, D, E, and K are given to prevent symptoms of vitamin deficiency visual problems, rickets, neuropathy, and coagulopathy, respectively. Fat-soluble vitamin levels need to be monitored. Pruritus is often severe and is not readily treatable. Several medications have been tried, including ursodeoxycholic acid, antihistamines, cholestyramine, phenobarbital, and rifampin. Ursodeoxycholic acid is beneficial in some infants with cholestasis, and helps to improve bile excretion, thus reducing serum bile acid levels. Biliary diversion has been effective in some cases. Ascites can be managed with sodium restriction and diuretics.

JAUNDICE IN THE CHILD AND ADOLESCENT

◆ History

Chronic fatigue, though nonspecific, is a common symptom of liver disease and should trigger at least a basic evaluation including aminotransferases even in the absence of overt jaundice. Myalgias, nausea, vomiting, and fever are often seen in patients with viral hepatitis or autoimmune hepatitis. **Acute biliary obstruction** is signaled by right upper quadrant pain, vomiting, fever, and acholic stools in addition to jaundice. Neurologic and psychiatric symptoms may be among the manifestations of Wilson disease. Autoimmune hepatitis may be accompanied by manifestations of other autoimmune disorders.

The child's age at the onset of symptoms may be helpful. Wilson disease commonly manifests in school-aged children and adolescents. Similarly, autoimmune hepatitis is most prevalent in school-aged children and adolescents with female predominance. A thorough history should include past and present use of prescription, over-the-counter (e.g., acetaminophen), and street drugs. Many medications have been associated with hepatobiliary damage; others, with hemolysis. Drug abuse is a risk factor for viral hepatitis and human immunodeficiency virus. Adolescents in particular should be asked about alcohol use.

Symptoms of cholestasis such as jaundice, dark urine, steatorrhea, symptoms of fat-soluble vitamin deficiency, failure to thrive, and pruritus should be explored in detail.

Information about exposure to viral hepatitis, either by travel to an endemic area or during an outbreak, should be pursued. There is a high transmission rate in daycare centers.

The patient's medical history should be reviewed because some chronic illnesses are associated with specific hepatobiliary complications. These should include acquired immunodeficiency syndrome, cystic fibrosis, heart disease, renal disease, hemolytic disorders, autoimmune disorders, celiac disease, and inflammatory bowel disease.

A family history of inheritable disorders, such as Wilson disease, autosomal recessive polycystic kidney disease, Alagille syndrome, or spherocytosis, is informative. Less specific but still useful clues are a history of autoimmune disorders, jaundice, anemia, cholecystectomy, or splenectomy in other family members.

◆ Physical Examination

Some patients present with previously unidentified chronic liver disease. The clinician should focus on signs of portal hypertension: spider angiomas, palmar erythema, dilated abdominal veins, ascites, and splenomegaly with a small liver. Cutaneous excoriation as evidence of pruritus, xanthomas, and jaundice support cholestasis. Clubbing of digits may suggest hepatopulmonary syndrome. A large, tender liver is suggestive of acute viral hepatitis or congestive heart failure. A small liver may be found in patients with severe hepatitis or cirrhosis. A tender gallbladder is indicative of choledocholithiasis or cholecystitis. Abnormal neurologic findings, including tremor, fine motor incoordination, clumsy gait, and choleriform movements, suggest Wilson disease. A slit-lamp examination should be included to look for the Kayser-Fleischer rings (a brownish discoloration at the periphery of the cornea) of Wilson disease.

◆ Differential Diagnosis
Unconjugated Hyperbilirubinemia

Most causes of unconjugated hyperbilirubinemia in the child and adolescent are secondary to hemolysis (Table 15.8) (see Chapter 37). A complete blood count with evaluation of the smear, reticulocyte count, and Coombs test can differentiate hemolytic from nonhemolytic disorders.

TABLE 15.8 Differential Diagnosis of Unconjugated Hyperbilirubinemia in Childhood and Adolescence

Increased Bilirubin Production

Autoimmune hemolytic anemia

  Idiopathic

  Secondary

    Infection (viral, mycoplasma)

    Diseases with autoantibody production

    Immunodeficiency

    Malignancy

Drug-induced hemolytic anemia

Paroxysmal nocturnal hemoglobinuria

Erythrocyte membrane defects

  Hereditary spherocytosis

  Hereditary elliptocytosis

Erythrocyte enzyme defects

  Glucose-6-phosphate dehydrogenase

  Pyruvate kinase

  Hexokinase

  Other

Hemoglobinopathy

  Sickle cell disease

  Thalassemia

Hemolytic uremic syndrome

Sepsis with disseminated intravascular coagulation

Reabsorption of hematoma

Transfusion reaction

Decreased Uptake, Storage, or Metabolism

Congestive heart failure

Sepsis

Acidosis

Gilbert syndrome

Crigler-Najjar syndrome type II

Prolonged fasting

Drugs

Portacaval shunt

Erythrocyte membrane defects (spherocytosis) and enzyme defects (pyruvate kinase deficiency, G6PD) may not be apparent until childhood or adolescence. Acquired autoimmune hemolytic anemia is characterized by pallor, abdominal pain, fever, and dark urine in addition to jaundice. Laboratory studies document anemia and reticulocytosis. The direct Coombs test result is positive. Hemolytic anemia can be associated with infection, immunodeficiency, malignancy, hemolytic uremic syndrome, or other autoimmune disorders, such as systemic lupus erythematosus, rheumatoid arthritis, thyroid disorders, and autoimmune hepatitis.

Unconjugated hyperbilirubinemia can be caused by congestive heart failure and infection should in such circumstances extrahepatic symptoms, cardiac failure, or sepsis dominate the picture. If no other explanation is found, Gilbert syndrome or Crigler-Najjar syndrome type II should be considered.

Conjugated Hyperbilirubinemia

In the child with conjugated hyperbilirubinemia, the PT and the albumin, glucose, AST, ALT, GGT, and alkaline phosphatase levels should be measured. Albumin and PT determinations provide evidence of hepatocyte synthetic function. Hypoglycemia is another marker of severity of hepatocellular damage. This is important in considering how quickly the evaluation should proceed or how closely the patient should be monitored. Patients with coagulopathy, hyperammonemia, encephalopathy, or hypoglycemia should be admitted to the hospital and observed very closely. PT should be repeated after a dose of parenteral vitamin K to differentiate synthetic liver failure from a vitamin K deficiency. Hypoglycemia should be corrected with frequent meals or intravenous dextrose.

Obstruction. The relative elevation of AST/ALT and alkaline phosphatase levels in the context of the clinical picture determines the likelihood of an obstructive cause. Although obstructions occur less commonly in children than in adults, it is important not to miss correctable causes of obstruction that, if left untreated, can cause hepatocellular damage. These patients usually have markedly elevated alkaline phosphatase and minimally elevated AST and ALT levels. They should be evaluated promptly with ultrasonography and possibly with MRCP, ERCP, or PTC. The possible causes of obstruction are listed in Table 15.9.

Gallstones. Gallstones are particularly common in children with hemolytic disorders, such as sickle cell disease, thalassemia, erythrocyte membrane defects, erythrocyte enzyme defects, and autoimmune hemolytic anemia. The mean age at presentation is 12 years. Gallstones are also associated with anatomic abnormalities of the biliary tract, cystic fibrosis, ileal dysfunction, obesity, parenteral nutrition, sepsis, prematurity, and pregnancy. Stones may be found incidentally on abdominal radiographs or ultrasound studies in asymptomatic individuals. Alternatively, gallstones may manifest with symptoms of biliary colic: nausea, vomiting, right upper quadrant or nonspecific abdominal pain and jaundice. Ultrasonography is a very sensitive diagnostic test. Treatment for symptomatic patients is cholecystectomy. ERCP can be used to remove common bile duct stones.

Primary sclerosing cholangitis. Primary sclerosing cholangitis (PSC) is characterized by focal dilatation and stenosis of the intrahepatic or extrahepatic bile ducts with surrounding fibrosis resulting from an inflammatory process. It can manifest from early childhood through adulthood. In adults, it is frequently associated with inflammatory bowel disease, especially ulcerative colitis. PSC may precede the onset of inflammatory bowel disease by many years. It can occur in the absence of any underlying condition. The onset may be insidious with fatigue and pruritus being the only symptoms. Steathorrhea, weight loss, and symptoms of fat-soluble deficiency can be present in some patients. Abdominal pain, fever, and jaundice may signify ascending cholangitis with bacterial infection complicating PSC. Diagnostic evaluation includes ultrasound studies, which may show dilated ducts. MR cholangiography can provide a detailed anatomy of the biliary tree and is more sensitive than an ultrasound. ERCP or PTC do not provide an advantage in diagnosing PSC but are useful, minimally invasive procedures that can be performed if the dominant stricture is identified and biliary obstruction can be improved by dilation and/or stent placement. PTC can progress to cirrhosis with ultimate liver failure. Cholangiocarcinoma complicates PTC in 10-15% of adults. No medical therapy has been shown to improve outcomes in PSC; thus treatment is supportive focused on management of cholestasis. Liver transplantation is available as curative intervention once disease progresses to end-stage liver disease.

TABLE 15.9 **Differential Diagnosis of Conjugated Hyperbilirubinemia in Childhood and Adolescence**	
Autoimmune Hepatitis	**Drug or Toxin**
Anatomic/Obstructive	***Drugs***
Gallstones	Chlorpromazine
Primary sclerosing cholangitis	Hormones (estrogens, androgens)
Choledochal cyst	Antibiotics (amoxicillin-clavulanate, dicloxacillin, erythromycin, sulfonamides, tetracycline)
Bile duct stenosis	Anticonvulsants (carbamazepine, phenytoin, valproate)
Anomalies of the choledochopancreaticoduodenal junction	Acetaminophen
Pancreatitis	Alcohol
Caroli disease	Halothane
Congenital hepatic fibrosis	Isoniazid
Tumor	Antineoplastics
Hepatic	
Biliary	***Toxins***
Pancreatic	*Amanita phalloides* (mushroom)
Duodenal	Insecticides
	Carbon tetrachloride
Infection	Phosphorus
Non–A-E hepatitis	Herbal teas
Hepatitis A	
Hepatitis B	***Total Parenteral Nutrition***
Hepatitis C	**Intrahepatic Cholestasis**
Hepatitis D	Benign recurrent intrahepatic cholestasis
Hepatitis E	Progressive familial intrahepatic cholestasis type 3
Epstein-Barr virus	
Cytomegalovirus	**Miscellaneous**
Human herpesvirus 6	Dubin-Johnson syndrome
Herpes simplex virus	Rotor syndrome
Varicella-zoster virus	Budd-Chiari syndrome
Enteroviruses	Systemic lupus erythematosus
Measles	Indian childhood cirrhosis
Human immunodeficiency virus	Cardiovascular
Leptospirosis	Ischemia
Sepsis/shock	Congestive heart failure
Liver abscess	Cardiomyopathy
	Oncologic
Metabolic Disorders	Leukemia
Wilson disease	Langerhans cell histiocytosis
Cystic fibrosis	Lymphoma
Cholesterol ester storage disease	Graft-versus-host disease
Alpers syndrome	Venoocclusive disease
α_1-Antitrypsin deficiency	Sickle cell disease with intrahepatic sickling
	Hemophagocytic lymphohistiocytosis
	Heat stroke
	Navajo neuropathy

*Many other drugs have been implicated in the etiology of conjugated hyperbilirubinemia; these are the most commonly cited.

Multiple **biliary strictures** have also been found in association with Langerhans cell histiocytosis, congenital hepatic fibrosis, autosomal recessive polycystic kidney disease, following ischemic/hypoxic injury, and in immunodeficiency states.

Overlap syndrome with features of both sclerosing cholangitis and autoimmune hepatitis and autoimmune cholangitis with inflammation focused on small bile ducts has been described as variants of the disease. In those conditions, response to immunosuppressive therapy is better than in PSC but worse than in autoimmune hepatitis.

Infection. Infections are a common cause of jaundice in the child and adolescent. The most important step is to evaluate patients for

synthetic liver failure and for signs of chronicity (portal hypertension, growth failure, risk factors for blood-borne or sexually transmitted disorders). Patients with synthetic liver failure should be referred for urgent evaluation by the liver transplant center.

Diagnostic work-up should focus on potentially treatable disorders (CMV, hepatitis B, and C), disorders preventable for contacts (hepatitis A). Screening for common community-acquired disorders such as EBV, adenovirus, or enterovirus is optional. In the absence of an identifiable viral agent, idiopathic acute hepatitis can be diagnosed only after the complete resolution of abnormal bilirubin and aminotransferases is documented. If abnormalities persist, a work-up for chronic liver diseases should be initiated.

Hepatitis A. Hepatitis A virus (HAV) infection is usually anicteric or asymptomatic in children younger than 5 years of age. However, in almost 66% of infected patients between 5 and 17 years of age, a symptomatic illness with jaundice develops. Two to 7 days before the onset of jaundice, there is a flulike illness with symptoms that can include malaise, headache, myalgias, anorexia, vomiting, diarrhea, right upper quadrant pain, and fever. Some children present with cough and coryza. The urine becomes dark, and jaundice and pale or acholic stools develop. Aminotransferase levels are 10-100 times normal. The diagnosis is confirmed by an HAV IgM study. Children generally recover within 2 weeks. On occasion, fulminant hepatitis develops from HAV infection. Small percentages develop either a relapsing or protracted cholestatic illness lasting up to 8 months. There is no carrier state or chronic illness.

HAV is an enterovirus of the picornavirus group. Transmission is by the fecal-oral route, which may include contaminated water and food, especially shellfish. The greatest fecal excretion is before the onset of jaundice when the disease has not yet been recognized (Fig. 15.4). Transmission rates are high in daycare centers and institutions with developmentally delayed children. The incubation period is 15-40 days. After exposure, infection can be prevented in 85-90% of cases by giving intramuscular immunoglobulin to contacts within 2 weeks of exposure. Hepatitis A vaccine is available for long-term prophylaxis.

Hepatitis B. Hepatitis B virus (HBV) is a DNA virus that is transmitted through blood products, shared needles, and sexual contact;

vertically during childbirth; and from occupational exposure. Infection in the newborn can be prevented by administration of hepatitis B immunoglobulin within 12 hours of birth and a series of 3 hepatitis B vaccinations. HBV infection is diagnosed mostly in children from countries with high prevalence of hepatitis B and no effective immunization or perinatal screening program. In developed countries, hepatitis B should be suspected in children born from mothers with preexisting hepatitis B or mothers with no prenatal care. Hepatitis B risk factors in adolescents include intravenous (IV) drug use and unprotected sex. The majority of children with hepatitis B are asymptomatic; few develop symptoms of acute or chronic hepatitis. Extrahepatic symptoms of arthritis, polyarteritis, urticaria, and nephritis from circulating immune complexes can be present. HBsAg is the first antigenic marker to appear; it disappears after 1-3 months if HBV resolves (Fig. 15.5). Hepatitis B surface antibody (anti-HBs) is a protective antibody that develops after immunization or resolution of infection. In patients whose infections resolve, there is a window of 2-6 weeks between the disappearance of HBsAg and the appearance of anti-HBs. During this window, anti-HBc or HBV DNA may be the only evidence of infection with HBV. Hepatitis B e antigen (HBeAg) correlates with viral replication. HBV DNA is a measure of viral replication. Screening for infection is made with HBsAg and anti-HBc. Although acute HBV infection is rarely a severe illness, fulminant hepatic failure develops in up to 1% of patients. Chronic infection, defined as the persistence of HBsAg for at least 6 months, occurs in 90% of infected neonates, 25-50% of infected children younger than 5 years, and 5-10% of infected adults. Children with chronic active hepatitis B can be treated with interferon α 2b or antiviral agents.

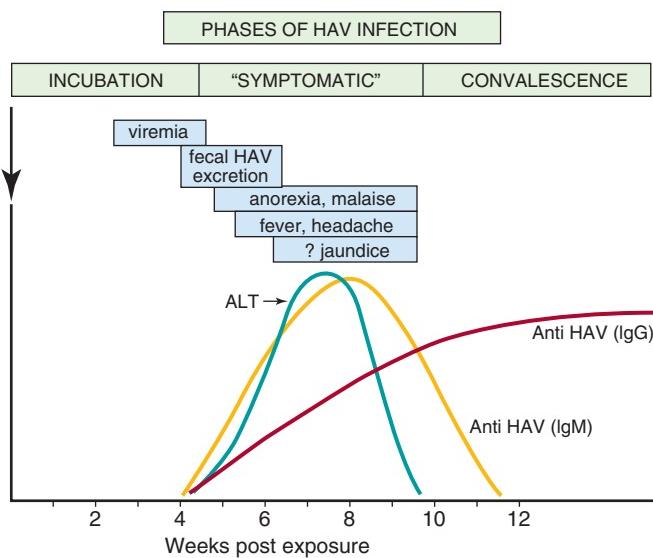
Hepatitis C. Acute hepatitis C virus (HCV) infection is often mild and usually subclinical. Jaundice is unusual. Chronic infection develops in 40-60% of affected children, in contrast with up to 80% of infected adults, and can progress to cirrhosis. Screening for hepatitis uses anti-HCV antibodies, and infection is confirmed via polymerase chain reaction (PCR) for HCV RNA. Transmission may be parenteral due to IV drug use or exposure to blood, or sexual or vertical transmission is also possible. Elimination of hepatitis C is possible with directly acting antiviral agents. The treatment regimen is selected based on


FIGURE 15.4 Typical course of hepatitis A virus (HAV) infection. ALT, alanine aminotransferase; IgG, immunoglobulin G; IgM, immunoglobulin M. (From Balistreri WF. Viral hepatitis. *Pediatr Clin North Am.* 1988;35:640.)
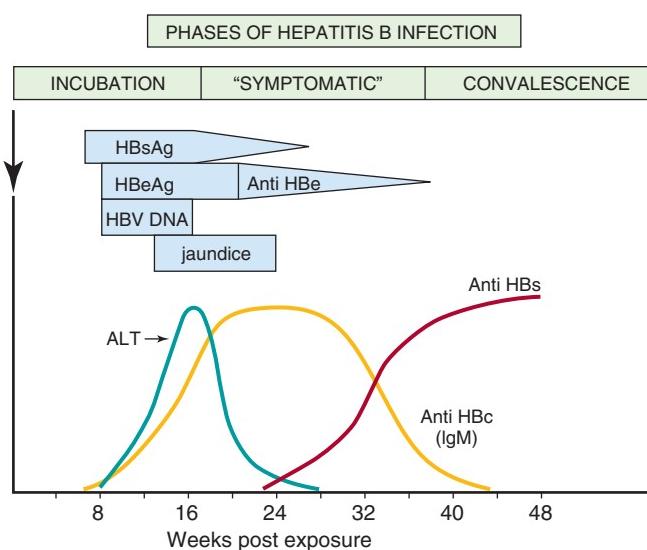

FIGURE 15.5 Typical course of acute hepatitis B virus (HBV) infection. ALT, alanine aminotransferase; HBc, hepatitis B core; HBe, hepatitis B e; HbeAg, hepatitis B e antigen. HBs, hepatitis B surface; HBsAg, hepatitis B surface antigen; IgM, immunoglobulin M. (From Balistreri WF. Viral hepatitis. *Pediatr Clin North Am.* 1988;35:647.)

hepatitis C genotype. It is a rapidly evolving area; however, pediatric experience with direct-acting antiviral regimens is limited.

Hepatitis D. Hepatitis D virus (HDV) infection can occur only in the presence of HBV as either a co-infection or a superinfection. Its route of transmission is parenteral. As with HBV, it can become chronic. The diagnosis is confirmed by the presence of HDV antibody.

Hepatitis E. Hepatitis E (HEV) infection is similar to HAV in its manifestation and mode of transmission. It is a self-limited illness with no chronic state. However, fulminant hepatitis may occur in up to 20% of cases. Serologic diagnosis can be made by finding antibodies to HEV.

Epstein-Barr virus. Epstein-Barr virus infection can mimic HAV, HBV, or HCV infection. Often there is an exudative pharyngitis and lymphadenopathy. Fatal hepatic necrosis can occur. This is rare, but it is of particular concern in the immunocompromised host. The diagnosis is confirmed by elevation of Epstein-Barr virus PCR.

Cytomegalovirus hepatitis can be symptomatic particularly in infants. Hepatitis is usually self-limited. Ganciclovir can be used as treatment in severe cases.

Other viruses. Other viruses including herpes simplex, human herpesvirus 6, parvovirus B19, and norovirus can also cause hepatitis, particularly in the immunosuppressed patient.

Wilson disease. Wilson disease is an autosomal recessive disorder of copper metabolism. As a result of ATP7B mutation, copper cannot be excreted and it accumulates in the liver, which causes hepatic steatosis and necrosis. Copper is then released into the circulation and is ultimately deposited in the central nervous system, kidneys, and cornea. The hepatic manifestation predominates in childhood; a neuropsychiatric manifestation becomes more common later, in adolescence and adulthood. The liver involvement may manifest as acute hepatitis, fulminant hepatic failure, chronic hepatitis, cirrhosis, or asymptomatic elevation of serum aminotransferases. Neurologic symptoms such as dysarthria, clumsiness, tremor, and mood disorders may or may not be present. In the kidney, the result is tubular dysfunction; in the cornea, the result is Kayser-Fleischer rings. Hemolysis can be present as a result of copper toxicity. The diagnosis is supported by documenting a low serum ceruloplasmin level, high urinary copper excretion, and increased hepatic copper concentrations on liver biopsy. D-Penicillamine or trientin chelate copper can successfully treat Wilson disease. Dietary restriction of copper can aid treatment. Wilson disease requires lifelong therapy. Wilson disease is a potentially lethal treatable disorder that should be promptly diagnosed. Patients presenting with synthetic liver failure should be promptly referred for liver transplant evaluation.

Drugs and toxins. Numerous drugs and toxins are associated with hepatic injury (see Table 15.9) and should be considered in the evaluation of jaundice. The reaction can be idiosyncratic or dose related. In the latter case, this may be associated with either accidental or purposeful overdose. The manifestation can be that of acute hepatitis, fulminant hepatic failure, or cholestatic disease, depending on the drug.

Autoimmune hepatitis. Autoimmune hepatitis (AIH) is a common cause of chronic liver injury (Table 15.10). The most frequent course is insidious with fatigue as a dominant symptom. Autoimmune hepatitis can present acutely with malaise, anorexia, nausea, vomiting, and jaundice. Autoimmune disorders such as arthritis, thyroiditis, vasculitis, nephritis, hemolytic anemia, or diabetes mellitus are often associated with AIH. Autoimmune hepatitis may be associated with inflammatory bowel disease. Laboratory studies demonstrate elevated aminotransferase levels, mild hyperbilirubinemia, and hypergammaglobulinemia. ANA, actin, or anti–smooth muscle antibody is present in type 1 AIH, whereas anti–liver-kidney microsomal antibody is found in type 2 AIH (see Table 15.10).

Liver biopsy is required for diagnosis. Characteristic findings are plasma cells and an inflammatory infiltrate expanding the portal area and moderate to severe piecemeal necrosis. Treatment consists of steroids and azathioprine.

TABLE 15.10 Classification of Autoimmune Hepatitis

Variable	Type 1 Autoimmune Hepatitis	Type 2 Autoimmune Hepatitis
Characteristic autoantibodies	Antinuclear antibody* Smooth-muscle antibody* Antiactin antibody[†] Autoantibodies against soluble liver antigen and liver-pancreas antigen[‡] Atypical perinuclear antineutrophil cytoplasmic antibody	Antibody against liver-kidney microsome type 1* Antibody against liver cytosol type 1* Antibody against liver-kidney microsomal type 3
Geographic variation	Worldwide	Worldwide; rare in North America
Age at presentation	Any age	Predominantly childhood and young adulthood
Gender of patients	Female in ~75% of cases	Female in ~95% of cases
Association with other autoimmune diseases	Common	Common[§]
Clinical severity	Broad range, variable	Generally severe
Histopathologic features at presentation	Broad range, mild disease to cirrhosis	Generally advanced
Treatment failure	Infrequent	Frequent
Relapse after drug withdrawal	Variable	Common
Need for long-term maintenance	Variable	~100%

*The conventional method of detection is immunofluorescence.
[†]Tests for this antibody are rarely available in commercial laboratories.
[‡]This antibody is detected by an enzyme-linked immunosorbent assay.
[§]Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy is seen only in patients with type 2 disease.

(See *Nelson Textbook of Pediatrics,* p. 1939.)

SUMMARY AND RED FLAGS

In evaluating the older child or adolescent with jaundice, it is important to determine whether the condition represents a hepatobiliary problem, a hematologic disorder, or a systemic illness. If there is conjugated hyperbilirubinemia, it is essential to evaluate for severe dysfunction, as manifest by, prolonged PT, hyperammonemia, encephalopathy, and hypoglycemia. Coagulopathy, encephalopathy, or hypoglycemia can signify hepatic failure, which mandates early intervention.

Constipation

Joshua Noe

Constipation is defined symptomatically as the infrequent passage of hard stools, straining while passing a stool, or pain associated with the passage of a hard stool. The range of normal defecation patterns in children is widely variable, though in general, formula-fed infants may have 4-5 stools per day in the 1st weeks of life while breast-fed infants usually pass softer and more frequent stools. Stool frequency in both gradually decreases to 1-2 per day by 1 year of age. Most children aged 1-4 years have 1 or 2 daily bowel movements, with a range of 3 daily bowel movements to 1 bowel movement every other day.

Constipation is classified broadly either as functional or as secondary to underlying conditions, such as anatomic abnormalities, metabolic disorders, neurologic dysfunction, or medication effects (Table 16.1). The majority of childhood constipation is functional. The Rome III Criteria for Functional Gastrointestinal Disorders defines **functional constipation** in 2 age groups as noted in Tables 16.2 and 16.3.

Changes in diet, such as formula changes or the addition of solid foods, may lead to transient constipation in infants. Minor illnesses, including infectious diarrhea, can subsequently result in episodic constipation as well. More long-standing constipation is often secondary to inadequate intake of dietary fiber, fluid, or both. The evaluation of constipation involves first determining whether the change in the frequency or consistency of stools is secondary to functional constipation or is related to an underlying organic disorder. This determination is based on identifying historical features and examination findings that suggest an underlying disorder and prompt further investigation.

PHYSIOLOGY OF NORMAL DEFECATION AND CONSTIPATION

Fecal continence and physiologic defecation are dependent on the **anal inhibitory reflex,** which is in turn dependent on the proper structure and function of the internal and external anal sphincters and the pelvic floor. The **internal anal sphincter** is an involuntary muscle that is contracted at rest. When a bolus of stool distends the rectum, the internal anal sphincter relaxes. This process generally results in the child sensing the need to defecate. The **external anal sphincter** and the **puborectalis muscle** of the pelvic floor, under voluntary control, contract upon rectal distention, respectively closing the anus and decreasing the rectoanal angle, thus allowing the child to hold stool until it is socially convenient to defecate. Voluntary relaxation of the puborectalis muscle and the external anal sphincter straightens the anorectal angle and allows the child to stool. In situations where there is **encopresis** secondary to **overflow incontinence**, the child typically consciously withholds stool by refusing to relax the external anal sphincter in the setting of a relaxed internal anal sphincter. Over time, the child is not able to keep the external anal sphincter fully contracted and stool leaks out of the anal canal. The presence of overflow incontinence is an important indicator that the anal inhibitory reflex is likely intact, as patients with anatomic or neurologic abnormalities of the

distal colon and internal anal sphincter are unable to reflexively relax the internal anal sphincter to allow for the passage of stool.

Patients with chronic constipation have physiologic abnormalities upon anorectal manometric evaluation. The most consistent abnormality is blunted rectal sensation, rendering the patient unable to feel the bolus of stool in the rectum. Other findings include incomplete relaxation of the internal anal sphincter and paradoxical contraction of the external sphincter during attempted defecation. Patients who have paradoxical anal contraction are less likely to respond to routine medical therapy or may be more likely to have recurrent constipation if treatment is withdrawn.

DATA COLLECTION AND ASSESSMENT

◆ History

Functional constipation may be distinguished from secondary causes of constipation by assessing the age of symptom onset, the stool consistency, and the presence of associated signs or symptoms.

The age at symptom onset differentiates disease processes that are congenital versus those that are acquired. Failure to pass meconium within the first 48 hours of life suggests a diagnosis of **Hirschsprung disease**; however, up to 50% of patients with Hirschsprung disease will pass meconium prior to this. In addition to Hirschsprung disease, constipation in the 1st month of life or a history of constipation since infancy suggests organic causes (Table 16.4). The appearance of symptoms beyond infancy suggests acquired organic constipation or functional constipation.

Stool consistency in constipation can differ by etiology. Functional constipation tends to produce large, bulky stools, whereas constipation secondary to Hirschsprung disease or other organic etiologies tends to produce harder, pebble-like, or ribbon-like stools. Stool consistency may be objectively rated via use of the **Bristol stool scale** (Fig. 16.1), and can be used to follow response to therapy.

The assessment of associated signs and symptoms should include evaluating for a history of blood in the stool, as well as for the presence of urinary symptoms. Bright red blood on the surface of the stool suggests an anal fissure indicative of straining, which is seen in approximately 25% of patients with constipation. Blood on the periphery of the stool may suggest pathology in the distal colon or anorectal vault.

Urinary symptoms may take the form of either retention or incontinence. Retention may be secondary to congenital or acquired abnormalities in the neurologic regulation of bladder voiding and may be associated with similar abnormalities in the regulation of defecation. Alternately, retention may be secondary to urinary tract outflow obstruction, which is secondary to a large stool burden. Incontinence may be due to a large stool mass distending the rectum and placing pressure on the posterior bladder wall, or may indicate overflow incontinence in the setting of a neurogenic bladder. Urinary retention is also seen in patients with chronic intestinal pseudoobstruction and is thought to be secondary to autonomic dysregulation.

Barium
Opiates (codeine, diphenoxylate–atropine sulfate [Lomotil], loperamide [Imodium])
Antidepressants
Anticholinergics
Phenothiazines
Vincristine
Calcium channel blockers
Bismuth
Clonidine
Antihistamines
Diuretics
Other
Milk protein–induced anal inflammation and fissure formation
Celiac disease
Collagen vascular disease (SLE, mixed connective tissue disease, scleroderma)
Amyloidosis

SLE, systemic lupus erythematosus.

TABLE 16.2 Functional Constipation: Infant/Toddler

Diagnostic criteria Must include 1 mo of **at least two** of the following in infants up to 4 yr of age:
1. Two or fewer defecations per week
2. At least one episode/week of incontinence after the acquisition of toileting skills
3. History of excessive stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large-diameter stools, which may obstruct the toilet
Accompanying symptoms may include irritability, decreased appetite, and/or early satiety. The accompanying symptoms disappear immediately following passage of a large stool.

From Rome III Diagnostic Criteria for Functional Gastrointestinal Disorders. 2006(Appendix A):895. Available at: http://www.romecriteria.org/assets/pdf/19_RomeIII_apA_885-898.pdf.

TABLE 16.3 Functional Constipation: Child/Adolescent

*Diagnostic criteria** Must include **two or more** of the following in a child with a developmental age of at least 4 yr with insufficient criteria for diagnosis of IBS:
1. Two or fewer defecations in the toilet per week
2. At least one episode of fecal incontinence per week
3. History of retentive posturing or excessive volitional stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large diameter stools, which may obstruct the toilet

*Criteria fulfilled at least once per week for at least 2 mo prior to diagnosis.
IBS, irritable bowel syndrome.

TABLE 16.4 Causes of Constipation During the Neonatal Period

Meconium plug (rule out cystic fibrosis)
Meconium ileus (rule out cystic fibrosis)
Hirschsprung disease
Intestinal pseudoobstruction
Anteriorly displaced anus
Ectopic anus
Anal stenosis
Imperforate anus
Spina bifida
Hypothyroidism
Hypercalcemia
Neuronal intestinal dysplasia types A and B
Medications (opioids, paralytic agents, magnesium)

Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on its surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges (passed easily)
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type y		Watery, no solid pieces. **Entirely liquid**

FIGURE 16.1 The Bristol stool chart allows for qualitative comparisons of stool consistency in the setting of both constipation and diarrhea.

TABLE 16.5   Historical and Physical Findings Suggestive of Organic Etiologies of Constipation

Symptoms or History	Physical Findings
Acute Signs	Severe abdominal distension
Delayed passage of meconium (after 48 hr of life)	Pelvic mass (e.g., sacral teratoma)
Fever, vomiting, or diarrhea	Lumbosacral dimple, hair tuft or lipoma, or deviation of the gluteal cleft
Rectal bleeding (unless attributable to an anal fissure)	Anal scars
Severe abdominal distension	Anteriorly displaced anus
Chronic Signs	Patulous anus (i.e., low resting sphincter tone)
Constipation present from birth or early infancy	Perianal fistula
Ribbon stools (very narrow in diameter)	High anal canal tone with empty rectum
Urinary incontinence or bladder disease	Explosive expulsion of stool after digital examination of the rectum
Weight loss or poor weight gain	Absent anal wink
Delayed growth (e.g., decreasing height percentiles)	Absent cremasteric reflex
Extraintestinal symptoms (especially neurologic deficits)	Decreased lower extremity tone or strength
Congenital anomalies or syndrome associated with Hirschsprung disease (e.g., Down syndrome)	Abnormal lower extremity deep tendon reflex: absence of delay in relaxation phase
Family history of Hirschsprung disease	Abnormal thyroid gland
	Extreme fear during the anal inspection

Modified from Tabbers MM, DiLorenzo C, Berger MY, et al. Evaluation and treatment of functional constipation in infants and children: evidence-based recommendations from ESPGHAN and NASPGHAN. *J Pediatr Gastroenterol Nutr.* 2014;58(2):258.

Abdominal pain is common in constipated patients; when present, it is often mild, nonspecific, and periumbilical. Older children may describe discomfort in the lower abdomen and a history of relief of pain after a stool is passed. Appetite is often diminished. A diary recording the passage of stools, the timing of meals, and the onset of abdominal pain over a period of several days to a few weeks can aid in the diagnosis of constipation and in monitoring of therapy. The personal medical history and the family history may reveal illnesses and conditions associated with constipation (Table 16.5; see Table 16.1).

The child's behavior during defecation should be noted. A history of straining, as an index of difficulty in defecation, can be misinterpreted by parents, who often view a child's efforts to withhold stool as efforts to pass a bowel movement. Parents often describe a toddler who hides in a corner, with stiffened straight legs, or who may lean into the wall or hold onto a table while "straining." More often, these actions represent attempts at withholding stool. The young child, having become constipated, passes a painful stool. Passage of a large, painful stool may be associated with an anal fissure. If a fissure is present, a small amount of blood is usually passed with the stool. The child associates the passage of stools with pain and tries to prevent further painful episodes by withholding fecal matter. This behavior results in the formation of even larger, harder stools, which are painful to pass, thus establishing a link between pain and defecation that perpetuates the cycle. Children with stool retention may go 3-5 days without defecating. Enuresis and encopresis may occur.

◆ Physical Examination

Abnormal growth patterns should alert the physician to the possibility of underlying organic disease, such as hypothyroidism or celiac disease (see Table 16.5). Abdominal examination is usually benign; there may

be some mild tenderness in the left lower quadrant on palpation of a segment of bowel that is full of stool. Stool may be palpable through the abdominal wall in the sigmoid and descending colon. On occasion, a large, firm fecal mass extends from the symphysis pubis to the umbilicus, which may mimic findings of an abdominal malignancy.

The spine and sacral area should be examined closely. A tuft of hair, a dimple, or a palpable defect or mass in this area should prompt consideration of **spina bifida occulta** or a **tethered spinal cord**. Sensory and motor function should be assessed. The presence of a normal **anal wink**, as elicited by gentle stroking of the perianal skin with a sharp object, such as a wooden tongue blade or the corner of a small package of lubricant, gives evidence of intact lumbosacral innervation. Presence of a normal **cremasteric reflex** in males also gives evidence of intact lumbosacral innervation. The cremaster muscle, innervated by the genitofemoral nerve of the lumbar plexus, typically contracts when the observer brushes a finger along the upper surface of the inner thigh, resulting in withdrawal superiorly of the ipsilateral testis.

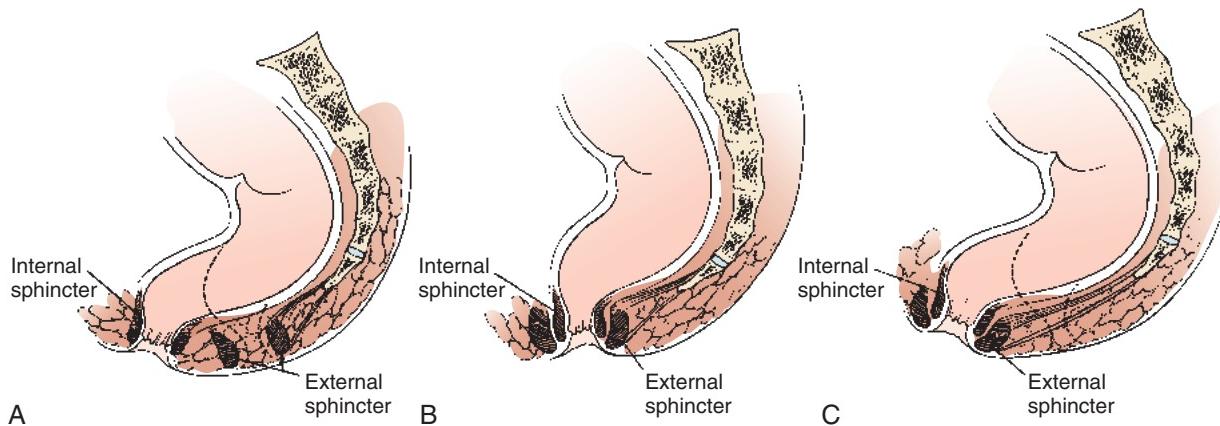
The perianal area should be examined for evidence of fissures suggestive of the passage of large, hard stools. The examination is facilitated if an assistant gently spreads the patient's buttocks apart while the examiner illuminates the area. Soiling in the undergarments may indicate fecal impaction with overflow incontinence. The anus should be located in relation to the other perineal structures to assess for anatomic or structural anomalies, such as **anterior displacement of the anus** (Fig. 16.2). The anus is typically situated in the center of the


FIGURE 16.2 *A,* Anterior ectopic anus. *B,* Normal anal anatomy. *C,* Anterior anal displacement.

slightly hyperpigmented skin surrounding the anal sphincter. An anteriorly displaced anus is indicated by an abnormal **anal position index** (**API**), which is defined as the ratio of the distance between the anus and the posterior aspect of the genitals (the fourchette in females and scrotum in males), to the distance between the coccyx and the posterior genitals. Measurements may be obtained using calipers or by placing clear plastic tape adjacent to the landmarks and marking with a pen, and then subsequently measuring the distance on the tape. The normal API for females is 0.45 ± 0.15, and for males is 0.54 ± 0.14.

Digital examination is indicated in the evaluation of infantile constipation, if the cause or degree of constipation is unclear, or if there are signs of organic disease. The examiner should note the patency and tone of the anus. High tone and an empty rectal vault may suggest Hirshsprung disease. If the aganglionic segment is short enough, withdrawal of the finger might result in an explosive release of stool as the finger acts as a dilator to reach the dilated, ganglion-containing segment. Conversely, a dilated rectal vault with a large stool impaction is more suggestive of functional constipation with withholding behavior. In a cooperative patient, the examiner can ask the patient to bear down against their finger as if attempting to push out stool, which should result in relaxation of the anal canal. Patients who have paradoxical contraction of their anal canal upon this request may have **functional dyssnergia**, a condition in which the patient's pelvic floor fails to relax upon attempted defecation.

◆ Diagnostic Evaluation

Routine laboratory evaluation is usually not helpful in the evaluation of constipation, though it is indicated if a metabolic abnormality is suspected on the basis of the history or physical examination. Endocrinologic disturbances, such as hypothyroidism, can be associated with constipation. If **celiac disease** (see Chapter 11) is a consideration, serum anti–tissue transglutaminase immunoglobulin A (IgA) antibody levels should be assessed. A total IgA level should be performed concomitantly to exclude IgA deficiency confounding interpretation. If the patient does have IgA deficiency, anti–tissue transglutaminase IgG levels or esophagogastroduodenoscopy with duodenal biopsies can be performed. Stool studies may be obtained to exclude infection if indicated by the history.

Plain films of the abdomen are rarely necessary, although if obtained may demonstrate stool in the large bowel. This information is occasionally useful in the case of a child with complaints of diarrhea whose symptoms are due to fecal impaction and overflow of liquid stools. Suspected Hirschsprung disease is evaluated radiographically via a liquid contrast enema. Neurologic symptoms are evaluated with magnetic resonance imaging of the spine and/or brain, particularly to assess for evidence of spinal dysraphism or a tethered cord. Concerns

for intestinal dysmotility may be evaluated with a **Sitz marker study**, in which the patient swallows a capsule of radiopaque circular markers and undergoes serial abdominal radiographs to determine the distribution of the markers. After 3 days, any markers that have not yet been evacuated in the stool should be located in the rectum. The presence of markers more proximally in the gastrointestinal tract suggests enteric nervous system or neuromuscular pathology (e.g., chronic intestinal pseudoobstruction).

A rectal motility evaluation may be helpful in the diagnosis and management of chronic constipation. **Anorectal manometry** can be used to evaluate the integrity of the muscles and the innervation of the defecatory mechanism. Determining the sensory threshold provides valuable diagnostic information: patients who cannot detect a balloon filled with 120 mL of air usually have encopresis. Hirschsprung disease is unlikely if reflexive relaxation of the internal anal sphincter occurs in the presence of rectal distention. Manometry and **electromyography** document the presence of paradoxical contraction of the external anal sphincter on attempted defecation. Anorectal manometry can also be used as a therapeutic modality in biofeedback therapy in patients with constipation and encopresis and in patients with paradoxical external anal sphincter contraction. **Total colonic motility** is performed by placing a catheter in the colon to monitor pressures from the rectum to the cecum. Motility tracings reveal information about the function of the colon that is useful in diagnosis and treatment, particularly if surgical options need to be explored.

DIFFERENTIAL DIAGNOSIS

The algorithmic approach to the evaluation of delayed passage of meconium in neonates is presented in Fig. 16.3. An algorithmic approach to the evaluation of pediatric constipation is presented in Fig. 16.4.

Hirschsprung Disease

Congenital aganglionic megacolon, or Hirschsprung disease, is a common cause of neonatal intestinal obstruction, occurring in approximately $1:5000$-$1:15,000$ live births, with a male-to-female ratio of about $4:1$. The disease is rare in premature births, may be familial, and is associated with trisomy 21, Waardenburg syndrome, multiple endocrine neoplasia type 2A syndrome, and piebaldism. The absence of ganglion cells in both the Meissner (submucosal) plexus and the Auerbach (myenteric) plexus results in an inability of the involved segment of bowel to relax in response to distention from the presence of stool. In the newborn, passage of meconium is often delayed beyond 48 hours after birth. Most affected patients

are diagnosed during infancy; 50% are diagnosed in the 1st months of life, 75% by 3 months, and 80% by the end of the 1st year. Diagnosis may be delayed into childhood and, in rare cases, into adolescence or even adulthood in some patients with ultrashort-segment disease. These patients complain of constipation; manifestations usually start in infancy. Differentiating Hirschsprung disease from functional constipation may be challenging in older patients or in those with short-segment disease (Table 16.6). Other conditions that may mimic Hirschsprung disease include other abnormalities of intestinal innervation such as chronic intestinal pseudoobstruction and hyperganglionosis.

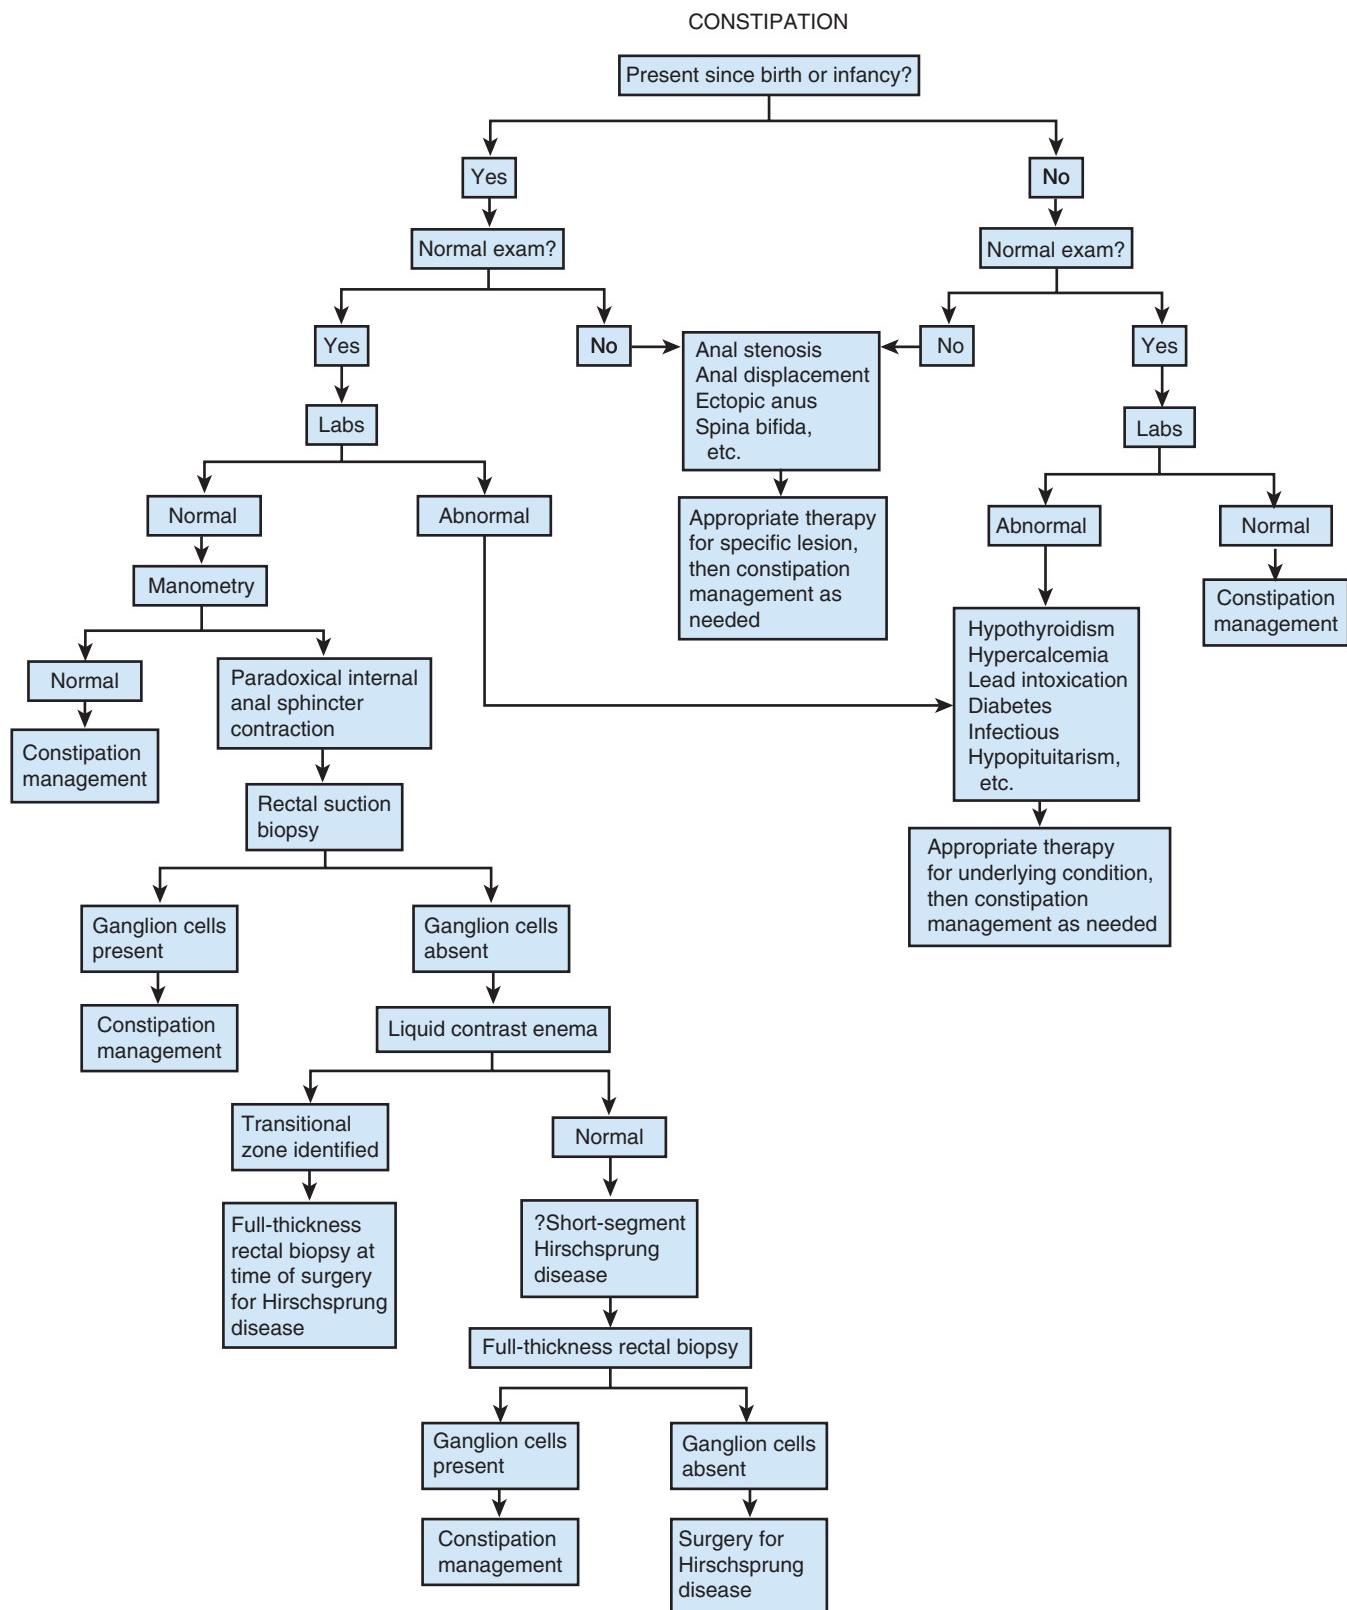
The lesion begins at the internal anal sphincter and extends continuously into the rectum or the rectosigmoid in 75-80% of cases. In 10% of cases, there is total colonic aganglionosis; in another 10%, there is variable involvement of the small intestine in addition to total colonic disease. Delayed passage of meconium is the most common manifestation in the neonate, followed by lower intestinal obstruction (distention, bile-stained emesis), obstipation (no stools), failure to thrive, or, in rare cases, intestinal perforation. Meconium plug syndrome may be an initial presentation. In addition, if stool is passed immediately after a rectal examination is performed in an obstipated or constipated patient, Hirschsprung disease should be suspected.

A plain abdominal film occasionally reveals distention of the normally innervated bowel proximal to the affected segment. The most useful radiographic test, though, is a liquid contrast enema, which may demonstrate a small-caliber rectum with a transition in the rectosigmoid to the dilated, obstructed, normal proximal colon. Patients

undergoing contrast enema should not undergo preparatory bowel evacuation procedures, which decrease test specificity, particularly in short-segment disease. A delayed lateral radiograph performed 24 hours after the barium enema aids in identifying a transition zone in the sigmoid colon.

Anorectal manometry is a valuable diagnostic procedure if radiographic procedures are unrevealing. Normal internal anal sphincter relaxation with transient rectal distention rules out Hirschsprung disease. Paradoxical contraction of the internal anal sphincter suggests an absence of ganglion cells and is most common in Hirschsprung disease. Absence of relaxation has been noted in premature infants, in neonates with infection or sepsis, and in thyroid aplasia; normal function is seen after appropriate therapy. The sensitivity and specificity of this test varies somewhat among the different age groups (children versus infants versus neonates). This test has a sensitivity that ranges from 0.79 to 0.90, a specificity ranging from 0.97 to 1.00, and a positive predictive value of 0.94-1.00.

A definitive diagnosis of Hirschsprung disease requires histologic confirmation of the absence of ganglion cells; such confirmation may be accomplished by a simple submucosal suction biopsy, which may be performed in the physician's office. Suction biopsy excludes the diagnosis if ganglion cells are present. However, there may be a 10% false-negative rate. A full-thickness rectal biopsy procedure is reserved for infants with bowel obstruction and for older children with abnormal rectal motilities and inconclusive suction biopsies.

Complications of undiagnosed Hirschsprung disease include **acute toxic megacolon** or infectious enterocolitis, most frequently caused by


CONSTIPATION

FIGURE 16.4 Algorithmic approach to the diagnosis of constipation.

TABLE 16.6	**Distinguishing Hirschsprung Disease from Functional (Acquired) Constipation**	
	Functional Constipation	**Hirschsprung Disease***
History		
Gender of patient	Male	Male
Onset of constipation	After 2 yr of age	At birth
Prevalence	1-3% of boys	1:5000-1:15,000
Encopresis	Common	Very rare
Forced bowel training	Usual	None
Stool size	Very large	Small, ribbon-like
Enterocolitis	None	Possible
Abdominal pain	Common	Rare except with obstruction, toxic megacolon, or enterocolitis
Failure to thrive	Uncommon	Common
Examination		
Abdominal distention	Variable	Common
Poor growth	Rare	Common
Anal tone	Patulous	Tight
Rectal examination	Stool in ampulla	Ampulla empty
Malnutrition	Absent	Possible
Laboratory		
Barium enema	Massive amounts of stool, no transition zone	Transition zone, delayed evacuation (>24 hr)
Rectal biopsy	Normal	No ganglion cells; ↑ acetylcholinesterase staining
Anorectal manometry	Distention of the rectum causes relaxation of the internal sphincter	No sphincter relaxation

*Note that ultrashort-segment Hirschsprung disease may have clinical features of functional (acquired) megacolon (e.g., constipation).
Modified from Behrman RE, ed. *Nelson Textbook of Pediatrics.* 16th ed. Philadelphia: Saunders; 2000:1140.

Staphylococcus aureus or *Clostridium difficile*. Therapy for these complications includes correcting electrolyte abnormalities (hypokalemia), broad-spectrum parenteral antibiotics, bowel rest, rectal tube placement, and if needed, emergency cecostomy or colectomy. Treatment for Hirschsprung disease is surgical resection of the affected segment of bowel and various strategies for an ileal or colonic rectal pull-through procedure.

Chronic Intestinal Pseudoobstruction

This disorder is characterized by manifestations of intestinal obstruction without an identifiable anatomic lesion and may be secondary to an intestinal **neuropathy** or **myopathy**. Congenital cases may be sporadic or inherited, in either autosomal dominant or recessive patterns.

Congenital disease often presents in the 1st months of life. Patients may be born prematurely and may have associated malrotation. Manifestations include abdominal distention, emesis, constipation, growth failure, and pain; diarrhea is less common. Diagnosis is based on the clinical manifestations in the absence of identifiable anatomic obstruction, as well as on motility studies that quantify abnormal bowel transit. Full-thickness intestinal biopsy should be reserved for severe or refractory cases, and care should be taken to pursue biopsy only if the patient is undergoing another indicated intraabdominal procedure, as biopsy in these patients increases the risk of postoperative adhesions and acquired obstruction.

Anterior Anal Displacement

There are two forms of displacement of the anus (see Fig. 16.2). In **anterior ectopic anus**, the anal canal and the internal anal sphincter are displaced anteriorly in the perineum as a unit and are separated from the external anal sphincter, which remains posterior in its usual position. On physical examination, it may be possible to elicit an external sphincter anal wink in the usual location, posterior to the opening of the anal canal. Rectal examination often reveals a sharp posterior angulation in the anal canal. In **anterior anal displacement**, the entire normal anal unit is located in the anterior perineum. Both entities are found more commonly in females. Symptoms of constipation often begin in the neonatal period and are related to the difficulty in expelling stool through a canal that is angled anteriorly. If the displacement is severe enough to cause symptoms, surgical correction may be necessary to relocate the anus and relieve the obstruction.

Anal Stenosis

The diagnosis of **anal stenosis** may be delayed beyond the neonatal period, especially if the degree of stenosis is not severe. Any portion of the anal canal or the entire canal may be involved. The diagnosis can be made by digital examination or by endoscopy. Constipation is caused by fecal retention secondary to outlet obstruction. Treatment is by dilatation or anorectal myectomy.

Imperforate Anus

Imperforate anus is usually diagnosed in the neonatal nursery. Passage of meconium is delayed or is noted to take place through an abnormal location as a result of the presence of a fistula (e.g., rectovaginal, rectovesicular, or rectoperineal). Treatment is surgical; the actual procedure depends on the level and the extent of the defect.

Spina Bifida and Spina Bifida Occulta

Defecation disturbances, most frequently constipation, are common in patients with spina bifida and spina bifida occulta, especially if the defect involves the lumbosacral spine. The spinal and nerve root defects result in poor functioning of the terminal bowel. Voluntary external sphincter control and rectoanal sensation are most often diminished or absent, and the degree of difficulty with defecation is related to the degree and the extent of the injury.

Most patients can achieve an acceptable level of continence via an individualized bowel regimen. Dietary fiber, stool softeners, suppositories, and enema continence catheters are treatment options. Biofeedback and pudendal nerve stimulation are successful in some patients. In most patients, a combination of treatment modalities allows social continence to be achieved and dramatically improves the patient's quality of life. Treatment of patients with spinal or nerve injury or dysfunction from other causes is similar.

Metabolic Diseases

The appropriate laboratory tests should be performed to rule out the various metabolic and endocrinologic conditions that may manifest with constipation (see Table 16.1). The most important of

(See *Nelson Textbook of Pediatrics,* p. 1806.)

(See *Nelson Textbook of Pediatrics,* p. 3409.)

these conditions is hypothyroidism. In routine neonatal screening, hypothyroidism manifesting solely with constipation is rarely seen. It should be suspected in any infant presenting with constipation and a history of prolonged neonatal jaundice.

Neurologic Disease

Children with neurologic disease may have constipation for many reasons, including poor intestinal motility, lack of dietary fiber, and poor awareness of rectal vault distention with stool retention. Any illness affecting the spinal cord or sacral nerves, degenerative muscle diseases, cerebral palsy, and demyelinating diseases can result in constipation.

Medication-Related Constipation

A complete medication history may reveal substances that can cause constipation (see Table 16.1).

ENCOPRESIS

Idiopathic constipation is much more common than Hirschsprung disease. Long-standing constipation leads to **encopresis**, the deposition of stools in the undergarments or other unorthodox locations that persists or occurs beyond the age that is considered culturally appropriate for achieving continence. In some cultures, delayed bowel training up to the age of 6 years is normal. It is generally accepted in the United States that healthy children should be bowel trained by the age of 4 years.

Encopresis is related to the chronic withholding of stool. As the fecal mass accumulates, it causes rectal distention, increases rectal compliance, and eventually results in blunted or absent sensitivity of the rectum to the presence of liquid stool passing around a firm fecal mass. Children with encopresis usually pass small stools and do not completely empty the rectum. Periodically, they pass huge stools, which may block the toilet. It is important to specifically question the patient or parents regarding these massive stools because this information is frequently not volunteered.

Encopresis has been incorrectly considered a symptom or manifestation of psychiatric illness. It was thought that the patient retained stools either consciously or subconsciously as a way to rebel against, please, or anger caretakers. Although encopresis may be seen in association with emotional and behavioral problems, it is usually the result of painful defecation followed by a pattern of stool withholding, leading to chronic constipation, overflow encopresis, and possibly poor relations with peers as a result of fecal soiling. In the few patients in whom encopresis is truly a manifestation of psychiatric disease, there is often no stool retention, and the prognosis for fecal continence with therapy is poor.

Idiopathic constipation with or without encopresis may compress the bladder by a dilated rectum, thus causing stasis and urinary tract infections.

SUMMARY AND RED FLAGS

Constipation is a common concern in infants and young children. A detailed history of bowel patterns identifies many children with normal bowel movements whose parents need reassurance. The majority of patients who do have constipation have functional constipation. The history should include a review of all medications and a search for an associated chronic disease, such as a metabolic or neurologic disease. This complete history, combined with a careful physical examination, including the spine and sacral area, the location of the anus, and a digital rectal examination, should alert the physician to the need for further evaluation. Red flags include onset in the neonatal period, growth failure, and prolonged jaundice in the neonatal period. Distinguishing features associated with Hirschsprung disease are listed in Table 16.6.

Abdominal Masses

John C. Densmore and Emily M. Densmore

An abdominal mass or abdominal fullness in a child usually becomes apparent when it enlarges enough to be visualized during bathing or palpable on physical examination. Masses may arise from intraperitoneal, retroperitoneal, or abdominal wall locations and emanate from both solid and hollow viscera (Figs. 17.1 and 17.2). An abdominal mass may prove life threatening (e.g., malignant neoplasm, splenic sequestration crisis in sickle cell disease), arise from congenital malformation or disorganized development (e.g., mesenteric cyst, enteric duplication), or be benign or correctable nonoperatively (fecaloma). Hepatomegaly and splenomegaly often represent systemic illnesses such as infection, hemolysis, storage disease, or malignancy. A child with an abdominal mass requires a prompt and thorough work-up with testing guided by history, physical examination findings, age, and gender. Early surgical referral may assist in this work-up following a directed screening approach.

DIAGNOSTIC STRATEGIES

◆ Clinical History

A child's age, gender, and thorough clinical history help to identify the most likely disease category (Tables 17.1 and 17.2). The duration and character of associated symptoms are important for narrowing the differential diagnosis (e.g., fatigue, fever, appetite changes, vomiting, stooling history, weight loss, night sweating, character and frequency of pain, hematuria, flushing, palpitations, lower extremity swelling, lymph nodal prominence, and jaundice). A history of abdominal trauma should be elicited, as solid organ injuries may result in hematoma, seroma, persistent pseudocyst, or arteriovenous malformation. Infectious disease may have sequelae of cyst, lymphadenopathy, or intraabdominal abscess. Some systemic diseases (e.g., glycogen storage, hereditary spherocytosis), genetic syndromes (e.g., Beckwith-Wiedemann, Peutz-Jeghers, familial adenomatous polyposis), and anomalies (aniridia with Wilms tumor, isolated hemihypertrophy with neuroblastoma and Wilms tumor) are associated with intraabdominal tumors. A family and sexual history are also pertinent, particularly in adolescent females. Modern prenatal imaging frequently identifies congenital malformations and neoplasms, requiring postnatal imaging and surgical assessment.

◆ Physical Examination

A complete physical exam should be performed in children with abdominal masses. Attention should be paid to the general condition of the child and to signs of metastatic disease. Enlarged lymph nodes and their locations should be noted, the skin inspected, and the lungs and heart auscultated. Extremities should be evaluated for evidence of swelling, venous phlegmasia, or evidence of embolic disease. Genitourinary exam should make note of any inappropriate virilization, testicular changes, and hymenal patency in the case of a female with a

low pelvic mass. In addition, a neurologic examination may reveal signs of nervous system involvement. The eyes should be carefully inspected for periorbital ecchymosis, proptosis, squint, opsoclonus-myoclonus syndrome, heterochromia of the iris, Horner syndrome, and scleral icterus. The patient's blood pressure must be determined and may be elevated in patients with Wilms tumor, neuroblastoma, or pheochromocytoma.

To successfully perform abdominal palpation in a child, the physician must approach the patient calmly and gently, as the most reliable exams are completed in cooperative and relaxed children. Enlarged organs may be missed in a struggling child who does not lie quietly. When cooperation proves difficult in an infant, the examining hand should be placed and remain static on the abdomen and the exam completed between cries or as the child calms in the parent's arms. Creative play is sometimes necessary, with the use of pacifiers or bottles to distract the child from the exam. Re-examination after voiding or defecating elucidates contributions of constipation and urinary retention in the child's presentation.

The abdominal quadrants should be examined systematically (Table 17.3; Figs. 17.1 and 17.2). With the patient in the supine position, the symmetry of the abdomen should be inspected, and any visible masses or the presence of ascites should be noted. A very enlarged spleen is frequently visible, with fullness of the left side of the abdomen. The presence of tense fluid-filled hernias or prominent periumbilical veins as sequelae of portal hypertension should be noted. The mass should be localized, and its size, shape, texture, mobility, tenderness, and relation to midline noted. The umbilical position is a useful marker of abdominal asymmetry.

Signs of peritoneal inflammation must be sought (see Chapter 10). Dull visceral pain conducted by slow C nerve fibers may be reported for inflammatory processes in the vascular distributions of the celiac, superior mesenteric, and inferior mesenteric arteries and referred to the epigastrium, umbilical region, or hypogastrium, respectively. When the inflamed process contacts the peritoneum, peritoneal fast A nerve fibers allow discrete localization of sharp pain to the abdominal wall. Ultrasound is often a very useful adjunct in the evaluation of an abdominal mass and is often available at the bedside.

Approximately half of abdominal masses in older children are caused by enlargement of the liver or spleen, or both. The liver is normally palpated in the right upper quadrant and epigastrium extending 1-2 cm below the costal margin. The inferior hepatic margin may be palpated in a thin child, is usually nontender, and moves with respiration. Detection of liver edge by auscultation using skin scratches has been proven unreliable and has been supplanted by the use of readily available ultrasound. The spleen is located in the left upper quadrant and is nonpalpable in most healthy children. To locate an enlarged spleen, the examiner must begin palpation in the patient's right iliac fossa (to avoid missing a grossly enlarged spleen or liver with

(See *Nelson Textbook of Pediatrics,* p. 1766.)

extension of the left hepatic lobe into the splenic area in the left upper quadrant); the examiner's right hand should move toward the patient's left upper quadrant to find the spleen's lower pole or medial border. The examiner's left hand is placed in the patient's left flank, and gentle displacement of the thoracic cage toward the examiner's right hand often displaces the spleen forward enough to make it appreciable. The spleen has a rounded tip and should move downward with inspiration and is more superficial than a renal mass. It is equally important for the examiner to palpate the spleen as it is for the spleen to "touch" the examiner during its descent with inspiration. Overaggressive palpation may push the spleen away, whereas gentle or light palpation permits the examiner to feel the spleen's edge passively. The characteristic notch in the medial or inferior border may not be palpable when the spleen is enlarged only a few centimeters, but the notch's presence usually clearly distinguishes an enlarged spleen from other abdominal masses on the examination alone. Because the extent to which the spleen extends below the costal margin depends heavily on the patient's position, the extent of the spleen below the costal margin should be measured with the patient in the supine position. Measurement from the left costal margin to the lower pole of the spleen defines the splenic axis. Ordinarily, the long axis of the spleen is along the length of the 10th rib. As it enlarges, it extends medially and downward. Masses in the left upper quadrant, especially left renal masses, may be difficult to distinguish from an enlarged spleen. In general, the presence of the splenic notch helps identify the mass as a spleen, but nodular masses, such as Wilms tumors of the kidney, neuroblastomas, and

retroperitoneal teratomas may masquerade as splenomegaly. Many enlarged spleens are not palpable on physical examination because of their relationship to other organs and the thoracic cage. Hyperinflation of lungs (as occurs in asthma, bronchiolitis, ipsilateral pneumothorax) may make a normal-sized liver or spleen palpable.

Flank masses are the next most frequent, particularly in newborn to toddler-aged children. Renal masses extend caudally, are fixed with respiration, and cause abdominal asymmetry. Lower abdominal masses are most commonly caused by constipation or urinary retention. These may be functional or secondary to neurogenic dysfunction. A perforated appendix with resulting abscess formation may create a tender right lower quadrant mass. Ovarian or uterine tumors often grow undetected in the pelvis until large enough to exit the pelvis as a large palpable abdominal mass.

◆ Laboratory and Imaging Studies

Screening laboratory data, including complete blood count with differential and cell morphology, measurements of serum electrolytes, urinalysis, urine pregnancy test when appropriate, and inflammatory markers, are broadly applicable. Liver function tests, serum amylase,

tumor marker levels (Table 17.4), and renal function tests are often important initial objective data points.

Plain abdominal radiographs may reveal tumor calcifications, organomegaly, excess fecal load, and mass effect upon intestines. Views in at least 2 different positions should be obtained to appreciate ascites or intestinal obstruction. As a screening modality, ultrasonography is a highly efficient, low-cost, and widely available test. It is noninvasive, nonirradiating, and can give detailed information on the location, vascularity, and nature of the mass and adjacent structures (Fig. 17.3). The most widely used axial imaging technique is computed tomography (CT) (Fig. 17.4), followed by magnetic resonance imaging (MRI). These modalities often provide radiologic diagnosis, are invaluable for surgical planning, and are unhampered by bowel gas, a common limitation of ultrasound. MRI pulse sequences have evolved to discriminate between primary malignant, metastatic, and hamartomatous liver lesions.

SPLENOMEGALY

Unlike many other abdominal masses, splenomegaly is usually secondary to another process; it can be caused by diseases that result in hyperplasia of the lymphoid and reticuloendothelial systems (infections, connective tissue, inflammatory disorders), infiltrative disorders (Gaucher disease, leukemia, lymphoma, histiocytosis, hemophagocytic lymphohistiocytosis), hematologic disorders (thalassemia, hereditary

TABLE 17.4	Tumor Markers

Germ cell tumors	β-hCG

hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase

spherocytosis), and conditions that cause distention of the sinusoids whenever there is increased pressure in the portal or splenic veins (portal hypertension) (Table 17.5). In addition, palpable spleens in children and adolescents are not always indicative of disease. A palpable spleen (≤2 cm below the left costal margin) is a normal finding in a child younger than 3 years and may be a normal finding in an older child. Up to 15% of full-term neonates, 10% of children, and 3% of college freshmen have palpable spleens unassociated with an increase in lymphoreticular malignancy and with equivalent health. Painful splenomegaly generally follows stretching of the splenic capsule with rapid enlargement of the spleen. Malfixed spleens may undergo torsion,

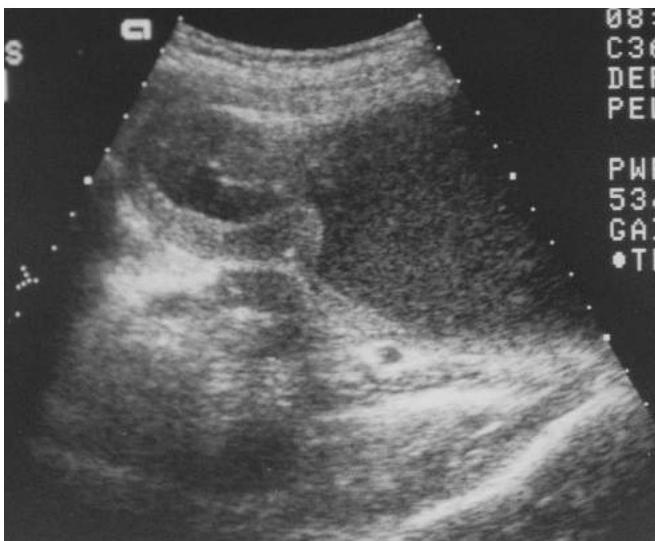
(See *Nelson Textbook of Pediatrics,* p. 2408.)


FIGURE 17.3 An ultrasonic longitudinal view of the pelvis reveals hydrometrocolpos. The uterus and cervix are readily seen superior to the large collection of fluid in the vagina located at the right of the image.

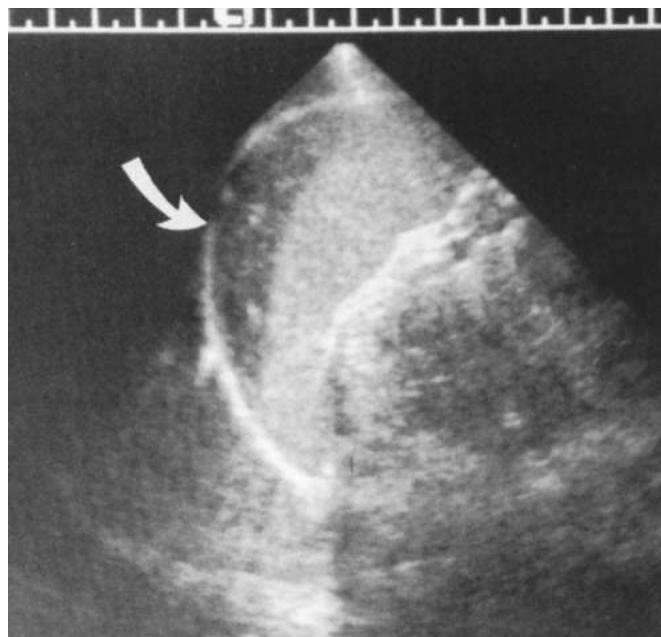
FIGURE 17.4 Computed tomogram revealing a large Wilms tumor replacing the right kidney. Notice that the renal cortex, enhanced by contrast medium, is splayed out around the mass. This characteristic helps differentiate Wilms tumor from neuroblastoma, which would displace a normal-appearing kidney.


FIGURE 17.5 The subcapsular splenic hematoma *(arrow)* in a 15-year-old boy who had been in an automobile accident was best seen on coronal scans through the left intercostal spaces.

◆ History

Birth and medical history, including transplacentally acquired infections, especially congenital syphilis, are often associated with splenic enlargement. History of a neonatal umbilical venous catheter, perhaps accompanied by occult portal venous injury or thrombosis, may progressively obstruct the extrahepatic portal vein, leading to congestive splenomegaly. Causative previous infections include hepatitis, mononucleosis, and malaria. Liver disease may lead to portal hypertension, which may in turn lead to splenomegaly. Congestive heart failure and associated congenital cardiac malformations have an increased risk of splenic malformation and splenomegaly. Abdominal trauma may acutely produce a splenic hematoma (Fig. 17.5) or may be followed by development of a chronic splenic pseudocyst.

A family history of anemia, transfusions, early biliary stones, cholecystectomy, and splenectomy may indicate hemolytic anemia. Identification of Mediterranean (thalassemia, glucose-6-phosphate dehydrogenase [G6PD] deficiency), African (sickle cell disease, G6PD deficiency), southern Asian (thalassemia, G6PD deficiency), or Ashkenazi Jewish (storage disease) ancestry in patients with splenomegaly is helpful in identifying an inherited process.

Systemic symptoms, such as fever or weight loss, are seen in many disorders that manifest splenomegaly, particularly infections, malignancies, and inflammatory or granulomatous processes, such as hemophagocytic lymphohistiocytosis (HLH) and sarcoidosis. When fever is acute in onset, infection is most likely. Chronic fever, often gradual in onset and not associated with chills, is more likely to be caused by inflammatory processes (systemic lupus erythematosus [SLE], juvenile idiopathic arthritis [JIA], sarcoidosis, Langerhans cell histiocytosis), or tumors (lymphomas, especially Hodgkin disease, or leukemia). Exposure to infectious agents or a travel history that might result in exposure to infectious agents unusual for the patient's community (malaria, leishmaniasis, schistosomiasis, trypanosomiasis for U.S. citizens with a travel history to an endemic country) should be determined. Social and behavioral issues of parents, children, and adolescents heavily affect certain risks and exposures. Sexual encounters and intravenous

presenting the upper pole to the abdominal wall as a prominent painful abdominal mass. Splenic enlargement that is noted not in the context of an acute illness (i.e., it is noted incidentally, for instance on a well child examination or check up) is more likely to be caused from a chronic process such as a storage disease than splenomegaly that is noted in the context of an acute illness. Acute onset of splenomegaly is most characteristic of an acute infection or a rapidly progressive malignancy (acute leukemia, lymphoma). **Chronic splenomegaly** (present for ≥1 month) is much more likely to represent a chronic process, such as storage diseases, congestive processes (portal hypertension, congestive heart failure), hemolysis, chronic infection or inflammation.

human herpesvirus 6; HIV, human immunodeficiency virus.

and illicit drug exposure may expose patients to hepatitis, cyto-megalovirus, and human immunodeficiency virus (HIV). Sexual abuse may place even young children at risk, and it may be difficult to elicit an accurate history.

A review of systems in a patient with splenomegaly should elucidate related conditions. Pallor suggests anemia (hemolysis, bone marrow infiltration, hypersplenism); purpura and petechiae suggest thrombocytopenia (bone marrow failure, autoimmune disorder, hypersplenism, bone marrow infiltration); and jaundice or conjunctival icterus suggest hemolytic anemia, liver dysfunction, or both. Rashes caused by a variety of acute and chronic infections (SLE, JIA, infective endocarditis, HLH) and hemangiomata that are part of a systemic process involving the spleen may provide clues to splenic disease. Dyspnea, cough, orthopnea, and fatigue suggest respiratory disease (Langerhans cell histiocytosis or sarcoidosis), anemia, congestive heart failure, or malignancy (Hodgkin disease). Diarrhea caused by *Salmonella* infection or inflammatory bowel disease may be accompanied by splenic enlargement. Abdominal pain accompanied by splenomegaly may be attributable to acute splenic capsule distention or caused by coincident gallstones, hepatitis, or trauma. Joint pain resulting from SLE, JIA, and other autoimmune inflammatory diseases may be associated with splenomegaly. Bone pain is a feature of bone marrow infiltrative processes, particularly leukemia or neuroblastoma. Poor vision in an infant with splenomegaly suggests osteopetrosis (with deafness) or uveitis-iritis (sarcoidosis, JIA). Loss of developmental milestones occurs with storage diseases. Myasthenia gravis may in rare cases be accompanied by splenomegaly.

◆ Physical Examination

Nutritional status and growth parameters provide clues to disorders that affect the patient's metabolic state and tissue oxygenation. Poor nutrition (as evidenced by such problems as weight loss and failure to thrive) in a child with splenomegaly suggests malignancy, chronic hemolysis, immunodeficiency or chronic infection, a metabolic disorder, or liver disease. Pallor, petechiae, purpura, icterus, hemangiomata, septic emboli to the skin, infiltrative lesions (leukemia cutis, solid tumors), seborrhea, or eczema (as occurs in Langerhans cell histiocytosis and immunodeficiency) should be noted. Cherry-red retinal spots or cloudy corneas suggest storage diseases. Conjunctival pallor, scleral icterus, fundal hemorrhages, evidence of sinus infection or otitis media, condition of gingivae, and evidence of salivary gland enlargement should be noted. The clinician should look for signs of heart failure or new or changing murmurs, which suggest valvular or other structural heart disease or endocarditis. Any distress, rales, rhonchi, or suggestions of pneumonia or asthma should be noted. Abdominal distention, prominent veins on the abdomen, hepatomegaly, fluid wave, tenderness, or rebound should be noted, as should specific characteristics and size of the spleen itself. A hard or nodular spleen suggests malignancy or chronic hemolysis. A tender spleen suggests either acute enlargement or infection, or both. A spleen that is more than 5 cm below the left costal margin is usually not transient and represents significant disease. Arthritis, splinter hemorrhages, and poor bone growth (as occurs in storage diseases and osteopetrosis) should be noted. Size, texture, mobility, tenderness, and distribution of lymph nodes should be noted. Enlarged (>1 cm), firm, fixed lymph nodes are suggestive of lymphoma or leukemia. Tender, enlarged lymph nodes are suggestive of more common infections. Developmental delay suggests chronic infection, immunodeficiency, or storage diseases.

Approach to the Child with Splenomegaly

The most common cause of splenomegaly in childhood is viral infection, which should induce only moderate splenomegaly (<5 cm below

the left costal margin) that is transient, lasting less than 4-6 weeks. Other common causes include autoimmune disorders and destruction of abnormal blood cells (such as brisk hemolysis). The approach to the child with splenomegaly is affected by several key factors, each of which indicates the probability of significant disease necessitating diagnosis and intervention (Fig. 17.6*A* and *B*).

◆ Laboratory Investigation

Table 17.6 summarizes key diagnostic laboratory investigations.

Complete Blood Cell Count

A complete blood count is the first test indicated in all patients with undiagnosed splenomegaly. This count provides extensive information about hematologic, infectious, and inflammatory processes, and the result may be abnormal in patients with hypersplenism caused by portal hypertension.

Leukocyte Count and Differential. Elevation or decrease in the number of total white blood cells (WBCs), the neutrophil count, and the lymphocyte count and the presence of abnormal cells (atypical lymphocytes, blasts) should be noted. Viral infection is the most common cause of splenomegaly in children, and atypical lymphocytosis may be a clue. Viral infections may be associated with an increased (early) or decreased WBC count. Most significant bacterial infections produce neutrophilia and reactive changes in the neutrophils. Infections with intracellular bacteria or some viruses may produce neutropenia. Leukemia can manifest with an increased or decreased total WBC count. The presence of blasts is confirmatory, but they are not always present.

Hemoglobin, Erythrocyte Morphology, and Reticulocyte Count. Hemolytic anemia may be unsuspected without examination of the blood smear and the reticulocyte count. Malarial parasites may be seen on the blood smear but may be missed unless a thick preparation is examined. Clues found on the blood smear include spherocytes (present in hereditary spherocytosis and hemolytic anemias); elliptocytes (present in hereditary elliptocytosis); polychromasia, poikilocytes, and fragmented cells (present in hemolytic anemias); sickled cells with target cells, spherocytes, and nucleated red blood cells (present in sickle cell anemia and variants); and microcytosis, hypochromia (present in thalassemias), and Howell-Jolly bodies (present in splenic dysfunction).

Platelet Count. Thrombocytopenia (<150,000 platelets/mm^3) may be caused by decreased platelet production or increased platelet destruction. Production is diminished in conditions characterized by bone marrow infiltration (leukemia, neuroblastoma). Increased destruction accompanies immunologic processes, drug reactions, HLH, and viral infections. Thrombocytosis (>400,000 platelets/mm^3) often accompanies iron deficiency or acute infection as an acute-phase reactant.

Pancytopenia. Pancytopenia implies bone marrow dysfunction, bone marrow infiltration, or portal hypertension with hypersplenic destruction (increased sequestration and lysis by splenic macrophages) of all the formed elements of the blood. A bone marrow aspiration and biopsy should be performed in any child with splenomegaly and pancytopenia. Tests of liver function, including prothrombin time and albumin, are indicated.

Erythrocyte Sedimentation Rate

Elevation of erythrocyte sedimentation rate (ESR) is nonspecific but suggests infection, especially bacterial, mycobacterial, or fungal infection, or an inflammatory process, such as JIA, HLH, or SLE. The ESR may be normal despite significant inflammation. The C-reactive protein level may be elevated when the ESR is normal.

(See *Nelson Textbook of Pediatrics,* p. 2409.)

TABLE 17.6   Summary of Laboratory Investigations for Suspected Diagnosis with Splenomegaly

Suspected Diagnosis	Tests to Be Performed
Hemolysis	CBC, reticulocyte count, blood smear, serum bilirubin measurement, Coombs test, osmotic fragility study, RBC enzyme assays, hemoglobin electrophoresis
Infection	CBC, differential, blood cultures, viral studies (EBV, CMV, HIV), toxoplasmosis, TB test, malaria test
Liver disease	Liver function tests, albumin measurement, prothrombin time, α_1-antitrypsin, serum copper, ceruloplasmin
Portal hypertension	Liver function tests; albumin measurement; prothrombin time; ultrasonography/CT of portal veins, liver, and spleen
Immunologic and inflammatory disease	ESR; C3, C4, antinuclear antibody, rheumatoid factor measurements; urinalysis; blood urea nitrogen, serum creatinine, and immunoglobulins measurements
Infiltrative disease	Bone marrow aspiration, CT, enzyme assay for Gaucher disease, tests as indicated for other storage diseases

CBC, complete blood count; CMV, cytomegalovirus; CT, computed tomography; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; RBC, red blood cell; TB, tuberculosis.

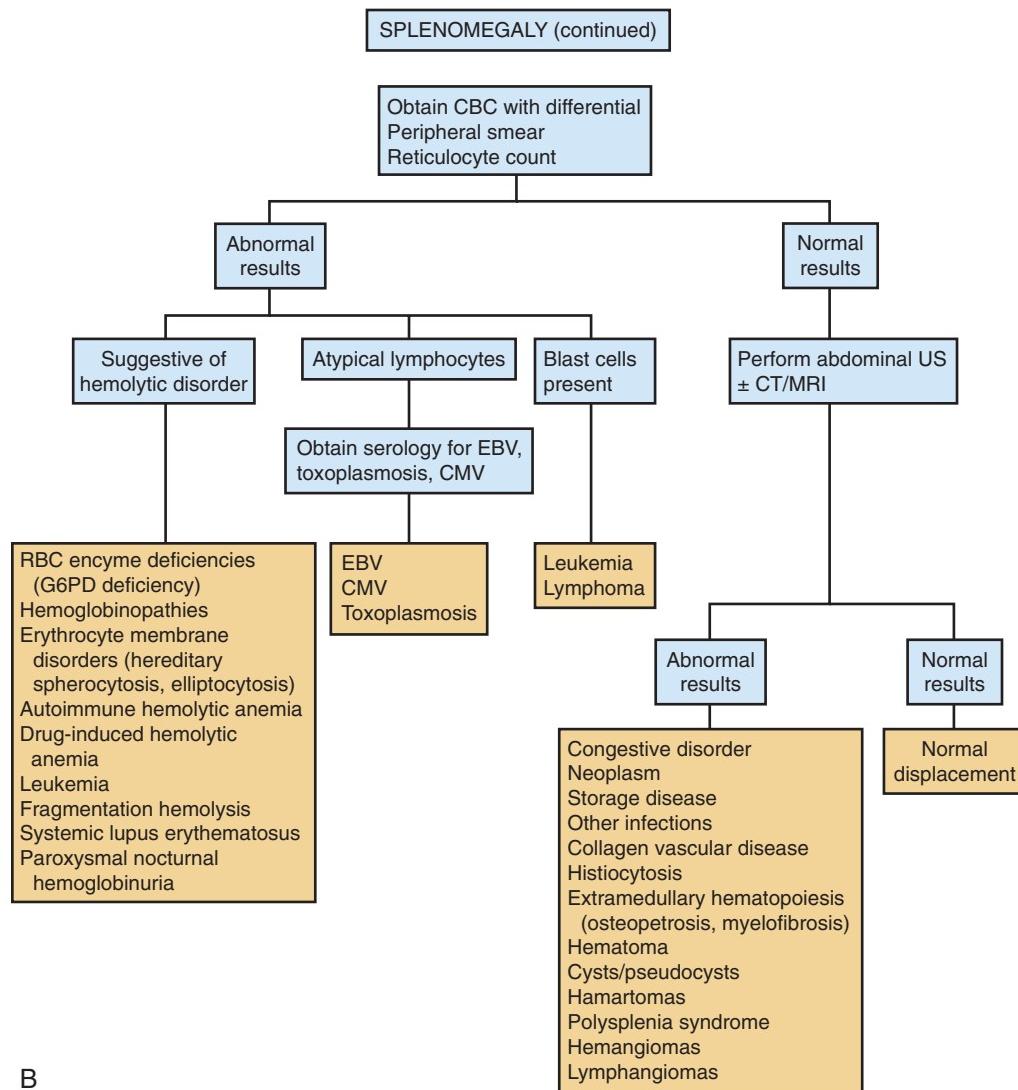

FIGURE 17.6, cont'd

Liver Function Tests

Liver function tests are indicated if splenomegaly is significant (>2 cm) or persists longer than 1 month. Portal hypertension is often asymptomatic until hepatic fibrosis is far advanced. Liver synthetic function (albumin, prothrombin time, fibrinogen), direct bilirubin levels, and transaminase levels should be assessed.

Immunologic Evaluation

Immunologic evaluation is needed when autoimmune disorders (JIA, SLE) or immunodeficiency disorders (inherited or acquired) are suspected. This assessment includes measurements of antinuclear antibody titer, immunoglobulin levels, and immunoglobulin subclass levels; tests of neutrophil function; and measurements of T-cell subclasses. Repeated infections stimulate the immune system and may cause splenomegaly.

Viral Antibody Titers

Viral antibody titers for Epstein Barr virus and cytomegalovirus should be obtained when a mononucleosis syndrome is present, especially when splenomegaly persists. The results of these tests rarely affect management but may permit a presumptive diagnosis of a self-limited process to be made, and they may preclude more invasive tests such as imaging and/or bone marrow examination. Toxoplasmosis should also be considered. Primary infection with HIV frequently causes splenomegaly. Acute infection with HIV may not be noted on screening labs; therefore additional testing may be required.

Cultures

Bacterial, fungal, and other cultures may be necessary and are dictated by the suspected infection.

Bone Marrow Examination

Bone marrow examination is appropriate for diagnosing infiltrative processes (acute leukemia and other malignancies), storage disorders (Gaucher disease, Niemann-Pick disease, sea-blue histiocyte syndrome), HLH, and some infections that may be difficult to diagnose from other tissues (disseminated histoplasmosis, miliary tuberculosis, bacterial endocarditis, and other chronic infections, especially in immunocompromised patients).

◆ **Imaging**

Imaging of the spleen has several roles but should be performed selectively. It is useful for the confirmation of splenic size, assessment of splenic architecture, and evaluation of other organs involved in the differential diagnosis. It can be useful in determining whether there are other abdominal masses that suggest widespread involvement by tumor, and if there is silent portal hypertension.

The choice of imaging depends on the questions to be asked. Ultrasonography has been the preferred method of imaging as it is used to assess size, perfusion, and to visualize cysts and other lesions. Guidelines are available for the upper limit of normal splenic length (measured as the greatest longitudinal distance between the dome of the spleen and the tip). Dopplerflow ultrasonography can detect portal hypertension.

CT of the spleen can define focal lesions (Fig. 17.7) and nonfocal enlargement, as well as evaluate the splenic and portal veins and the vasculature of the spleen. Less common in children than in adults, splenic cysts and pseudocysts may manifest with palpable spleens (Fig. 17.8). Both CT and ultrasonography identify such cysts well, and they also image the pancreas. Pancreatitis is a common cause of splenic cysts. Subcapsular hematoma can also be visualized by ultrasonography. Splenic lacerations are seen well on CT (Fig. 17.9). Persistent

splenomegaly after systemic infections may be caused by splenic abscesses, which are visualized with ultrasonography (Fig. 17.10). CT is an alternative imaging procedure for each of these problems.

SPLENECTOMY

Surgery plays an important role in the management of splenomegaly due to congenital hemolytic anemia. Laparoscopic splenectomy procedures have been demonstrated to significantly decrease sequestration events in both hereditary spherocytosis and sickle cell disease. Partial splenectomy outcomes are durable in 5 year followup with only a 4.8% failure rate according to the congenital hemolytic anemia registry. The use of partial splenectomy may be helpful in hereditary spherocytosis where total splenectomy has been associated with pulmonary artery hypertension, thrombosis, and overwhelming postsplenectomy sepsis. Pediatric surgeons initiated nonoperative approaches for the management of splenic lacerations resulting from trauma. The American Association for the Surgery of Trauma grading scales for splenic injury have been employed to prospectively follow outcomes in stable pediatric trauma patients. Patients with grade I-II lacerations are confined to bed for 24 hours, and those with grade III-V lacerations are confined to bed for 48 hours with restriction of activity for grade plus 2 weeks postinjury. Even for the highest grades of injury, the need for splenectomy due to hemorrhage and clinical deterioration is less than 5%.

NEUROBLASTOMA

Neuroblastoma is the most common extracranial solid malignancy in childhood. It accounts for 10% of all childhood tumors and 15% of pediatric cancer deaths. The incidence of neuroblastoma is approximately 10.2 per million U.S. children under age 15 and is more common in boys than in girls (1.2:1). The tumor affects primarily children younger than 8 years, and more than 50% occur in children older than 2 years of age.

It arises from neural crest cells forming primitive sympathetic innervation. Seventy-five percent of the tumors are abdominal, and 65% of these originate in the adrenal medulla or lumbar sympathetic ganglia. The biology of neuroblastoma is exceptionally heterogeneous as mature lesions, particularly in neonates, may regress spontaneously or mature into more benign forms of ganglioneuroblastoma or ganglioma. Unpredictably, other lesions may degenerate despite intensive chemotherapy. As a derivative of sympathetic ganglia, this tumor produces catecholamines (90%) and expresses surface disialoganglioside

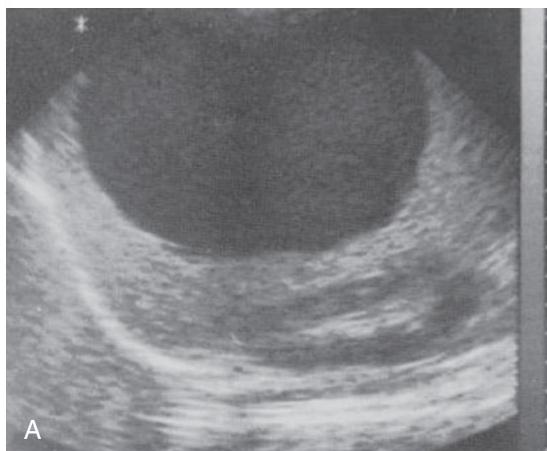
FIGURE 17.7 Abdominal computed tomographic scan of a 15-year-old with fever, weight loss, and orthopnea. The diagnosis was Hodgkin disease. The spleen shows hypoechoic lesions, typical of lymphoma.


FIGURE 17.8 The large epidermoid cyst of the spleen in a boy, shown on ultrasonography (A), is shown by computed tomographic scan (B) to compress the left renal vein (arrows). The boy presented with varicocele.
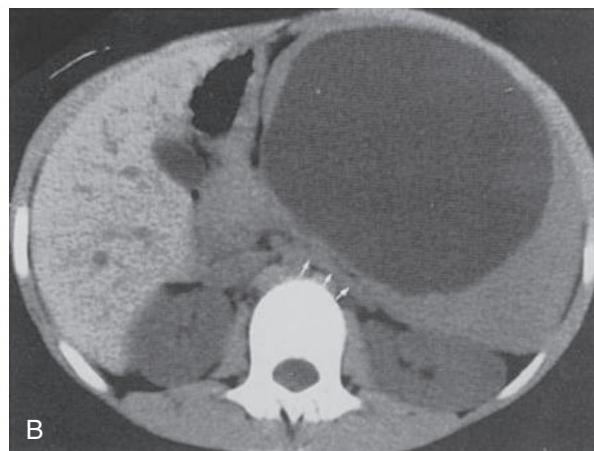


(See *Nelson Textbook of Pediatrics,* p. 2411.)

(See *Nelson Textbook of Pediatrics,* p. 2461.)

2 (GD2). These features are exploited via MIBG scans and GD2 epitope-directed immunotherapy. Neuroblastomas evade T and NK cells and exploit inflammatory macrophages to enhance survival. MYCN, X-linked alpha thalassemia/mental retardation syndrome (ATRX), anaplastic lymphoma receptor tyrosine kinase (ALK), and paired like homeobox 2b (PHOX2B) mutations have been recognized among neuroblastomas.

Toddlers present with progressive abdominal distention or abdominal discomfort. The mass is retroperitoneal and tends to encase rather than displace other viscera. Catecholamine production by the tumor occasionally results in flushing, sweating, and irritability. Vasoactive intestinal polypeptide, also produced by the tumor, may cause **secretory diarrhea** rarely. A variety of neurologic symptoms (**opsoclonus-myoclonus**) may also be seen, as may weight loss and anorexia. Most patients have metastases at the time of diagnosis, mainly to regional and distant lymph nodes, bone marrow and bone cortex, the orbit, the liver, and occasionally the lungs. Signs and symptoms related to metastases include bone pain, proptosis, and skin lesions.

Diagnostic studies must define relative anatomy and size of the tumor, determine regional invasion, metastatic disease, function, and ultimately histologic features. In 90% of patients, high levels of catecholamines and their detectable metabolites (homovanillic and vanillylmandelic acid) are found in spot urine samples. Twenty-four-hour urine collections show no additional sensitivity. Other serum markers include lactate dehydrogenase, ferritin, and neuron-specific enolase. In 50% of cases, a plain radiograph shows finely stippled tumor calcifications and displacement of gas-filled bowel loops. Ultrasonography confirms its solid nature and position in relation to the kidney. CT or MRI should be completed with arterial and venous phase contrast prior to biopsy or resection (Fig. 17.11). Axial imaging may reveal any intraspinal extension of the tumor or its metastases. Bone marrow metastases are detected by bone marrow aspiration. Technetium 99m (Tc-99m) bone scans can be used to detect cortical bone lesions and are necessary for staging. Metaiodobenzylguanidine (MIBG) scans are utilized to detect remote metastatic disease.

Surgical resection is the primary treatment of localized neuroblastoma. Two exceptions to this rule currently exist—neonates with stage 4S disease (primary lesion, cutaneous, hepatic, and/or bone marrow metastases) and infants under 6 months of age with stage 1 small adrenal tumors (<16 mL). In these cases careful observation may be employed with intervention for disease progression. Adjuvant chemotherapy and radiotherapy are employed postoperatively, depending on

FIGURE 17.9 Splenic laceration that resulted from trauma in a 15-year-old boy.

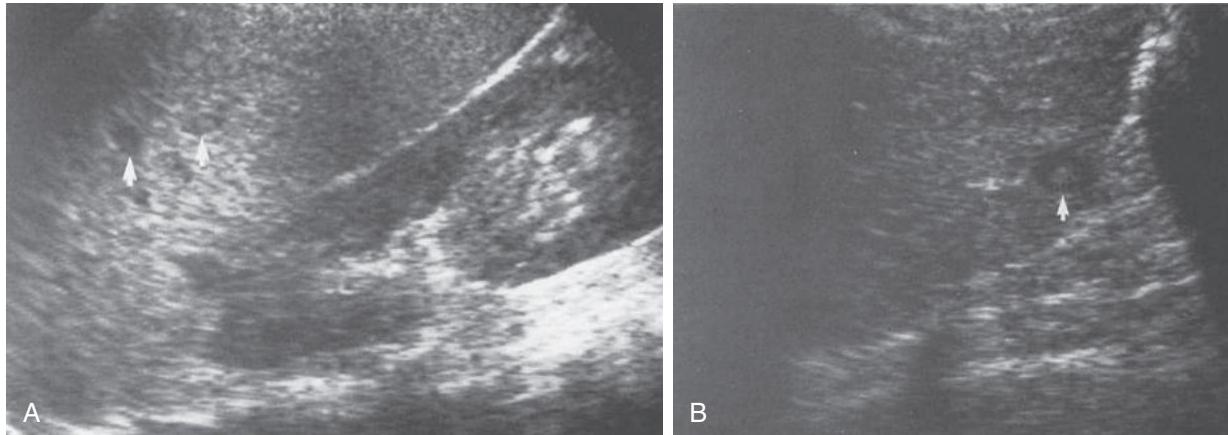
FIGURE 17.11 Computed tomogram of a left adrenal neuroblastoma reveals metastatic disease in the right kidney and liver. The patient, in whom the disease was diagnosed before 1 year of age, died of the disease.


FIGURE 17.10 A 10-year-old girl had been treated for acute myelogenous leukemia. She had taken multiple antibiotics for recurrent infections. Unremitting fevers then developed. Candidiasis was strongly suspected, and ultrasonography was requested. Two weeks after the clinical suspicion of candidiasis was raised, obvious focal defects *(arrows)* could be seen within the spleen *(A)* and liver *(B)*.

the stage of the disease. For initially unresectable tumors, a diagnostic open biopsy or a needle biopsy is performed, preferably retroperitoneally. Bone marrow aspiration findings, necessary for staging, may demonstrate classic small, round blue cells forming rosettes. For large encasing tumors surrounding major vasculature, neoadjuvant chemotherapy may be employed following biopsy and prior to resection. This strategy has been shown to improve resectability, the goal being to achieve greater than 90% tumor volume reduction at resection. In high-risk neuroblastoma, at least 4 cycles of high-dose chemotherapy precede resection, followed by postoperative radiation therapy, autologous stem cell rescue, and continued chemotherapy. The use of differentiating agents, such as retinoic acid, is indicated in high-risk disease. Interleukin 2 (IL-2), granulocyte macrophage colony-stimulating factor (GM-CSF), and anti-GD2 therapy are being used in high-risk protocols as well. Staging is based on the regional extension of the tumor, the level of metastatic disease, and the degree of resection. The outcome of the patient is determined primarily by the child's age, tumor stage, histologic classification, MYCN amplification, and 11q deletions. Hyperploid DNA is associated with a lower stage and better prognosis (contrary to most other tumors). Five year survival for infants is 90% and for older children is 62-68%.

RENAL MASSES

The most common causes of a renal mass in neonates and infants are congenital **hydronephrosis** and congenital **multicystic-dysplastic kidney** (often unilateral). In older infants and toddlers, Wilms tumor (nephroblastoma) emerges as the leading cause. Ultrasonography immediately reveals whether the mass is solid or cystic, thus directing further investigation. An ectopic or horseshoe midline kidney may also be palpable.

Congenital Hydronephrosis

Hydronephrosis secondary to ureteropelvic obstruction due to aberrant renal artery or adhesion may result in a flank mass discovered in the neonatal period or in later childhood. It is more common in boys and on the left side. The most common presenting symptom in infants is an abdominal mass or urinary tract infection. In older children, distention of the renal pelvis may cause intermittent pain, and hematuria may occur following minor abdominal trauma.

The diagnosis is confirmed with ultrasonography. A voiding cystourethrogram excludes ureterovesical reflux and posterior urethral valves (in boys). Diuretic renal scintigraphy is useful to demonstrate degree of obstruction and relative renal function. Treatment consists of pyeloplasty with resection of the obstruction and, if necessary, parts of the distended renal pelvis.

Prenatally diagnosed hydronephrosis can be detected in up to 5% of pregnancies and rarely requires fetal intervention (Fig. 17.12). Postnatally, infants with unilateral neonatal hydronephrosis will spontaneously resolve in over 90% of cases, with higher rates of intervention required in infants with bilateral hydronephrosis, ureteric dilatation >12 mm, and bladder thickening.

Cystic Abnormalities of the Kidney

A unilateral multicystic-dysplastic kidney usually manifests as a flank mass in the newborn. Ultrasonography, MRI, or CT demonstrates a cystic kidney with absence of renal parenchyma and decreased function and readily allow for evaluation of the contralateral kidney. Treatment usually consists of surgical excision, as a dysplastic kidney increases the child's risk for hypertension, urinary tract infection, malignant transformation, and pain. Alternatively, select patients without recurrent infection, hypertension, or severe proteinuria and with small lesions may be managed nonoperatively and followed long-term.

In the more serious case of **autosomal recessive infantile polycystic disease**, both kidneys are affected. The kidneys are filled with thousands of small cysts derived from the collecting tubules. The clinical manifestation varies, depending on the degree of renal failure. Unfortunately, almost 50% of patients experience severe renal insufficiency before the age of 15 years. The neonatal form is fatal without renal transplantation. Abdominal ultrasonography discloses the cystic nature of the condition, and diuretic renal scintigraphy shows

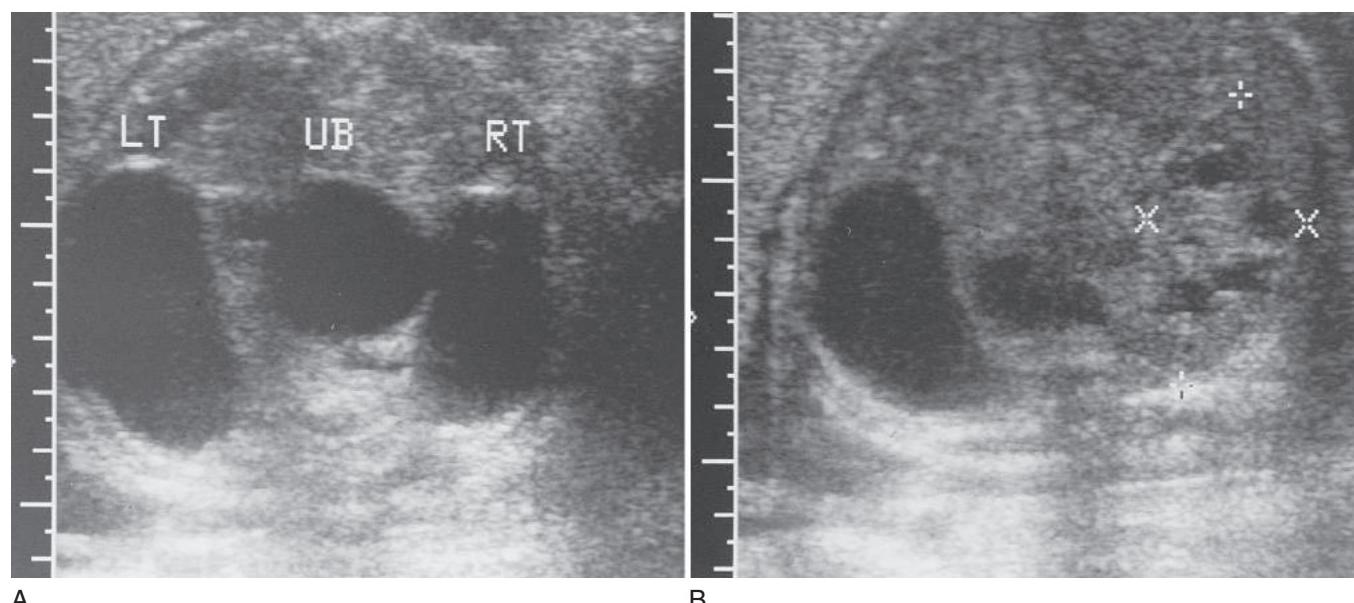
A   B


FIGURE 17.12 Fetal ultrasonography showing bilateral hydronephrosis. *A,* The urinary bladder (UB) is seen between the two dilated renal pelvises (LT and RT). *B,* The renal cortex is seen on the right side of the same fetus, between the two Xs.

symmetrically diminished function. Following peritoneal dialysis, renal transplantation is the definitive management.

Wilms Tumor (Nephroblastoma)

Wilms tumor (WT) is an embryonal renal neoplasm, one of the most common childhood abdominal malignancies. The estimated incidence is close to 1 in 15,000 live births, with a male-to-female ratio of 0.9:1. The mean age at diagnosis is 3.5 years, and at least 90% of the patients present before the age of 8 years. Between 4% and 10% of children have bilateral disease with a mean age of 2.5 years. Associated conditions include aniridia, hemihypertrophy, genitourinary anomalies, and Beckwith-Wiedemann syndrome. Wilms tumor arises in precursor lesions called nephrogenic rests, which may be intra- or extralobar and usually spontaneously regress. The tumor suppressor gene *WT1* (11p13) and the transcription factor *WT2* (11p15) are associated with Wilms pathogenesis. Germline mutations in these genes induce Wilms-associated syndromes (Denys-Drash, Wilms tumor–aniridia–genitourinary malformation–mental retardation). Microscopic hematuria is present in about 30% of patients. In rare cases, obstruction of the left renal vein may induce a left-sided varicocele via the gonadal vein. Other less common symptoms or signs include anemia, polycythemia, weight loss, hypertension, or frank hematuria.

In this age group, the most useful imaging modality is a CT scan of the abdomen with arterial and venous phase contrast due to the speed of the study and high resolution afforded for surgical planning (Fig. 17.13). The location, size, resectability of the tumor, presence of local tumor invasion, and infiltration of the renal vein and inferior vena cava are assessed. Metastatic or bilateral disease must be ruled out. Differentiation of Wilms tumor from neuroblastoma on axial imaging is based on whether the renal pelvis is splayed by an intrinsic renal mass or simply displaced by a suprarenal mass. In Wilms tumor, lung metastases from the renal vein and inferior vena cava infiltration may be present, whereas bone metastases are rare; these features distinguish it from neuroblastoma. In some cases, however, the overwhelming size of the tumor may obfuscate radiologic differentiation between Wilms tumor and neuroblastoma. A chest CT scan should be completed.

Treatment includes a transabdominal nephrectomy with early ligation of the renal vein to avoid tumor mobilization. Chemotherapy and radiotherapy are added postoperatively, depending on the stage and histologic features of the tumor. For very large or complex tumors, especially those with extension of the tumor into the renal vein, inferior vena cava, and right atrium, preoperative chemotherapy has been

FIGURE 17.13 An exophytic Wilms tumor noted incidentally on a computed tomogram obtained for trauma.

employed in selected patients following tumor biopsy. In cases of bilateral disease, partial resection with nephron-sparing surgery is employed. For children with excessive loss of functional renal parenchyma, transplantation is an option.

Tumor staging is based on radiographic evaluation (metastatic disease) and intraoperative findings (tumor size, extrarenal extension of the tumor, tumor spillage, status of local lymph nodes). The stage determines the prognosis and treatment of the disease. Survival depends on the prognostic factors, cytogenetics, the histologic features of the tumor, and the age of the patient. Younger patients have a better prognosis. Most children have either stage I or stage II disease (regional extension of the tumor but complete surgical removal), and most cases of Wilms tumor have favorable histologic features. Overall, the 5-year survival rate for favorable histology tumors exceeds 90%, with steadily decreasing chemotherapeutic toxicity and radiation exposure. The late complications of therapy for Wilms tumor include the development of acute myelogenous leukemia, short stature, and congestive heart failure.

LIVER TUMORS

Hepatomegaly or a hepatic mass may be caused by infection (hepatitis, abscess, cyst), storage disease, extramedullary hematopoiesis, as well as by benign or malignant lesions. Primary liver tumors are uncommon in children, but when they occur, 66% are malignant. Hepatoblastomas predominate, followed by hepatocellular carcinoma, mesenchymoma, and rarely sarcoma.

Hepatic abscesses are caused by pathogens such as *Staphylococcus aureus*, anaerobic bacteria, or *Escherichia coli*. Chronic granulomatous disease, appendicitis, or immunocompromised state may predispose a child to this complication. Amebic infection of the liver caused by *Entamoeba histolytica* and parasite infestation with *Echinococcus* species may also lead to abscess formation in tropical climates. Abscesses are treated with appropriate antibiotics and percutaneous drainage, only rarely requiring surgical intervention.

Benign tumors can be of either mesenchymal or epithelial origin. Mesenchymal tumors include disorders such as hamartomas, cavernous hemangiomas, and infantile hemangioendotheliomas in young children. These conditions manifest as asymptomatic abdominal masses. Hemangiomas, particularly diffuse ones, may be difficult to resect and should be managed nonoperatively unless complications develop. Hamartomas, which usually manifest in the 1st year of life, should be resected. Epithelial lesions include focal nodular hyperplasia, hepatic adenoma, and nonparasitic solitary or multiple cysts.

The initial radiographic evaluation for liver masses should include plain abdominal radiography to detect calcifications and the mass effect, and ultrasonography to determine the origin, size, and echogenicity of the tumor. In addition, an abdominal CT or MRI scan can be obtained to define the exact localization and extent of the tumor (Fig. 17.14). MRI is more capable of discerning hamartomatous versus malignant lesions than CT scan, especially using EOVIST, a gadolinium agent preferentially taken up by hepatocytes. Angiography is often useful for determining resectability. Chest radiography or CT is used to determine the presence of pulmonary metastases.

Hepatoblastoma

Hepatoblastoma is the most common primary liver tumor in children under 3 years of age affecting 1.5 million/year, and it is twice as common in boys as in girls. Premature birth and very low birthweight are associated with increased risk. The most common presentation is a child with a palpable abdominal mass, occasionally associated with anemia, nausea, vomiting, weight loss, or abdominal pain. An unusual

(See *Nelson Textbook of Pediatrics,* p. 2479.)

FIGURE 17.14 Magnetic resonance image showing a liver hamartoma in a 13-month-old boy. Note the excellent visualization of the blood vessels. The child presented with abdominal distention, poor appetite, and decreased activity. The liver was nontender and was palpated 15 cm below the costal margin. Operative resection was successful.

FIGURE 17.15 Computed tomogram of a hepatoblastoma in an 8-month-old girl. The child presented with hepatomegaly, increased abdominal girth, weight loss, and lethargy. The voluminous tumor occupies a large part of the upper abdominal cavity.

manifestation is precocious puberty resulting from tumor secretion of human chorionic gonadotropin. Elevated levels of serum α-fetoprotein are seen in about 90% of cases, and this feature is helpful in the post-therapy monitoring of disease activity. Ultrasonography, MRI, or CT (Fig. 17.15) may be used to image the lesion and assign a PRETEXT (PRETreatment EXTent of Disease) stage. Designed by the International Childhood Liver Tumor Strategy Group (SIOPEL), PRETEXT classifies tumors into 4 risk groups based upon the number of contiguous uninvolved liver segments as well as metastatic, portal venous, or systemic venous invasion (Fig. 17.16). The goal is to accurately predict resectable lesions and plan for transplantation when appropriate without the complications associated with attempted resection in all cases, as surgical resection of hepatoblastoma is the mainstay of therapy. Biopsy and neoadjuvant chemotherapy are undertaken in unresectable lesions, and axial imaging is repeated. Hepatic transplantation may be undertaken when lesions remain unresectable in the absence of metastatic disease. Incompletely resected lesions have a poor prognosis. Pretreatment variables associated with survival are the extent of the tumor, histologic classification, and the presence of metastases.

Hepatocellular Carcinoma

Hepatocellular carcinoma, more common in adults, usually occurs in an already diseased liver, such as that found after hepatitis B or C virus infection, tyrosinemia, galactosemia, biliary atresia, or cirrhosis. It is rare in younger children and has a peak incidence between the ages of 10 and 15 years. The tumor manifests as a painful abdominal mass; in

more than 65% of patients, it is unresectable. In these cases and in the absence of metastatic disease, liver transplantation should be considered. The diagnostic evaluation, staging, and treatment of hepatocellular carcinoma are similar to those of hepatoblastoma.

CONGENITAL DILATATION OF THE BILE DUCTS

Any congenital cystic dilatation of the bile ducts is commonly called choledochal cyst. There are several anatomic varieties of this condition, and the cause remains unknown. The most common choledochal cyst is seen when the common bile duct is grossly dilated (Todani type I, Fig. 17.17). However, the size varies, and the child may remain asymptomatic for many years. About 20% of patients present with the classic triad of jaundice, pain, and a right upper quadrant abdominal mass. Obstructive jaundice may result from coincident gallstones, manifesting in pruritus, dark urine, and acholic stools.

Ultrasonography reveals the location, size, and nature of the cyst. If there is any doubt about its origin, magnetic resonance cholangio-pancreatography (MRCP) or liver-phase CT scan (Fig. 17.18) may be used to outline the biliary tract and help differentiate it from other lesions such as duodenal duplication. Treatment consists of resection of the cyst and drainage of the hepatic duct into an intestinal segment (Fig. 17.19). Incomplete resection of at least the mucosa of the affected portion of the biliary tree predisposes the patient to the development of cholangiocarcinoma, which is a 20-30% lifetime risk in this population.

INTESTINAL AND PANCREATIC MASSES

Appendiceal Phlegmon and Abscess

Either delayed manifestation (walled off by mesentery) or delayed diagnosis of acute appendicitis may enable the development of a right lower quadrant mass after perforation as the inflamed tissues amalgamate into a phlegmon. Further maturation of this process may lead to an abscess. Diagnosis is often facilitated by the history, which can differentiate from many other causes of abdominal mass by the recent (days to weeks) history of fever associated with abdominal pain and nausea. Antibiotic therapy may mask the diagnosis of appendicitis. CT

scan is warranted in this circumstance because of the desirability of treating an abscess by percutaneous aspiration and antibiotics (Fig. 17.20). Interval appendectomy in an uninflamed field may be performed safely 6-8 weeks later. This approach is not appropriate for either suspected uncomplicated acute appendicitis or for diffuse peritonitis.

Bezoar

Children with mental illness or developmental delay occasionally eat their own hair (trichotillomania) or other indigestible material (e.g., persimmon peel). Ninety percent of these patients are girls, usually in

FIGURE 17.20 A large appendiceal abscess with a calcified fecalith. The abscess was drained percutaneously and treated with antibiotics. Interval appendectomy was performed 8 weeks later.

their teens. A **trichobezoar** (hair) or a **phytobezoar** (vegetable matter) forms in the stomach and causes partial gastric outlet obstruction. Gastric bezoars may massively distend the stomach and extend into the small intestine. If hair manages to pass the stomach, it collects in the duodenum and causes biliary tract obstruction; if it collects in the ileum, it may lead to intestinal obstruction.

The clinical picture is characterized by poor appetite, vague abdominal discomfort, and intolerance to solid foods. Physical examination reveals loss of hair on the scalp and a movable mass in the epigastrium. Abdominal radiographs will show gastric outlet or intestinal obstruction. Axial imaging subsequently demonstrates the size and location. The bezoar may be removed endoscopically, but operative removal is often required. Bacterial counts within a bezoar are high, and operative removal is associated with a high rate of postoperative infection.

Duplications

Duplications of the gastrointestinal tract occur anywhere from the esophagus to the anus and are either cystic or tubular. The more common cystic duplications are lined with endothelium and are enclosed in a muscular wall common with the adjacent intestinal segment. Tubular duplications are located on the mesenteric side of the bowel and are either blind or in communication with the bowel. The lining is usually that of the adjacent intestine but may be heterotopic, such as gastric mucosa in a duplication of the small bowel.

Duplications are often detected prenatally. When discovered, they should be resected after birth as volvulus has been seen as early as 2 postnatal weeks. In older children, the manifestations depend on the size and location of the malformation. Many intra-abdominal duplications manifest as an asymptomatic, palpable mass but may also cause pain, intestinal obstruction, hemorrhage, or volvulus. Ultrasonography differentiates the cystic nature of duplications from solid tumors and also demonstrates the intimate association between the duplication and the bowel wall. Treatment consists of resection of the duplication alone or, more commonly, along with the part of the gut from which the duplication arose, depending on the anatomic location and amount of shared wall and blood supply (Fig. 17.21).

Neoplasms of the Gastrointestinal Tract

Neoplasms of the gastrointestinal tract of children are rare. The symptoms are often nonspecific, and diagnosis tends to be delayed.

FIGURE 17.21 Operative photograph of the typical appearance of an intestinal duplication.

FIGURE 17.22 Computed tomographic scan of the abdomen in an 11-year-old boy, showing a mesenteric cyst in the transverse mesocolon.

A gastric teratoma may appear as an epigastric mass, while gastric leiomyosarcomas or leiomyomas manifest with bleeding. Non-Hodgkin lymphoma is the most common malignant tumor of the small intestine and may act as a lead point for **intussusception**. Other malignant tumors of the small intestine include leiomyosarcoma, angiosarcoma, and carcinoid tumor. These conditions also occur in the large intestine. Carcinoid tumors are most commonly found in the appendix, where they can cause obstruction and lead to appendicitis. The colon is the most common site for the rare adenocarcinoma of the gastrointestinal tract in children. Colon adenocarcinoma in children is usually nonsyndromic, mucinous in nature (80%), and often at an advanced stage upon discovery. Benign neoplasms of the small and large intestine include hemangiomas, lymphangiomas, leiomyomas, and polyps. Malignant neoplasms and most benign neoplasms should be resected.

Mesenteric, Omental, and Retroperitoneal Cysts

Benign cysts located in the omentum or mesentery can be simple or multilocular, and contain clear serous fluid. They arise from a developmental abnormality of the lymphatic system that results in lymphatic obstruction. Most of these cysts are diagnosed during the 1st 5 years of life. They may be asymptomatic for years or manifest with a distended abdomen, abdominal mass, intestinal obstruction, volvulus, or abdominal pain. The abdomen is usually nontender with a mobile mass. In contrast to ascites, the flanks do not bulge when a child with an abdominal cyst is in the supine position.

A plain abdominal radiograph shows intestinal gas displaced forward in the case of a mesenteric cyst and backward in the case of an omental cyst. Small amounts of calcification may be seen in the wall of the cyst. Ultrasonography, MRI, or CT further elucidates the nature, size, and location of the cyst (Fig. 17.22). An ovarian, pancreatic, or choledochal cyst or an intestinal duplication may be difficult to differentiate from a mesenteric or omental cyst. Cerebrospinal fluid from a **ventriculoperitoneal shunt** or lumbar drain fails to be resorbed because of scarring of the peritoneum, leading to a "CSFoma" (Fig. 17.23), which also may be mistaken for a mesenteric or omental cyst. Treatment of these lesions consists of surgical marsupialization or extirpation, occasionally requiring segmental small bowel resection. Retroperitoneal lymphatic malformations are amenable to percutaneous sclerotherapy with good results.

FIGURE 17.23 A large fluid collection associated with a ventriculoperitoneal shunt ("CSFoma").

Pancreatic Pseudocyst and Neoplasms

Pancreatic tumors are rare in children and are cystic or solid, benign or malignant. Young children and infants may have pancreaticoblastoma. Functional neoplasms arise from the islet cells, and the clinical manifestation is not of an abdominal mass but rather is characterized by the effects of the endocrine substances secreted by the tumor (e.g., hypoglycemia caused by insulinoma). Tumors arising from the acinar or ductal parts of the pancreas are nonfunctional and usually manifest as an abdominal mass. They may be benign (cystadenoma) or malignant (adenocarcinoma). Embryonic pluripotent cells may give rise to solid pseudopapillary tumors, accounting for less than 5% of all pediatric pancreatic masses. Metastases are common in pancreatic neoplasms given the frequent delay in diagnosis. Diagnosis is aided by ultrasonography, endoscopy, CT or MRI and, in cases of suspected endocrine tumors, by measurements of active hormones. Both benign and malignant tumors should be surgically resected. A 35 year review

FIGURE 17.24 Torsion of an ovarian teratoma in a 5-year-old girl. The child presented with acute abdominal pain and a movable mass. A preoperative radiograph showed calcified material in the mass.

TABLE 17.7 **Red Flags**
1. Lower Abdominal Mass in Girls
May be an indication of pregnancy, imperforate hymen, torsion of ovarian tumor, tuboovarian abscess
2. Appendiceal Abscess
Can often appear as a small bowel obstruction in younger children, in whom the diagnosis is often missed
3. Nonmobile Mass
Is suggestive of malignancy
4. Skeletal Pain or Pathologic Fracture
Is suggestive of metastatic disease (neuroblastoma) or lymphoma
5. Sudden Increase in Size of Clothing
May represent a mass or ascites
6. Left-Sided Varicocele
May be a consequence of a left-sided Wilms tumor
7. Systemic Signs of Weight Loss, Fever, Night Sweats, Anorexia, Petechiae, Anemia
Should trigger concern for malignancy, inflammatory bowel disease, or atypical infections

of malignant non-MEN pancreatic tumors in children at one center revealed only 17 cases. Eighty percent of patients were alive at follow-up, significantly better than adult counterpart data.

A pancreatic pseudocyst lacks epithelial lining and is the result of pancreatitis or pancreatic blunt trauma. Often, there is a symptom-free interval of several weeks or months between the trauma and the appearance of symptoms. The cause of pancreatic pseudocyst in the absence of trauma should prompt investigation of causes of recurrent pancreatitis including pancreas divisum and mutations in *PRSS1* and *SPINK1* genes, allowing inappropriate release of pancreatic trypsin. Typical signs and symptoms are nausea, abdominal pain, and an epigastric mass. Ultrasonography and axial imaging locate the cyst and identify any displacement of the bowel. The cysts usually resolve spontaneously; however, if they do not, they should be drained percutaneously or into the gastrointestinal tract.

OVARIAN TUMORS

Ovarian tumors in children are uncommon, with an incidence of about 25 in 100,000 children's hospital admissions. They must be considered in any girl with lower abdominal pain, an abdominal mass, or precocious puberty. They manifest at any age from birth to adulthood but occur slightly more frequently in children at an average of 13 years of age. The risk of malignancy increases with age. Cystic tumors are more common than solid tumors, and the majority of masses are benign. An ovarian lesion may also be the presenting manifestation of other metastatic diseases, such as neuroblastoma or

rhabdomyosarcoma. Malignant gonadal tumors (dysgerminoma, gonadoblastoma) may be seen in girls with gonadal dysgenesis and boys with cryptorchidism. Other causes of lower abdominal mass in a girl include pregnancy and imperforate hymen, which leads to hydrocolpos or hydrometrocolpos.

Diagnosis is made by ultrasonography, which provides information on the size, consistency, location, perfusion, and wall characteristics of the tumor. Abdominal radiography may reveal calcifications. CT can locate local or distant metastases. Endocrinopathies are present in 5-10% of children with ovarian tumors, so consideration of the anterior pituitary–adrenal–gonadal axis is warranted. Levels of tumor markers, such as α-fetoprotein, β-human chorionic gonadotropin (β-hCG), CA-125, and inhibin A should be considered, especially in older children with masses >8 cm, inappropriate virilization, or other concerns for operative findings consistent with epithelial cancer.

A simple cyst may appear in a neonate as a mobile abdominal mass or may even be detected incidentally by ultrasonography. Small cysts (generally <6 cm) can be monitored with ultrasonography and should spontaneously disappear. Larger cysts should be excised, because they can undergo torsion. The symptoms of ovarian torsion in an older child simulate those of appendicitis or ectopic pregnancy (Fig. 17.24).

All other tumors of the ovaries should be excised, whether benign (cystic teratoma, cystic adenoma, granulosa cell tumor) or malignant (endodermal sinus tumor, yolk sac tumor, embryonal carcinoma, malignant teratoma, adenocarcinoma, dysgerminoma, choriocarcinoma). Great care should be taken to spare as much of the adnexa as possible to preserve future fertility. Depending on the histologic appearance and stage, most malignant lesions should be treated postoperatively with chemotherapy. Survival depends on the nature of the lesion; however, with the exception of highly malignant tumors such as endodermal sinus tumors and embryonal carcinoma, the prognosis is good.

SUMMARY AND RED FLAGS

Although the discovery of an abdominal mass in a child is of great concern, the prognoses of most congenital masses are excellent. Splenomegaly is often a manifestation of acute and benign common viral infections in children. Red flags for splenomegaly include chronicity, a positive family or travel history, pancytopenia, and signs of disease in addition to splenomegaly (weight loss, pallor, jaundice, fever, malaise, petechiae). Additional red flags for abdominal masses are listed in Table 17.7. With modern diagnostic techniques and advanced multimodal therapy, the prognoses for malignant tumors continue to improve.

Dysuria

Paula Cody

Dysuria is defined as painful urination and can be related to uncomfortable contraction of the muscles of the bladder or when urine comes into contact with the inflamed genitourinary mucosa. The differential diagnoses for a patient presenting with dysuria are extensive (Table 18.1) and can be due to infectious or noninfectious causes. The cause of dysuria varies based on age of the child or adolescent; therefore, specific elements of the patient history, potential causes, and diagnostic evaluation will vary with age. With every patient, the provider must elicit a history of signs and symptoms outside the genitourinary tract, including fever, weight loss, generalized rash, involvement of other mucosa, and joint pain or swelling. Physical examination for every patient should include temperature, blood pressure, inspection of the genitalia for skin lesions or discharge, abdominal palpation, pelvic examination when indicated, and neurologic examination in children with voiding dysfunction to exclude spinal cord pathology.

NEONATES

Neonates and infants cannot complain of dysuria; however urinary tract infections (UTIs) are prevalent in this age group and a major source of morbidity. In this age group, it is difficult to distinguish between upper UTI (pyelonephritis) and lower UTI (cystitis) based on signs and symptoms alone. Unlike UTIs in older children, neonatal UTIs are more common in male neonates compared to females. In neonates, UTIs are associated with bacteremia and/or congenital abnormalities of the kidney and urinary tract. In term infants, infections tend to be community acquired and present in the 2nd to 3rd week after birth. UTIs can be caused by either hematogenous spread or an ascending infection. In preterm infants, infections are more likely to be hospital acquired.

The symptoms suggestive of a UTI in the neonate are the same as those for **suspected sepsis**; therefore, major presenting symptoms include fever, poor feeding, weight loss, lethargy, and vomiting (see Chapter 39). Neonates may also present with jaundice or abdominal distention. A maternal urinary infection at or near term may increase the risk for neonatal pyelonephritis. A mother whose vaginal culture is positive for group B streptococci or who presents with fever, prolonged rupture of the amniotic membranes (>18 hours), uterine tenderness, or preterm labor is at an increased risk for delivering a premature baby with pyelonephritis as part of the neonatal sepsis syndrome. Family history is also important. There is a high genetic component to the presence of **vesicoureteral reflux (VUR)**; the siblings of children with known VUR also have a significant risk of reflux,

with or without infection. Children with a UTI and VUR are at increased risk of pyelonephritis and renal scarring. However, the screening for VUR in an asymptomatic sibling of an index case of VUR is controversial; a voiding cystourethrogram (VCUG) is recommended if there is evidence of renal scarring on ultrasound or if there is a history of UTI in the sibling who has not been tested. Given that the value of identifying and treating VUR is unproven in the absence of a UTI, an observational approach without screening for VUR may be taken for siblings of children with VUR, with the prompt treatment of any acute UTI and subsequent evaluation for VUR.

Physical examination of a neonate suspected of having a UTI should include the palpation of the abdomen to identify obstructive lesions or cystic kidneys. Urine culture should be obtained by suprapubic or bladder catheterization, as sterile bag collection has a high rate of contamination with perineal flora. Because of the associated risk of bacteremia, blood cultures and cerebrospinal fluid (CSF) cultures should be obtained in all neonates in whom UTI is suspected. Initial empirical therapy should be initiated after collection of urine, blood, and CSF cultures. The empirical therapy should provide broad coverage against probable uropathogens, and is initially administered parenterally, as the risk of urosepsis is higher in neonates than in other age groups. Common empirical therapy includes ampicillin in addition to either gentamicin or a 3rd-generation cephalosporin. Therapy is then tailored according to the specific uropathogen identified on culture and the antimicrobial sensitivity.

Ultrasound is the first-line imaging method in neonates after the first UTI. The main purpose of diagnostic imaging is the detection of risk factors, such as anomalies of the kidney and urinary tract or vesicoureteral reflux, as well as any renal damage acquired from the infection. Clinical practice guidelines from the American Academy of Pediatrics do not recommend DMSA (dimercaptosuccinic acid) scans as part of routine evaluation of infants with their first febrile UTI because the findings rarely affect acute clinical management.

CHILDREN 2-24 MONTHS OF AGE

Like neonates, children 2-24 months of age cannot report dysuria. Nonetheless, urinary tract infections (UTIs) are common (see Chapter 39). The main risk factor for febrile infant males is whether or not they are circumcised; other individual risk factors for UTI in males include nonblack race, temperature >39°C, fever for at least 24 hours, and absence of another source of infection. Individual risk factors for UTI in infant females include white race, age less than 12 months,

TABLE 18.1 Causes of Dysuria

Infectious causes	Urinary tract infection (cystitis, pyelonephritis) Urethritis Herpes simplex virus infections Varicella infections Epstein-Barr virus infections Hemorrhagic cystitis (adenovirus) Prostatitis Vaginitis* Renal tuberculosis Urinary schistosomiasis Sexually transmitted infections
Urinary tract abnormalities (congenital and acquired)	Urinary calculi Urethral stricture Meatal stenosis Prostate enlargement Malignancy Urethral diverticulum Bladder diverticulum Idiopathic hypercalciuria Bladder outlet obstruction Urethral prolapse
Genital tract abnormalities	Sexually transmitted infections Vaginitis Prostatitis Endometritis Endometriosis Labial adhesions Phimosis Paraphimosis Balanitis Foreign body
Medications and irritants	Primary irritant dermatitis Chemical irritants (soaps, detergents, bubble baths, feminine hygiene products, spermicides) NSAIDs Anticholinergics (amitriptyline, imipramine, and antihistamines) Anti-infectives (isoniazid, sulfonamides) Chemotherapy-related hemorrhagic cystitis (cyclophosphamide)
Other	Trauma Stevens-Johnson syndrome/toxic epidermal necrolysis Behçet syndrome Inflammatory bowel disease Toxic shock syndrome Reactive arthritis (in conjunction with urethritis, conjunctivitis) Neurologic conditions that impact bladder emptying Pinworms Lichen sclerosus Appendicitis (if inflamed appendix or periappendiceal abscess lies low in iliac fossa) Tumor (bladder, kidney, uterus, vagina) Foreign body (urethral, vaginal) Perianal group A streptococcus

*Vaginitis; chemical, nonspecific bacterial, *Candida albicans*, *Trichomonas vaginalis*, herpes simplex, gonorrhea, group A streptococcus, gram-negative organisms.
NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 18.2 Sensitivity and Specificity of Components of Urinalysis, Alone and in Combination

Test	Sensitivity (Range) (%)	Specificity (Range) (%)
LE test	83 (67-94)	78 (64-92)
Nitrite test	53 (15-82)	98 (90-100)
LE or nitrite positive	93 (90-100)	72 (58-91)
Microscopy (WBCs)	73 (32-100)	81 (45-98)
Microscopy (bacteria)	81 (16-99)	83 (11-100)
LE, nitrite, or microscopy positive	99.8 (99-100)	70 (60-92)

LE, leukocyte esterase; WBC, white blood cell.
Modified from Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management: Clinical practice guideline. Urinary tract infection: clinical practice guideline for the diagnosis and management of the initial UTI in febrile infants and children 2 to 24 months. *Pediatrics.* 2011;128:595-610.

temperature of at least 39°C, fever for at least 2 days, and absence of another source of infection.

The method of collecting urine for testing is dependent on the risk factors of the child. Culture of a urine specimen from a sterile bag attached to the perineal area has a high false-positive rate; this method of urine collection is not suitable for diagnosing UTI. However, a culture of a urine specimen from a sterile bag that shows no growth is strong evidence that UTI is absent; if growth of a single uropathogen is present, it may represent a UTI. Nonetheless, a clinical practice guideline from the American Academy of Pediatrics outlines several recommendations in testing and treatment of UTIs in febrile infants:

- If a febrile infant with no apparent source for fever requires antibacterial therapy, a urine specimen should be obtained via suprapubic aspiration or catheterization for both culture and urinalysis (UA) prior to the initiation of antibacterials.
- If the clinician determines that the patient is at low risk for having a UTI, clinical monitoring without urine testing is acceptable.
- If the febrile infant is not in the low-risk category:
  - Clinician should obtain urine sample for UA and culture through catheterization or suprapubic aspiration.
  - Or clinician can obtain clean-void bagged urine sample. If UA results suggest UTI (Table 18.2), then an additional urine specimen for culture should be obtained via catheterization or suprapubic aspiration.

Diagnosing a UTI in young children requires both a positive UA (for white cells and/or bacteria) and >50,000 CFU/mL of a single urinary pathogen on urine culture from a suprapubic or catheterized urine specimen. The usual choices for empirical antibacterial therapy include a 3rd-generation cephalosporin, amoxicillin plus clavulanic acid, or trimethoprim-sulfamethoxazole. The clinician should base choice of antibacterial on local antimicrobial sensitivity patterns if available and should adjust according to sensitivity results of the isolated uropathogen. Most infants can be treated orally.

The rationale for imaging infants with UTI is to identify abnormalities of the genitourinary tract. Renal ultrasound is the first-line imaging modality to identify anatomic abnormalities. Voiding cystourethrogram (VCUG) to detect vesicoureteral reflux (VUR) should not be performed after the first febrile UTI. It is indicated if the ultrasound reveals hydronephrosis, renal scarring, or other findings that suggest high-grade VUR or obstructive uropathy.

PRESCHOOL CHILDREN

A young child may or may not be able to verbalize dysuria; however, they may show signs of urethral irritation including delayed toilet training (especially during the day), secondary enuresis, dribbling, and frequent squatting. Due to the large variability in the time of achievement of daytime dryness (15 months-4 years), delayed toilet training may be an unreliable sign of dysuria; however, **primary diurnal enuresis** should be evaluated if the child is older than 48 months of age. Nocturnal enuresis is rarely a sign of UTI, but urine cultures should probably be obtained in children who do not stay dry at night by 5 years of age. A more significant symptom in young children is the *acute onset* of daytime enuresis after a period of continence.

UTIs are the most common cause of dysuria in preschool children. It may be difficult to distinguish between pyelonephritis and cystitis in these young children. Both urine and stool withholding have a role in causing UTIs in young children. Constipation is associated with large residual urine volumes after voiding, thus the treatment of constipation leads to a reduction in UTIs. Females are at increased risk of UTI due to the ease at which pathogens can migrate from the gastrointestinal tract to the periurethral area and urethra, and ultimately ascend to the bladder. Improper toileting habits can further increase the risk of UTI. Uncircumcised males, patients with neurogenic bladders (spina bifida), patients with indwelling catheters, and patients with renal or bladder anomalies (e.g., cysts, obstructed hydronephrosis, double collecting systems, ectopic ureter, horseshoe kidney, posterior urethral valves, VUR) are at increased risk for UTI.

Children who are toilet-trained can give a clean-void urine sample. Those that are not toilet-trained can give a urine specimen from a sterile bag attached to the perineal area, although this has a high false-positive rate.

Preschool children may also have irritant urethritis.

SCHOOL-AGED/PREPUBERTAL CHILDREN

Dysuria in school-aged children can be due to infectious and noninfectious causes (Table 18.1). Most children with a UTI present with dysuria, frequency, or fever. It is worthwhile to ask about any urine color change, which suggests the presence of hematuria. The child should be questioned about the frequency, character, and size of his or her bowel movements. **Constipation** may predispose the school-aged child to a UTI; stool softeners, such as mineral oil or fiber, may be indicated. Pyelonephritis can be clinically distinguished from cystitis by presence of systemic features (fever, vomiting) and signs (flank pain, costovertebral angle tenderness).

A careful inspection of the genitalia is important in the diagnosis of the cause of dysuria. Boys may have nonspecific bacterial infection of the glans penis (**balanitis**); uncircumcised boys can have infection of both the glans and the prepuce (**balanoposthitis**). Both of these are usually accompanied by painful swelling and inflammation. Irritants can cause a nonspecific urethritis in males, with dysuria being the main symptom.

Prepubertal females can have dysuria as the presenting symptom of **vaginitis**, along with other symptoms including vaginal discharge. In prepubertal females, the vulvar mucosa is thin and susceptible to inflammation from chemicals and mechanical irritation. Because the labia are not well developed, the vulvar mucosa is not anatomically shielded and is thus vulnerable to irritation. Vaginitis in prepubertal females can be nonspecific, due to irritants (soaps, detergents) or may be due to the presence of a foreign body (Table 18.3). Whereas vulvovaginal candidiasis is common in postpubertal females, the vaginal environment in prepubertal females is not typically conducive to

TABLE 18.3 Causes of Noninfectious Vulvovaginitis and Dysuria

Condition	Historical Cues
Poor hygiene	Infrequent bathing, hand washing, and clothing changes, soiled underwear, toilet independence
Poor perineal aeration	Tight clothing, nylon underwear, tights, leotards; wet bathing suits, hot tubs, obesity
Frictional trauma	Tight clothing, sports, sand from sandbox or beach, obesity, excessive masturbation or sexual abuse
Chemical irritants	Bubble baths, harsh or perfumed soaps or detergents, powders, perfumed and/or dyed toilet paper, ammonia, perfumed and/or dyed sanitary products; douches and feminine hygiene products
Contact dermatitis	Topical creams or ointments
Vaginal foreign bodies	Wiping habits, excessive masturbation or self-exploration, sexual abuse
Parasites, insect bites, infestations	Home environment, pets, sandboxes, travel, camping, exposure to woods or beach
Medications	Topical steroid or hormone creams, antibiotics, chemotherapy
Generalized skin disorders	History of pruritus, chronic skin lesions, prior diagnosis
Anatomic anomalies	Vesicovaginal or rectovaginal fistula, ectopic ureter, spina bifida, cloacal anomalies, urogenital anomalies
Neoplasms	Discharge, bleeding, bulging abdomen, change in bowel or bladder function, premature puberty
Systemic illness (Stevens-Johnson syndrome, Crohn disease, toxic shock syndrome)	Tampon use, systemic evidence of inflammatory bowel disease including rash, oral ulcers, failure to gain weight or height, abdominal pain

Modified from Succato GS, Murray PJ. Pediatric and adolescent gynecology. In: Zitelli BJ, Davis HW. *Atlas of Pediatric Physical Diagnosis.* 5th ed. Philadelphia: Mosby Elsevier; 2007 p. 693-730.

Candida species growth, unless she has an immunodeficiency or recent antibacterial use. In the majority of cases, vulvovaginitis in prepubertal females is a mixed, nonspecific bacterial infection secondary to contamination by urine and feces. The responsible bacteria are usually normal flora (Table 18.4). Bloody vaginal discharge in young females may be caused by *Shigella species* or group A streptococcal infections, a foreign body (e.g., toilet paper), neoplasm (such as rhabdomyosarcoma), or trauma. Most cases of prepubertal nonspecific vaginitis can be managed with hygiene; some vulvovaginitis may require a course of antibacterial agents or topical estrogen vaginal cream (Table 18.5).

Several **vulvar skin disorders** can be confused with vulvovaginitis and present with dysuria due to contact of urine with inflamed mucosa. **Lichen sclerosus** manifests as white patches on the glabrous skin that are thinned and atrophic and are easily traumatized with resultant bullae (which may be blood-filled) in the vulvar region. **Seborrheic dermatitis** may manifest with inflammation and secondary infection of the intertriginous areas; the face and scalp may be involved as well. Labial or vulvar agglutination may be noted and can be secondary to previous vulvovaginitis of unestrogenized epithelia.

TABLE 18.4 Normal Vaginal Flora

TABLE 18.5 Treatment of Nonspecific Vulvovaginitis in Young Females

- Toilet Hygiene
  - Urinate with knees apart
  - Wipe in an anterior-to-posterior direction with supervision
  - Scent- and dye-free wipes may be useful
- Clothing
  - Choose white cotton underpants, may need to change underpants midday if urinary dribbling
  - Wear loose-fitting clothing
  - Change out of wet swimsuits immediately
- Bathing
  - Take sitz baths in clear water up to four times a day
  - Wash gently with unperfumed soap
  - Do not use bubble bath or wash hair in bath
  - Rinse perineum with clear water, dry gently with towel
- Management of Inflammation and Pruritus
  - Premarin vaginal cream topically twice daily for 10-14 days
  - Hydroxyzine, 0.5 mg/kg/dose orally 4 times daily as needed
  - Diphenhydramine, 1.25 mg/kg/dose orally 4 times daily as needed

TABLE 18.6 Approach to Clinical Evaluation of Sexually Transmitted Infections: Sexual History

Age at coitarche
Gender of partners
Date of most recent sexual encounter
Duration of relationship with current partner
Numbers of current, recent (within past 3-6 mo), and lifetime partners
Condom usage (overall consistency)
Contraceptive usage
Vaginal intercourse
Oral intercourse
Anal intercourse
Dyspareunia
Involuntary sexual encounters (abuse, rape)
Partner's sexually transmitted infection symptoms and relevant sexual history (i.e., other sex partners)

ADOLESCENTS

There are many causes for dysuria in an adolescent. A detailed sexual history is mandatory (Table 18.6). Greater than 46% of high school students have engaged in sexual intercourse, with an increase to 64% among 12th graders. Over 5% initiated sexual intercourse before 13 years of age, and 34% had a sexual encounter within the previous 3 months. Adolescents are likely to have multiple sexual partners over relatively short periods of time, fail to recognize the symptoms of sexually transmitted infections (STIs), and use condoms inconsistently. It is critical that the provider perform a thorough history in a nonjudgmental and nonthreatening manner. Interviewing the adolescent in the room alone (i.e., without a parent present) for at least a portion of the visit is the standard of care for all adolescent health care visits. The terms of a confidential visit should be explained to the adolescent and parent; all information disclosed by the adolescent remains confidential unless he or she reveals a risk of rendering harm to himself or herself or others, such as with suicidal or homicidal ideation. Questions about victimization and abuse are part of the sexual history, regardless of age or gender.

Urinary tract infections (UTIs) are much more common in adolescent females than adolescent males. Risk factors for recurrent UTIs in females include frequency of sexual intercourse (higher frequency leads to higher risk), maternal history of recurrent UTI, a new sexual partner in the past year, and spermicide use in the past year. Common pathogens in this age group include *Escherichia coli*, *Proteus* species, *Klebsiella* species, *Staphylococcus saprophyticus*, and enterococcus. Although often recommended by clinicians, no evidence supports the thought that postcoital urination leads to a reduction in the frequency of UTIs.

One of the most common causes of dysuria in adolescent males and females is **sexually transmitted infections (STIs)**. Adolescents represent an age group at high risk for acquisition and transmission of STIs. Although many STIs are asymptomatic and are diagnosed by screening asymptomatic sexually active individuals, STIs can present with dysuria, vaginal discharge, penile discharge, and genital lesions (Table 18.7). The most likely time for this to happen is within 1 month of beginning a relationship with a new sexual partner.

Chlamydial genital infection is the most frequently reported bacterial STI. Infections with *Chlamydia trachomatis* may be asymptomatic or may present with dysuria, discharge, intermenstrual bleeding, or

Urethritis caused by herpes simplex virus may occur in both males and females of this age group from autoinoculation from herpes stomatitis; however, presence of genital ulcers should always elicit questioning about sexual activity and/or assault.

Other etiologic factors that may lead to urethritis and resultant dysuria include infection (fungi, pinworms, scabies), irritation (soap, shampoo, detergent, bubble bath), systemic illness (Stevens-Johnson syndrome), and trauma (abuse, play, tight clothing, masturbation).

TABLE 18.7	Diagnostic Characteristics of Genital Lesions				
Syndrome	**Appearance**	**Number of Lesions**	**Pain**	**Adenopathy**	**Occurrence in the United States**
Herpes	Vesicles and superficial ulcers on erythematous base (1-2 mm)	Multiple	Often	Bilateral; inguinal; firm; movable; tender	Frequent
Syphilis	Papule and superficial or deep ulcer (5-15 mm)	Single	No	Bilateral; inguinal; firm; movable; nontender	Uncommon
Lymphogranuloma venereum	Ulcer (2-10 mm), resolves quickly	Single	Yes	Unilateral; inguinal; fluctuant; may suppurate; tender	Uncommon
Human papillomavirus	Anogenital exophytic warts; may resemble cauliflower or be papular with projections	Single or multiple	No	None	Frequent
Lice or nits	Tiny (≤1 mm) insects or eggs adherent to hair shaft; excoriations	Multiple	No but pruritic	None	Common
Chancroid	Deep, purulent ulcers (2-20 mm)	Multiple	Yes	Unilateral; inguinal; fluctuant; may suppurate; tender	Rare

dyspareunia. *C. trachomatis* has also been associated with Fitz-High–Curtis syndrome (perihepatitis) and reactive arthritis. *C. trachomatis* infection may lead to pelvic inflammatory disease (PID), ectopic pregnancy, and infertility. *C. trachomatis* urogenital infection can be detected in women by testing urine or collecting swab specimens from the endocervix or vagina; in men, the diagnosis can be made through urine or urethral swab. Nucleic acid amplification tests (NAATs) are the most sensitive methods for detecting *C. trachomatis.* Treatment of infection improves symptoms, decreases the risk of sequelae, and prevents sexual transmission of the disease (Table 18.8).

Gonorrhea, caused by *Neisseria gonorrhoeae*, is the second most frequently reported bacterial STI. Infections with *N. gonorrhoeae* may be asymptomatic or may present with dysuria, discharge, intermenstrual bleeding, or dyspareunia. *N. gonorrhoeae* infection may lead to pelvic inflammatory disease (PID); late complications include ectopic pregnancy, and infertility. *N. gonorrhoeae* urogenital infection can be detected in women by testing urine or collecting swab specimens from the endocervix or vagina; in men, the diagnosis can be made through urine or urethral swab. Nucleic acid amplification tests (NAATs) are the most sensitive methods for detecting *N. gonorrhoeae*. Treatment of infection improves symptoms, decreases risk of sequelae, and prevents sexual transmission of the disease (Table 18.8). Treatment of gonorrhea is complicated by the ability of *N. gonorrhoeae* to develop resistance to antibacterials.

Trichomoniasis, caused by *Trichomonas vaginalis*, may be asymptomatic or may present with dysuria, frothy yellow-green vaginal discharge, genital pruritus, or intermenstrual bleeding. Diagnosis of *T. vaginalis* is usually assessed by microscopy of vaginal or urethral secretions; however, there are more sensitive methods of detection, including a specific culture, a nucleic acid probe, and an immunochromatographic capillary flow dipstick. See Table 18.8 for treatment recommendations.

Primary herpes simplex virus (HSV) infection can cause genital ulcers and dysuria, as well as other conditions, including nongenital lesions, cervicitis, urethritis, cystitis, proctitis, and pharyngitis. Systemic complications, such as hepatitis, pneumonia, thrombocytopenia, and monoarticular arthritis may occur. HSV-infected patients can present with a primary infection, which can be asymptomatic; a first clinical episode, which may not necessarily occur during the primary infection; or a recurrent episode. Usually, the first clinical episodes are more painful and prolonged than are subsequent ones. Recurrent episodes occur less frequently with a genital HSV-1 infection and with intervals between episodes becoming longer, as compared to HSV-2. Treatment for initial and recurrent outbreaks of HSV is listed in Table 18.8.

Vaginitis due to various causes can cause dysuria in adolescent females. Vulvovaginal candidiasis, bacterial vaginosis, and trichomoniasis are common causes of vulvovaginitis in adolescents. Other causes are local chemical or allergic irritants, bacterial infections caused by *Streptococcus* or *Staphylococcus* species, trauma, and secondary infections from foreign bodies. Rare causes of vaginitis and subsequent dysuria include ulcerating conditions of the mucous membranes, such as toxic shock syndrome and Stevens-Johnson syndrome. Other noninfectious causes of genital ulcers that can be confused with infection include inflammatory bowel disease and Behçet syndrome. Inflammatory bowel disease usually manifests with intestinal symptoms, deeper ulcers, and a longer duration of ulcerative lesions. Behçet syndrome may manifest with lesions of other mucous membranes as well as ocular, central nervous system, and joint manifestations. If the clinical diagnosis is not definitive, viral culture of the lesions is recommended.

Males with dysuria may also have penile pain or dysuria as a result of phimosis, paraphimosis, balanitis, urethral trauma, epididymitis, or meatal stenosis. **Phimosis** is a scarring or narrowing of the preputial opening and manifests as failure to retract the foreskin. The foreskin is normally difficult to retract in neonates, but by 3 years of age, it is easily retracted. **Paraphimosis**, an emergent cause of dysuria and penile pain, is an incarceration of the prepuce behind the glans. Edema, pain, and swelling are present. Balanitis is an infection of the prepuce caused by *Streptococcus* species, *Candida* species, mixed flora, or *Trichomonas* species; it may be recurrent and warrants circumcision.

Evaluation for dysuria in the adolescent female should include a clean catch (midstream) urine for dipstick, microscopic exam, and culture. The presence of leukocytes on urinalysis may indicate vaginitis due to sexually transmitted infections (*N. gonorrhoeae*, *C. trachomatis*, herpes, *T. vaginalis*). To check for gonorrhea or *Chlamydia*, a firststream urine or a swab of the vagina or cervix should be obtained. Depending on sexual activity, the pharynx and rectum should also be tested to check for infections in those locations. Any lesions suggestive of HSV should be cultured or tested by PCR. The evaluation of any vaginal discharge includes description of the vaginal discharge, measurement of vaginal pH, saline preparation, performance of a whiff

(See *Nelson Textbook of Pediatrics,* p. 1493.)

TABLE 18.8	Recommended Treatments of Selected Sexually Transmitted Infections
Pathogen	**Recommended Regimen**
Chlamydia trachomatis	Azithromycin, 1 g orally in a single dose or Doxycycline, 100 mg orally twice a day for 7 days
Neisseria gonorrhoeae	Ceftriaxone, 250 mg intramuscularly in a single dose plus Azithromycin, 1 g orally in a single dose
Trichomonas vaginalis	Metronidazole, 2 g orally in a single dose or Tinidazole, 2 g orally in a single dose
Herpes simplex virus First clinical genital episode	Acyclovir, 400 mg orally 3 times a day for 7-10 days or Acyclovir, 200 mg orally 5 times a day for 7-10 days or Famciclovir, 250 mg orally three times a day for 7-10 days or Valacyclovir, 1 g orally twice a day for 7-10 days
Herpes simplex virus Episodic therapy for recurrent genital episodes	Acyclovir, 400 mg orally 3 times a day for 5 days or Acyclovir, 800 mg three times daily for 2 days or Acyclovir, 800 mg orally twice a day for 5 days or Famciclovir, 125 mg orally twice a day for 5 days or Valacyclovir, 500 mg orally twice a day for 3 days or Valacyclovir, 1 g orally once a day for 5 days

Modified from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2015. *MMWR.* 2015;64(3):1-135. See full document for alternative treatments and specific treatments in pregnancy and treatment for children <8 years old.

test, and microscopic examination (Table 18.9 and Figs. 18.1, 18.2, and 18.3). Thick, adherent cottage cheese–like discharge is suggestive of candidiasis; other physical examination findings include erythema, edema, and excoriation of the vagina. Thin, homogeneous, gray-white, foul-smelling discharge is suggestive of bacterial vaginosis (BV). Purulent, profuse, irritating, frothy green-yellow discharge often accompanies trichomoniasis. The Amsel criteria for diagnosis and treatment of bacterial vaginosis are listed in Tables 18.10 and 18.11, respectively.

The provider should perform a pelvic examination to exclude **pelvic inflammatory disease (PID)** in all sexually active adolescent females when vaginal discharge and/or pelvic pain are reported (Table 18.12). PID is an acute infection of the upper female genital tract (endometriosis, salpingitis, tuboovarian abscess, pelvic peritonitis). Features that suggest PID (vs lower tract infection) include cervical motion tenderness; uterine or adnexal tenderness; temperature >101°F; cervical mucopurlent discharge or friability; abundant white blood cells on saline prep of vaginal fluid; elevated erythrocyte sedimentation rate and C-reactive protein levels; and a documented cervical infection with *N. gonorrhea* or *C. trachomatis*. Table 18.13 lists differential diagnoses for PID, and Table 18.14 details the recommended treatment regimens for PID. Pregnancy testing is indicated when an adolescent female presents with dysuria or any symptoms of an STI; the test results may influence the treatment plan.

The Centers for Disease Control and Prevention recommend gonorrhea and *Chlamydia* testing of all males who meet

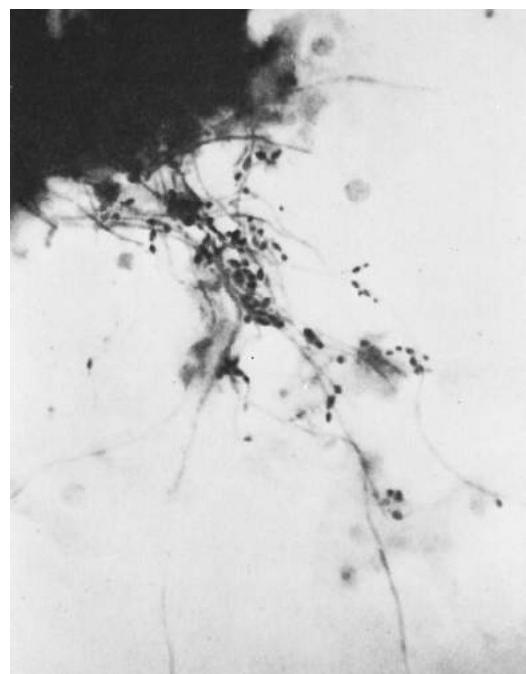
FIGURE 18.2 *Trichomonas vaginalis* identified in wet smears of the vaginal discharge. (From Huffman JW Genitourinary infections. In: Feigen RD, Cherry JD, eds. *Textbook of Pediatric Infectious Diseases*. 2nd ed. Philadelphia: WB Saunders; 1992:568.)


FIGURE 18.3 Hyphae of *Candida albicans* on a wet smear of vaginal discharge. (From Huffman JW. Genitourinary infections. In: Feigen RD, Cherry JD, eds. *Textbook of Pediatric Infectious Diseases*. 2nd ed. Philadelphia, WB Saunders; 1992:564.)

TABLE 18.10   Amsel Criteria for the Diagnosis of Bacterial Vaginosis

Three of the following 4 Amsel criteria are considered necessary to diagnose BV:
1. Vaginal discharge: thin, homogeneous, white, uniformly adherent
2. Vaginal pH >4.5
3. Positive result of whiff test: fishy odor after mixing discharge with 10% KOH
4. >20% clue cells on microscopic examination: bacteria-coated squamous epithelial cells, where both the periphery (cell membrane) and cytoplasm have a granular, irregular, "moth-eaten" appearance

Modified from Amsel R, Totten PA, Spiegel CA, et al. Nonspecific vaginitis. Diagnostic criteria and microbial and epidemiologic associations. *Am J Med*. 1983;74:14-22.
KOH, potassium hydroxide.

TABLE 18.11   Treatment Regimens for Bacterial Vaginosis

Bacterial Vaginosis
Nonpregnant Females
Metronidazole, 500 mg orally twice daily for 7 days
or
Metronidazole gel, 0.75%, 1 full applicator (5 g) intravaginally once a day for 5 days
or
Clindamycin cream, 2%, 1 full applicator (5 g) intravaginally once a day for 7 days

Pregnant Females
Metronidazole, 250 mg orally 3 times daily for 7 days

Modified from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2015. *MMWR*. 2015;64(3):1-135.

TABLE 18.12   Diagnostic Criteria for Pelvic Inflammatory Disease

Minimum Criteria
Uterine or adnexal tenderness (unilateral or bilateral)
or
Cervical motion tenderness

Additional Criteria to Increase Specificity of Minimum Criteria
Abnormal cervical or vaginal mucopurulent discharge
Presence of WBCs on saline microscopy of vaginal secretions
Oral temperature >38.3°C (101°F)
Elevated erythrocyte sedimentation rate or C-reactive protein
Laboratory evidence of *Neisseria gonorrhoeae* or *Chlamydia trachomatis* at cervix

WBCs, white blood cells.
Modified from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2015. *MMWR*. 2015;64(3):1-135.

TABLE 18.13   Differential Diagnosis for Pelvic Inflammatory Disease

Ectopic pregnancy
Ovarian cyst (with or without ovarian torsion)
Acute appendicitis
Endometriosis
Pyelonephritis
Septic or incomplete abortion
Pelvic thrombophlebitis
Functional pain
Psoas-pelvic muscle abscess
Mesenteric adenitis
Pelvic adhesions
Pelvic bone osteomyelitis
Chronic intestinal disease (e.g., inflammatory bowel disease)

TABLE 18.14   Treatment Regimens for Pelvic Inflammatory Disease

Parenteral Regimens (One of the Following)
Cefotetan, 2 g IV q12h, or cefoxitin, 2 g IV q6h, both plus doxycycline, 100 mg IV or PO q12h *or*
Clindamycin, 900 mg IV q8h, plus gentamicin, loading dose (2 mg/kg body weight) IV or IM, followed by a maintenance dose (1.5 mg/kg) q8h
Parenteral therapy may be discontinued 24 hr after clinical improvement and continue doxycycline, 100 mg PO twice daily, or clindamycin, 450 mg orally 4 times daily for 14 days of total therapy
For tuboovarian abscess, addition of either metronidazole, 500 mg PO twice daily, or clindamycin, 450 mg PO 4 times daily, to oral doxycycline provides better coverage against anaerobes

Outpatient Regimens (One of the Following)
Ceftriaxone, 250 mg IM in a single dose, or cefoxitin, 2 g IM, with probenecid, 1 g PO in a single dose once, or other parenteral 3rd-generation cephalosporin (e.g., ceftizoxime or cefotaxime) **plus** doxycycline, 100 mg PO twice daily for 14 days, with or without metronidazole, 500 mg PO twice daily for 14 days

IM, intramuscularly; IV, intravenously; PO, per os (orally).
Modified from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2015. *MMWR*. 2015;64(3):1-135.

TABLE 18.15   Treatment Regimens for Epididymitis

One of the following:
    For epididymitis most likely caused by gonococcal or chlamydial
        infection:
        Ceftriaxone, 250 mg intramuscularly in a single dose, **plus**
          doxycycline, 100 mg orally twice daily for 10 days
    For epididymitis most likely caused by enteric organism, or for patients
        who are allergic to cephalosporins and/or tetracyclines:
        Ofloxacin, 300 mg orally twice daily for 10 days*
        Levofloxacin, 500 mg orally once daily for 10 days*

*Fluoroquinolones have not been recommended for persons younger than 18 years because they damage articular cartilage in juvenile animal models. Among children treated with fluoroquinolones, no joint damage attributable to therapy has been observed. Quinolones should not be used to treat possible gonorrhea infections acquired in Asia or the Pacific, including Hawaii, or California.
Modified from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2015. *MMWR.* 2015;64(3):1-135.

TABLE 18.16   Common Pitfalls in the Correct Diagnosis of Dysuria

Neonates/Infants
Assume that significant bacteriuria in a bagged urine specimen is a true
   UTI, and treat before a confirmatory culture is obtained
Failure to obtain a urine culture in a neonate older than 3 days and miss
   obstructive uropathy with a secondary infection

Toddlers and School-Aged Children
Trust a urine culture from a bagged urine specimen
Accept a laboratory report of "no significant growth" on urine, without
   knowing that the laboratory reports only >100, 000 CFU/mL as
   "significant"
Failure to label a urine as "catheterized specimen," so that the laboratory
   can plate 0.1 mL as well as 0.01 mL

Adolescents
Fail to ask about sexual history suggestive of vaginitis, such as a new
   sexual partner and condom or other birth control device use
Treat pyuria as a UTI in a sample contaminated with vaginal leukocytes

CFU, colony-forming unit; UTI, urinary tract infection.

TABLE 18.17   Red Flags for Referral to a Pediatric Urologist or Nephrologist After a Urinary Tract Infection

- Dilating VUR (grade III, IV, or V)
- Renal scarring detected on sonography or a DMSA scan obtained >6 mo after the UTI
- Urinary obstruction seen on a sonogram
- Voiding dysfunction (enuresis, frequency, "curtsy" to stop voiding)
- Breakthrough UTI in the child with VUR receiving prophylaxis
- Elevated serum creatinine level
- Hypertension
- Antenatal hydronephrosis that is confirmed after day 3 after birth

DMSA, dimercaptosuccinic acid; UTI, urinary tract infection; VUR, vesicoureteral reflux.

TABLE 18.18   Red Flags and Things Not to Miss: Sexually Transmitted Diseases

Diagnosis of More Than One Sexually Transmitted Infection in the Same Patient
- If patient is diagnosed with syphilis, gonorrhea, or human immunodeficiency virus
- If patient reports engaging in unprotected sex with multiple partners
- If patient is immunocompromised
- If patient has a history of sexually transmitted infections

Abdominal Pain in an Adolescent Girl
- Pelvic inflammatory disease
- Tuboovarian abscess
- Ectopic pregnancy
- Appendicitis
- Ovarian cyst (rupture or torsion)

Fever, Rash, Malaise, Arthralgia
- Disseminated gonococcemia
- Reactive arthritis
- Human immunodeficiency virus infection

Rape
Pregnancy
Treatment of Partners
Asymptomatic Cervicitis

the diagnostic criteria for urethritis. NAATs, the most sensitive gonorrhea and *Chlamydia* diagnostic test, can be performed on a single urine or urethral specimen. Any lesion suspicious for HSV should be cultured. Table 18.8 lists the treatments for selected sexually transmitted infections. Epididymitis, typically presenting as unilateral testicular pain, is most frequently caused by *C. trachomatis* or *N. gonorrhoeae* or a sexually transmitted enteric organisms such as *E. coli* and *Pseudomonas* species. On examination, a hydrocele may be present. Treatment of epididymitis is listed in Table 18.15.

SUMMARY AND RED FLAGS

Dysuria in prepubertal children is usually a symptom of a UTI, but may also be due to other infectious or noninfectious causes of urethritis and vaginitis. The differential diagnosis expands greatly in adolescents, in whom a sexually transmitted infection may be the cause. Table 18.16 demonstrates common pitfalls in the appropriate evaluation of dysuria in children and adolescents. Red flags are noted in Tables 18.17 and 18.18.

Because children younger than 2 years cannot often verbalize a specific complaint of dysuria, the diagnosis of a UTI is more challenging in children this age. Awareness of specific risk factors for UTI

(uncircumcised status in boys, height of fever, and lack of other cause for fever on examination) especially in the first year of life will lead to the evaluation of those at highest risk and avoid unnecessary testing in those at low risk. Combining the results of the UA with an appropriately obtained urine culture allows for expeditious treatment and confirmation of the particular pathogen when the culture results are available.

Proteinuria

Raji Sreedharan

Proteinuria can be detected by various means, and the most common is the dipstick test, a calorimetric assay that spots only albumin and not low-molecular-weight proteins. In addition, alkaline urine and the presence of contrast media in urine can lead to false dipstick positivity. Though 24-hour urine collection is the gold standard to quantify the proteinuria, spot urine protein-to-creatinine ratio can be used for initial confirmation after a positive screen with dipstick or to trend proteinuria (Table 19.1). A ratio below 0.2 protein mg/creatinine mg is considered normal in children older than 2 years of age and a ratio less than 0.5 mg/mg is considered normal in younger children between 6 months and 2 years of age. In timed collection, protein excretion greater than 100 mg/m^2 in 24 hours or 4 mg/m^2/hour is considered abnormal, and over 40 mg/m^2/hr is considered nephrotic range. Qualitative analysis of protein in urine by immunonephelometry helps distinguish glomerular from tubular proteinuria.

Proteinuria in children can be transient, orthostatic, or persistent. Transient and orthostatic proteinuria are benign conditions and require no treatment. Several factors including fever, stress, hypovolemia, exercise, and seizures can lead to transient proteinuria (Table 19.2). **Orthostatic proteinuria** is defined as increased protein in urine only when upright. In this condition, absence of proteinuria when horizontal and resting can be confirmed by documenting absence of protein in a 1st morning void. Split day/night urine collection is the gold standard to diagnose orthostatic proteinuria, which is a common benign cause of proteinuria, especially in adolescents. Persistent proteinuria requires meticulous evaluation to rule out renal pathology.

Evaluation of proteinuria begins with a detailed history and physical examination. Pertinent histories that help distinguish pathologic from benign proteinuria include history of respiratory symptoms concurrent with or preceding the proteinuria, presence of red urine, edema, positive family history of kidney disease, or hearing loss. Findings of edema and hypertension suggest pathologic proteinuria. Repeating urine dipstick in asymptomatic children with a negative history can eliminate unnecessary further testing for transient proteinuria. If still positive, spot urine protein-to-creatinine ratio can help confirm the presence of proteinuria. If confirmed, a 1st morning void protein-to-creatinine ratio can then identify orthostatic proteinuria. Once the benign conditions are ruled out in asymptomatic children, further testing is similar to that of symptomatic children and these children should be referred to nephrologists. This more detailed evaluation begins with 24-hour urine collection where possible, complete urinalysis, and sediment evaluation looking for glomerular or other parenchymal pathology that could be causing the proteinuria (Fig. 19.1). Positive leukocyte esterase, nitrite, and presence of pyuria or bacteriuria suggest a urinary tract infection. If not resolved with treatment of infection, proteinuria will need further evaluation. Low molecular proteins, such as β2-microglobulin, α1-microglobulin, lysozyme, and retinol-binding protein are found in **tubular proteinuria** as is seen in Fanconi syndrome or Dent disease.

Red blood cell (RBC) cast is pathognomonic of **glomerulonephritis**. Serum chemistry including creatinine, BUN, electrolytes, albumin, and cholesterol will also help separate proteinuria secondary to glomerulonephritis or nephrotic syndrome. Lupus antibody studies, streptococcal infection, and complement C3 and C4 levels along with viral studies can help delineate the various causes of glomerulonephritis and nephrotic syndrome. Renal ultrasound should be considered to rule out any gross parenchymal etiology for the proteinuria, such as dysplastic kidney and cystic kidney disease. Renal biopsy may be indicated if there is evidence for worsening of proteinuria, hypoalbuminemia, deteriorating renal function, or a poor response to the initial therapy.

Differential diagnoses for proteinuria are extensive, as described in Table 19.2. The initial evaluation of a patient with proteinuria is presented in Table 19.3. Indications for a referral to a pediatric nephrologist are described in Table 19.4. If there is obvious edema with proteinuria, the diagnostic evaluation noted in Table 19.3 advances directly to the 2nd phase and, if necessary, to the 3rd phase.

The combination of proteinuria, hypoalbuminemia, edema, and hyperlipidemia are the defining features of nephrotic syndrome. Nephrotic syndrome may be a result of many primary etiologic factors, with varying renal pathologic processes and long-term consequences. Proteinuria that causes edema is always clinically significant, although not all edema is secondary to proteinuria (Table 19.5). All children with nephrotic syndrome invariably have "nephrotic-range" proteinuria, necessitating detailed evaluation, and most require treatment. In rare cases, a child with asymptomatic proteinuria has nephrotic-range proteinuria. If there is concomitant hypoalbuminemia and hyperlipidemia, the work-up proceeds as if the child presented with nephrotic syndrome, despite the absence of edema. Even without hypoalbuminemia and hyperlipidemia, nephrotic-range proteinuria is less likely to be benign than is less marked asymptomatic proteinuria.

NEPHROTIC SYNDROME IN YOUNG CHILDREN

◆ Differential Diagnosis

Three diseases constitute all cases of isolated nephrotic syndrome: minimal change disease (the most common); focal segmental sclerosis (also called focal glomerular sclerosis); and membranous glomerulopathy. These classifications are based on pathologic findings. Thus these presentations could be primary or secondary due to other causes. In addition, nephrotic syndrome can be present along with glomerulonephritis (GN), such as postinfectious GN, IgA GN, or membranoproliferative GN. Systemic diseases also cause childhood nephrotic syndrome, accounting for 10% of cases. The three foremost considerations include SLE, anaphylactoid purpura (Henoch-Schönlein purpura), and hemolytic uremic syndrome. These diseases have extrarenal manifestations in addition to the proteinuria and must be considered in any child who presents with systemic illness and significant

(See *Nelson Textbook of Pediatrics,* p. 2517.)

(See *Nelson Textbook of Pediatrics,* p. 2571.)

TABLE 19.1 Quantification of Proteinuria in Children

Method	Abnormal Proteinuria	Precautions
Urine dipstick	1+ or more in a concentrated urine specimen (specific gravity ≥1.020)	False positive if urine pH >8.0 or specific gravity >1.025 or tested within 24 hr of a radiocontrast study
Sulfosalicylic acid test	1+ or more	False-positive with iodinated radiocontrast agents
Urine protein/creatinine ratio (U_p /U_{Cr} ratio) in spot urine	>0.02 g/mmol or >0.2 mg/mg in children >2 yr >0.06 g/mmol or >0.6 mg/mg in children 6 mo-2 yr Nephrotic range: >0.2 g/mmol or >2 mg/mg	Protein excretion varies with child's age
Timed urine protein excretion rate	>4 mg/m^2/hr or >150 mg/1.73 m^2/24 hr Nephrotic range: >40 mg/m^2/hr or >3 g/1.73 m^2/24 hr	In an accurately collected 24-hr urine specimen, urine creatinine should be in the range of 0.13-0.20 mmol/kg or 16-24 mg/kg ideal body weight for females, and 0.18-0.23 mmol/kg or 21-27 mg/kg ideal body weight for males

proteinuria. Hereditary forms of nephrotic syndrome are a genetically heterogeneous group of disorders representing a spectrum of hereditary renal diseases. There are 13 subtypes of hereditary nephrotic syndrome associated with 35 genes. Several of the more common disorders along with other causes of nephrotic syndrome are noted in Tables 19.6 and 19.7.

MINIMAL CHANGE DISEASE

Most cases of nephrotic syndrome in children are caused by minimal change nephrotic syndrome, defined as normal histologic features of the kidney by light microscopy and immune stains. Preschool-aged children constitute the age group in which minimal change nephrotic syndrome is most common. Patients often present with asymptomatic edema, which may manifest as swollen or puffy eyes upon awakening in the morning; increasing abdominal girth (increased waist or belt size) from ascites; pedal or leg edema, which causes difficulty in putting on their regular-sized shoes, especially after being upright during the daytime; or swelling in other sites, such as the scrotum, penis, vulva, and scalp. Tense edema or ascites is occasionally painful.

Minimal change nephrotic syndrome is slightly more common in boys than in girls. The hallmark of this disease is total clearing of the proteinuria with oral prednisone therapy. A common misconception is that neither hematuria nor hypertension is present in children with minimal change disease. Microscopic hematuria and hypertension are present in up to 20% of children who have minimal change disease. The blood urea nitrogen (BUN) or serum creatinine level may also be elevated in up to 30% of the cases, usually from prerenal causes. Serum complement studies, specifically C3, are invariably normal. Older age, hematuria, hypertension, and azotemia may occur with minimal change nephrotic syndrome, but the combination suggests another disease.

◆ Diagnosis

Studies that would help confirm that a patient with nephrotic syndrome has minimal change disease include urinalysis, serum chemistry

including BUN, creatinine, albumin, and cholesterol levels, along with complements and lupus antibody titers.

The urinalysis would be expected to show 3+ to 4+ protein, which is correlated with a urine concentration of 300-2000 mg/dL. The urine may also occasionally yield positive results for blood. Microscopic examination of the urine sediment often shows oval fat bodies and/or refractile granular casts, which are seen when there is significant lipiduria. Red blood cells might also be present, but it is unusual to see red blood cell casts. Their presence would suggest a diagnosis of post-streptococcal glomerulonephritis or other causes of nephritis (see Chapter 20).

The complement C3 and C4 levels are normal in minimal change disease and are depressed in some other causes of nephritis (see Chapter 20). The serum cholesterol values are elevated in minimal change nephrotic syndrome and are usually higher than 250 mg/dL; levels in the range of 500-600 mg/dL may occur. The serum albumin concentration is invariably less than 2.5 and often less than 2.0 g/dL. A renal biopsy is not immediately indicated because most patients (>90%) with minimal change disease respond to prednisone, a response that is considered diagnostic.

◆ Treatment

With a presumptive diagnosis of minimal change nephrotic syndrome, it is recommended in the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines that patients be placed on a therapeutic course of prednisone, 60 mg/m^2/day or 2 mg/kg/day, up to a maximum of 60 mg for 4-6 weeks, followed by a dose of 40 mg/m^2 or 1.5 mg/kg (maximum 40 mg) given every other day for another 6 weeks. In most patients, there is total resolution of proteinuria within 10-21 days of initiating therapy. Patients who do not respond to prednisone therapy should be considered candidates for a renal biopsy to guide further therapy.

Total clearing of proteinuria in response to prednisone is an excellent prognostic sign. Very few patients progress to renal failure, although many patients (~80%) who initially respond to prednisone therapy with total clearing of proteinuria may have relapses and require intermittent prednisone therapy for many years. Approximately 18% of patients treated with prednisone for minimal change nephrotic syndrome respond to therapy and never experience a relapse.

Patients with **recurrent nephrotic syndrome** are subgrouped into those who experience frequent and infrequent relapses. A patient with infrequent relapse has fewer than 2 relapses in any 6-month period; a person with frequent relapse has 2 or more relapses within 6 months. Prednisone should be reinitiated at a dose of 60 mg/m^2/day or 2 mg/kg/day until a maximum of 60 mg/day and continued until the urine test results are negative for protein for 3 consecutive days. After that, alternate-day prednisone is given at a dose of 40 mg/m^2 or 1.5 mg/kg (maximum 40 mg) in the morning for another 4 weeks and then discontinued altogether. Relapses are frequent during the influenza virus seasons; any minor upper respiratory infection may trigger a relapse of nephrotic syndrome. Patients who suffer infrequent relapses may be treated with prednisone alone.

Patients with frequently relapsing nephrotic syndrome may be steroid dependent and require constant daily prednisone therapy to maintain a remission. Because constant daily prednisone has significant untoward side effects (growth failure, cushingoid facies, osteoporosis, cataracts, opportunistic infections, hypertension, and glucose intolerance), other therapies need to be considered. A renal biopsy is recommended prior to initiating alternative agents to confirm the

TABLE 19.6	Causes of Childhood Nephrotic Syndrome

Idiopathic Nephrotic Syndrome
Minimal change disease
Focal segmental glomerulosclerosis

Glomerulonephritis associated with nephrotic syndrome–membranoproliferative glomerulonephritis, crescentic glomerulonephritis, immunoglobulin A nephropathy

Genetic Disorders Associated with Proteinuria or Nephrotic Syndrome
Over 100 genetic syndromic disorders are associated with proteinuria, the more common disorders are listed below.

Nephrotic Syndrome (Typical)
Finnish-type congenital nephrotic syndrome (absence of nephrin)
Focal segmental glomerulosclerosis (mutations in nephrin, podocin, *MYO1E*, α-actinin-4, TRPC6)
Diffuse mesangial sclerosis (mutations in laminin β_2 chain)
Denys-Drash syndrome (mutations in WT1 transcription factor)
Congenital nephrotic syndrome with lung and skin involvement (integrin α_3 mutation)
Mitochondrial disorders (rare association, steroid resistance, MELAS)

Proteinuria With or Without Nephrotic Syndrome
Nail-patella syndrome (mutation in LMX1B transcription factor)
Alport syndrome (mutation in collagen 4 biosynthesis genes)

Multisystem Syndromes With or Without Nephrotic Syndrome
Galloway-Mowat syndrome
Charcot-Marie-Tooth disease
Jeune syndrome
Cockayne syndrome
Bardet Biedl syndrome

Metabolic Disorders With or Without Nephrotic Syndrome
Alagille syndrome
α_1-Antitrypsin deficiency
Fabry disease
Glutaric acidemia
Glycogen storage disease
Hurler syndrome
Partial lipodystrophy
Mitochondrial cytopathies
Sickle cell disease

Secondary Causes of Nephrotic Syndrome
Infections
Endocarditis
Hepatitis B, C
HIV-1
Infectious mononucleosis
Malaria
Syphilis (congenital and secondary)
Toxoplasmosis
Schistosomiasis
Filariasis

Drugs
Captopril
Penicillamine
Gold
Nonsteroidal antiinflammatory drugs
Pamidronate
Interferon
Mercury
Heroin
Lithium

Immunologic or Allergic Disorders
Vasculitis syndromes
Castleman disease
Kimura disease
Bee sting
Food allergens
Serum sickness

Associated with Malignant Disease
Lymphoma
Leukemia
Solid tumors

Glomerular Hyperfiltration
Oligomeganephronia
Morbid obesity
Adaptation to nephron reduction

diagnosis of minimal change nephrotic syndrome. Treatment strategies with corticosteroid-sparing agents for patients with frequent relapse who develop steroid-related adverse effects include, alkylating agents; cyclophosphamide or chlorambucil. It is not recommended that second courses of alkylating agents be given.

Complications of Nephrotic Syndrome

Even in patients with the frequent relapse variant of minimal change disease, the incidence of renal failure is only 1%. The reported mortality rate remains higher, at approximately 5%.

Infection.   The major cause of death in nephrotic syndrome is overwhelming infection, usually secondary to **spontaneous bacterial peritonitis**, which develops in as many as 10% of patients with nephrotic syndrome at some point in the course of illness. Such infection is most frequent in patients who are edematous with significant ascites. Peritoneal fluid interferes with macrophage function, whereas ascitic fluid may dilute local complement or immunoglobulin levels, altering host defense mechanisms in the peritoneum.

The most common pathogen is *Streptococcus pneumoniae. Escherichia coli* and *Staphylococcus aureus* are other etiologic agents that may cause spontaneous peritonitis in patients with minimal change disease. With the use of appropriate antibiotics, mortality from peritonitis is ~10%. Any child with nephrotic syndrome in relapse with evidence of ascites needs to be evaluated quickly if either abdominal pain or fever

develops. A blood specimen and paracentesis (e.g., Gram stain, culture, neutrophil count, measurement of glucose and protein levels) should be obtained, and the patient should be started on intravenous cefotaxime (or ceftriaxone) and an aminoglycoside without further delay.

Thrombosis. A second serious complication of nephrotic syndrome is spontaneous thrombosis, pulmonary embolus, or both. The blood of patients with nephrotic syndrome is hypercoagulable, and there is an increased incidence of thrombotic phenomena in these children. Children can have arterial thrombosis, as well as venous thrombosis with resultant pulmonary emboli. The renal vein and dural sinus veins are other possible sites of thrombosis. Use of injectable and oral antithrombolytic agents, in addition to heparin, have allowed for more effective treatment of thrombotic complications.

Hyperlipidemia. Hyperlipidemia is treated by some authorities with statins to lower the serum cholesterol levels and theoretically reduce vascular pathologic processes.

OTHER FORMS OF NEPHROTIC SYNDROME

Focal Segmental Sclerosis

Diagnosis

Clinical criteria do not always allow clinicians to differentiate minimal change disease from focal segmental sclerosis before completion of a course of prednisone therapy. Inability to clear proteinuria completely during prednisone therapy may be the first indication of focal segmental sclerosis. Patients who respond to prednisone initially with clearing of proteinuria but do not respond to a subsequent course of steroids

should also be considered to have focal segmental sclerosis. Such patients represent about 7% of those who have an initial response to prednisone therapy. A patient who does not respond to prednisone with total clearing of proteinuria should undergo renal biopsy.

Focal segmental sclerosis may be primary (idiopathic) or secondary to severe obesity, reflux nephropathy, sickle cell nephropathy, reduced renal mass (single kidney), opiate or analgesic abuse, chronic bacteremia (endocarditis), renal transplant rejection, or nephropathy resulting from human immunodeficiency virus infection. Genetic variants in several genes result in focal segmental glomerulosclerosis. The genetic basis of these hereditary focal segmental glomerulosclerotic disorders is genetically heterogeneous. Nine hereditary subtypes have been described. *FSGS1 : ACTN4; FSGS2 : TRPC6; FSGS3 : CD2AP; FSGS4 : APOL1; FSGS5 : INF2; FSGS6 : MYO1E; FSGS7 : PAX2; FSGS8 : ANLN; FSGS9 : CRB2.* Many of these genes code for proteins which are involved in the structure and function of the podocyte foot process.

Treatment

Results of treatment of focal segmental sclerosis have been poor. Patients have severe and unremitting proteinuria despite treatment with prednisone, chlorambucil, or cyclophosphamide. The long-term outcome has been poor; 33% are in renal failure ~10 years after diagnosis, and nearly 100% are in renal failure 20 years after diagnosis. The incidence of focal segmental sclerosis appears to be increasing, particularly in the African American population, possibly related to obesity and genetic predisposition.

Patients with focal segmental sclerosis present 2 difficult problems. First, renal function may be maintained reasonably well for years, but massive proteinuria persists. Hence, patients are often edematous for months or years, and stigmata of protein malnutrition may develop as a result of large protein losses. Symptomatic therapy with a low-sodium diet and judicious use of diuretics is sometimes effective. Dietary manipulation of protein intake is ineffective; increasing dietary protein intake is accompanied by a concomitant increase in urinary protein excretion. There is no evidence that protein restriction either modifies serum proteins or prevents progression to renal insufficiency.

The second problem occurs when affected patients progress to end-stage renal failure. Recurrence of the disease in transplanted kidneys occurs in 25-30% of recipients. Therefore, many patients undergo a long period of dialysis before receiving a kidney transplant in an effort to diminish the frequency of recurrent disease.

Some patients respond to calcineurin inhibitors, cyclosporine, or tacrolimus, with total clearing of their proteinuria. There may be no progression to renal insufficiency. It is unknown what percentage of patients with focal segmental sclerosis respond to cyclosporine; it is estimated that 25-60% have an initial response.

Membranous Nephropathy

Membranous nephropathy is a pathologic diagnosis made following renal biopsy and may be primary or secondary to other diseases (e.g., hepatitis, systemic lupus erythematosus [SLE] or malignancy) or toxins and drugs such as nonsteroidal antiinflammatory, gold, mercury, bismuth, silver, D-penicillamine, trimethadione, probenecid, and captopril. All the secondary causes must be considered and should be addressed and treated before the condition is considered primary. Antibodies against the phospholipase A_2 receptor (PLA_2R) in the serum or a renal biopsy by immune staining have been identified in 70% of patients with primary or idiopathic membranous nephropathy. Circulating antibodies against thrombospondin type-1 domain-containing 7A (THSD7A) are found in another 5-10% of the remaining patients with primary membranous nephropathy. The changes in

(See *Nelson Textbook of Pediatrics,* p. 2502.)

the antibody titers correspond to remission or relapse of proteinuria and can be used to monitor the disease.

Treatment

Addressing the triggers of secondary membranous nephropathy in itself may result in resolution of proteinuria in the majority of cases. Membranous nephropathy secondary to SLE is more difficult to treat. In addition, the increased incidence of spontaneous resolution of the proteinuria makes selecting the patients who should be treated very complicated. Close monitoring of primary membranous nephropathy to determine the need for treatment is recommended for 6 months prior to initiating treatment. Sodium restriction, diuretics, and angiotensin-converting enzyme (ACE) inhibitors can be used for control of proteinuria and symptoms. In patients with no decrease of proteinuria, or with severe, life-threatening symptoms related to the nephrotic syndrome, immunosuppression with steroids and cyclophosphamide can be tried.

NEPHROTIC SYNDROME IN INFANTS YOUNGER THAN 1 YEAR

Nephrotic syndrome that manifests very early in life is a much more serious entity, and the prognosis is guarded (see Table 19.7). The outlook is poorest in younger infants (<6 months of age) and improves as the age at presentation approaches 1 year. Minimal change disease is rarely seen in infants younger than 6 months of age. It is more common in infants who present at 6-8 months. By 1 year, it is the most common cause of nephrotic syndrome.

The conditions that result in nephrotic syndrome in infants differ markedly from those seen in older children. Secondary causes are more prominent and need to be considered, particularly in newborns or very young infants. It is especially important to test for syphilis because the early institution of penicillin therapy may lead to the resolution of the renal disease and may mitigate the involvement of other organ systems as well. Congenital toxoplasmosis is also treatable with the combination of steroids and pyrimethamine–sulfadiazine–folinic acid. Other congenital infections offer less opportunity for treatment to influence the outcome; extrarenal manifestations of these infections are much more serious than kidney disease.

Primary renal disease causing nephrotic syndrome in early infancy is most often caused by either congenital nephrotic syndrome or diffuse mesangial sclerosis (Table 19.8). In both diseases, the prognosis for survival is poor unless aggressive supportive therapy and kidney transplantation are undertaken.

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome is an autosomal recessive disorder resulting from mutations in the gene encoding the protein, nephrin (see Table 19.8). Infants with congenital nephrotic syndrome are often premature, with a low birthweight, placentomegaly, increased amniotic fluid α-fetoprotein levels, and hypogammaglobinemia (decreased immunoglobulin G levels).

Ascites and edema, caused by massive proteinuria, are usually present in affected infants during the first few weeks after birth. Patients do not respond to steroids or cytotoxic therapy. Infections and thrombosis are the two major complications; they cause considerable morbidity and mortality. Because of the massive proteinuria, patients fail to thrive; they require nasogastric feeding with a high-calorie, high-protein formula. Nephrectomy and peritoneal dialysis are often necessary to control protein losses and allow for adequate growth and control of uremia so that the infant can reach a size and nutritional state sufficient for renal transplantation.

Diffuse Mesangial Sclerosis

Diffuse mesangial sclerosis is the other diagnostic entity seen in infants (see Table 19.8). This disease is similar to congenital nephrotic syndrome, but it often results in less severe protein losses. Patients are often full term and of a normal birthweight. The amniotic fluid α-fetoprotein is normal, and the onset of edema (1 week-33 months) is later than in congenital nephrotic syndrome (birth-3 months). The patients have hypertension, hematuria, and renal insufficiency at presentation. When diffuse mesangial sclerosis is seen in association with a female phenotype, chromosome typing is recommended to look for patients with Drash syndrome (XY gonadal dysgenesis, nephropathy, and Wilms tumor). When this syndrome is present, bilateral nephrectomy and gonadectomy are recommended because the potential for malignancy is very high.

Treatment is similar to patients with congenital nephrotic syndrome and eventually requires renal transplantation. The major goal is to help these infants achieve the growth and good nutrition necessary for successful renal transplantation. Nephrotic syndrome occasionally occurs after transplantation for congenital nephrotic syndrome, probably secondarily to an autoimmune reaction to nephrin.

ASYMPTOMATIC PROTEINURIA DISORDERS

Many patients have proteinuria, but there is no edema, the blood pressure is normal, and serum protein levels are normal. The extent of the work-up must be tailored to the seriousness of the problem. Whether an evaluation should be performed depends on whether the proteinuria is both persistent and nonorthostatic (see Fig. 19.2). For a **child younger than 7 or 8 years of age** who has persistent proteinuria, normal total protein and serum albumin levels, normal complement, and no other signs of renal disease, there are two options.

One option is to observe the patient carefully with repeated urinalyses every 3-6 months and to counsel the parents with regard to swelling and/or ascites, which may develop in association with influenza or an upper respiratory infection. If there is evidence of overt nephrotic syndrome with edema, a decrease in serum albumin and an increase in serum cholesterol, a trial of daily prednisone therapy is indicated. It is good practice to give the pneumococcal vaccine to patients who have persistent proteinuria but no evidence of edema or nephrotic syndrome, because of the risk of pneumococcal peritonitis if nephrotic syndrome develops. The other option involves instituting prednisone therapy to document that proteinuria has disappeared; this confirms the suspicion that the patient has steroid-responsive nephrotic syndrome. The rationale for withholding prednisone unless symptoms develop is that the natural history of minimal change disease is to remit; this may occur with or without prednisone administration. If the patient has a more serious lesion, symptoms will develop, at which time evaluation and therapy may be undertaken.

In a **patient older than 8 or 9 years**, once the presence of persistent and nonorthostatic proteinuria is established, the next step is to quantify the amount of protein in a 24-hour specimen. If urinary protein excretion is greater than 8 mg/kg/day, a renal biopsy may be considered. Alternatively, these patients can also be treated with steroids and the response assessed. If proteinuria does not clear after 6-8 weeks of therapy, renal biopsy is then indicated. The choice of 8 mg/kg/day of proteinuria is arbitrary; the International Study of Kidney Disease in Children (ISKDC) definition of proteinuria is 8 mg/m²/hour, and nephrotic syndrome is defined as 40 mg/m²/hour. Hence, for an average 8-year-old patient who weighs 30 kg and is 1 m² tall, proteinuria by these definitions is a level of 96 mg/day, and nephrotic syndrome is at a level of 960 mg/day. Renal biopsy can be considered at a

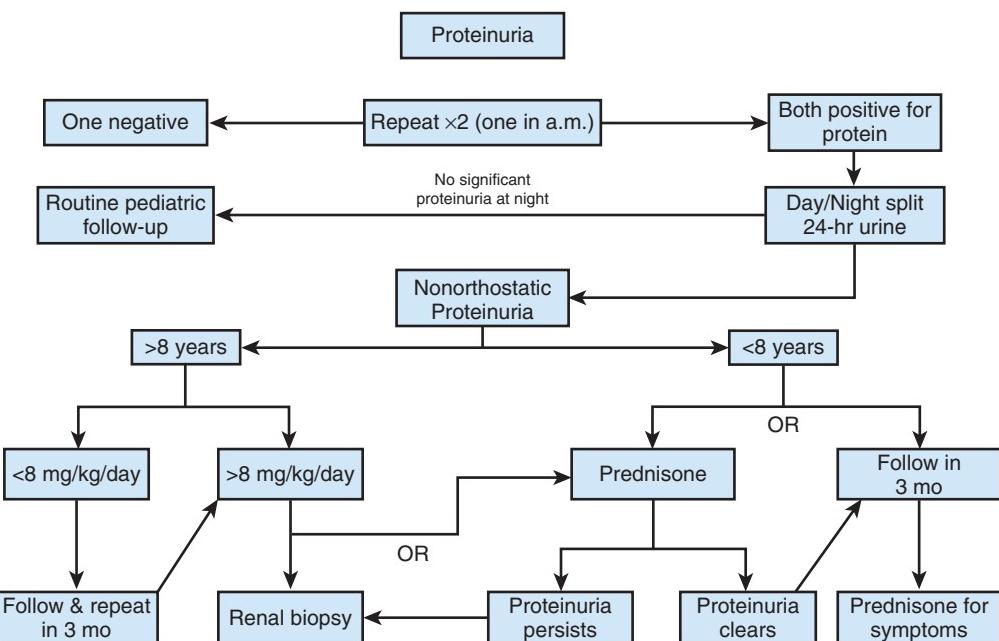

FIGURE 19.2 Algorithm for age-based management of proteinuria.

level of 240 mg/day of proteinuria. This guideline helps avoid a biopsy for the patient with minimal proteinuria but does not require full-blown nephrotic syndrome to develop before a definitive work-up is initiated. Because the patient has isolated proteinuria, membranoproliferative glomerulonephritis (MPGN) or SLE is an unlikely possibility. However, the incidence of focal segmental sclerosis is much higher in adolescents than in younger children. With the possibility of treatment with cyclosporine and/or ACE inhibitors preventing future renal failure, aggressive evaluation is warranted to identify patients who might benefit from these therapies.

Low molecular protein, such as β2-microblobulin, α1-microglobulin, lysozyme, and retinol-binding protein can be seen in urine in tubular disorders, such as Fanconi syndrome or Dent disease. If associated with acidosis, hypokalemia, and hypophosphatemia, Fanconi syndrome should be considered. In males, if proteinuria is associated with hypercalciuria and nephrocalcinosis, Dent disease, an X-linked proximal tubulopathy that eventually leads to end-stage renal disease, should be considered, and the urine should be tested for β2-microblobulin. Gene testing can confirm the diagnosis.

The presence of protein in the urine increases the risk of renal insufficiency, regardless of its cause. This has led to therapies that reduce proteinuria, thereby decreasing the risk of a progressive loss of renal function. The traffic of protein across the glomerular capillary membrane appears to stimulate a cascade of inflammatory events that cause interstitial fibrosis. ACE inhibitors result in efferent arteriolar vasodilatation, leading to a decrease in intraglomerular pressure, which in turn leads to a decreased transport of protein across the glomerular filter. Patients who are treated with ACE inhibitors are less likely to increase their level of proteinuria and are less likely to lose their renal function than are patients who are not treated with these agents. This was first apparent in the treatment of diabetic nephropathy, but there is evidence that ACE inhibitors offer advantages to patients with other nephropathies as well. Angiotensin II blockers offer another avenue for accomplishing a decrease in intraglomerular pressures, and these also decrease proteinuria when used alone or in conjunction with an ACE inhibitor. ACE inhibitors and angiotensin II blockers may be useful for patients with proteinuria either as a 1st step or as adjunctive therapy for those who fail to respond to other medications.

SUMMARY AND RED FLAGS

Asymptomatic proteinuria may be associated with nonspecific febrile benign illnesses, postural mechanisms, and glomerular or tubular dysfunction. Significant proteinuria with edema suggests nephrotic syndrome, which in most children suggests minimal change nephrotic syndrome. An age younger than 1 year or older than 10 years plus significant hematuria, azotemia, and hypertension are red flags that suggests a cause of nephrosis other than the more benign minimal change disease. Additional red flags include a poor response to prednisone therapy and signs of multiple organ system involvement by a primary systemic disease, such as SLE. Fever and abdominal pain in a patient with nephrotic syndrome should suggest spontaneous primary bacterial peritonitis.

Hematuria

Scott K. Van Why and Cynthia G. Pan

Hematuria is a common issue faced by primary physicians who care for children. While it can cause great anxiety in the patient and family when it presents as gross hematuria, rarely does hematuria alone herald a serious illness during childhood. Indeed, despite thorough evaluation, no cause can be found in a large percentage of children who have hematuria. Nearly 40% of children who present with gross hematuria and 80% of patients with persistent, isolated microscopic hematuria have no identifiable cause despite a thorough investigation. This raises the question of how much investigation should be performed on a child who presents with hematuria, particularly if it is isolated microscopic hematuria because the evaluation can be costly and at times invasive.

How extensive an evaluation is appropriate depends much on the context. Those children who present with gross hematuria or microscopic hematuria with associated signs or symptoms deserve a thorough evaluation. These two groups contain those more likely to have an identifiable cause and include the subset that has an acute or potentially serious illness that can progress to significant morbidity or sequelae if not identified and treated. Associated symptoms and signs that indicate the need for prompt evaluation include other urinary or systemic symptoms that led to testing the urine for blood, and findings of hypertension, edema, poor growth, fever, or other systemic signs at presentation.

The more difficult question is how much testing is required of an apparently healthy child discovered to have isolated microscopic hematuria on routine screening urinalysis. Thorough testing of such a child with no symptoms, a normal physical examination, and no significant family history of kidney disease rarely identifies a cause of hematuria. Therefore, the utility of performing a screening urinalysis in children, with the potential attendant costly and usually uninformative additional investigation, has long been questioned. The American Academy of Pediatrics does not recommend screening urinalysis for early school-aged children. It is reasonable to screen children who have a significant family history of kidney disease, particularly if there is a family history of hereditary nephritis.

GROSS HEMATURIA

Gross hematuria, defined as blood in the urine visible to the naked eye, is a dramatic symptom that is usually brought to medical attention, unless an older child with the symptom is too frightened to bring it to the attention of the parents. Carefully defining the appearance of the urine can be the first and a major clue to the origin of the blood. Hematuria emanating from a nonglomerular, lower urinary tract source can present as frankly bloody urine varying in color from dark red, cherry, or pink-tinged urine. On occasion, lower tract hematuria can result in passing blood clots. Seeing blood in the urine only on initiation or at termination of voiding is an additional clue that the source is from the lower tract. Blood seen at the urethral meatus or only on initiation of voiding suggests a urethral source. In contrast, hematuria originating from a glomerular source more often presents with description of other color changes in the urine, such as brown-, cola-, tea-, or on occasion, even green-colored urine.

The first step when presented with this symptom is to perform a urinalysis. If no hemoglobin is found on macroscopic urinalysis, then causes of urine discoloration other than hematuria need to be considered (Table 20.1). One fairly common presentation that can be particularly frightening to a parent is finding a pink or red-tinged wet diaper, thought to be blood in the urine. This most often is from a simple benign entity commonly called **red diaper syndrome**, caused by precipitation of urate crystals in the diaper. A macroscopic urinalysis negative for heme indicates this to be the most likely cause, and in an otherwise healthy infant, no further investigation is warranted.

If red blood cells are found in the urine of a child with a history suggestive of gross hematuria, then evaluation for potential causes is needed (Tables 20.2 and 20.3 and Fig. 20.1). The first step is a thorough history and physical examination.

◆ History

Development of **pain** with the onset of hematuria usually indicates a lower urinary tract source. Irritative symptoms, such as dysuria, urgency, or frequency can be seen in bleeding from the bladder from a variety of causes. Although not a typical feature of urinary tract infection (UTI), the most common identifiable cause of gross hematuria is a UTI, and is usually accompanied by significant dysuria or abdominal pain, and sometimes fever. Severe and episodic or colicky flank or abdominal pain should raise suspicion for urolithiasis, which may have accompanying dysuria as the stone is being passed. Urinary tract obstruction, such as posterior urethral valves in boys or ureteropelvic junction obstruction in either sex, may remain occult until infection or trauma causes hematuria. In the former, the only preceding symptoms may be a boy who voids only infrequently, commonly strains to void, or has ongoing urinary incontinence beyond the toddler years. Bleeding from renal tumors is an uncommon cause of gross hematuria in children, but should be considered particularly in the setting of associated abdominal pain, a palpable mass, or passing of blood clots.

Gross hematuria due to glomerular disease is rarely accompanied by significant pain, though some may report mild abdominal pain or flank discomfort. An exception is Henoch-Schönlein purpura, a common pediatric systemic vasculitis, which can have variable, including severe, gastrointestinal disease. Clues to underlying glomerular disease may be a recent history of pharyngitis, streptococcal skin infection, or other febrile illnesses, indicating possible acute postinfectious glomerulonephritis. Patients with glomerulonephritis or renal insufficiency may report shortness of breath, edema, or weight gain from fluid retention. They may also have a headache or visual changes secondary to severe hypertension. Abdominal pain, diarrhea, hematochezia, rash, and arthralgias are symptoms indicative of a systemic vasculitis, such as Henoch-Schönlein purpura (HSP).

(See *Nelson Textbook of Pediatrics,* p. 2494.)

Recurrent, painless gross hematuria is often seen in young patients with IgA nephropathy in association with concurrent respiratory illness. Recurrent fever, weight loss, alopecia, mouth ulcers, chest pain, fatigue, and arthritis suggest systemic lupus erthythematosis. Hemoptysis or cough is seen in pulmonary-renal syndromes caused by antineutrophil cytoplasmic antibody (ANCA) associated disease, and on occasion in lupus and HSP.

The patient's **medical history** may be most informative. Stressed neonates from birth asphyxia, infection, or volume depletion can develop renal vein thrombus that presents as gross hematuria. Patients with African ancestry should be queried for personal or family history of sickle cell hemoglobinopathy, since gross hematuria from renal papillary necrosis can occur in those with sickle cell disease as well as in children with simple sickle cell trait. Medication history can uncover a cause of gross hematuria from drug-induced interstitial nephritis, seen with several antibiotics, anticonvulsants, or nonsteroidal antiinflammatory drugs, the latter of which can also cause papillary necrosis. Cyclophosphamide can cause a severe hemorrhagic cystitis, which usually has concomitant prominent bladder symptoms.

A history of frequent or severe bleeding from other sites, such as heavy menses, prolonged nosebleeds, hemarthroses, or significant bleeding associated with surgical procedures suggests an undiagnosed bleeding disorder. Exposure history to tuberculosis should be obtained, as well as a travel history, as parasitic infections such as schistosomiasis of the bladder, uncommon in Western societies, is common in other parts of the world. Questions specific to other potential sources of blood in the urine include those directed at foreign body from self-instrumentation of the urethra, trauma, sexual abuse, and menstruation. Extreme sports activities such as running a marathon or long distance cycling can cause gross hematuria.

Review of the **family history** is important to uncover hereditary nephritis, hereditary cystic kidney disease, or potential benign familial hematuria. A family history of kidney disease leading to end-stage renal failure, especially if in men in multiple generations and if not clearly due to diabetes mellitus, would suggest Alport syndrome, the most common cause of hereditary nephritis. **Alport syndrome** is an X-linked recessive disorder that may cause gross hematuria in childhood although more often it is microscopic. When gross hematuria occurs in Alport syndrome, it is often triggered by any infectious process such as a common cold. The gross hematuria then subsequently clears, but microscopic hematuria is a persistent finding. The early clinical features of hereditary nephritis can be exactly the same as benign familial hematuria, but then evolve to develop other features. Early in the course of the disease, there is no associated proteinuria, but that feature develops later, often in childhood as the nephritis progresses. Hearing loss is a common but variable feature of Alport syndrome that tends to run in affected families. Female family members who are carriers usually have persistent and isolated hematuria that does not progress, but on occasion may develop progressive nephritis.

TABLE 20.1 Urine Discoloration from Sources Other Than Hematuria

Pink, Red, Cola-Colored, Burgundy

Disease Associated

Hemoglobinuria*	Porphyrinuria
Myoglobinuria*	

Associated with Drug or Food Ingestion

Aminopyrine	Nitrofurantoin
Anthocyanin	Phenazopyridine
Azo dyes	Phenolphthalein
Beets	Pyridium
Blackberries	Red food coloring
Chloroquine	Rifampin
Deferoxamine mesylate	Rhodamine B
Iron sorbitol	Rhubarb
Methyldopa	Sulfasalazine
	Urates

Dark Brown, Black

Disease Associated

Alkaptonuria	Methemoglobinemia
Homogentisic aciduria	Tyrosinosis
Melanin	Bile pigments

Associated with Food or Drug Ingestion:

Alanine	Resorcinol
Cascara	Thymol

*Heme tests positive.

TABLE 20.2 Laboratory Testing in Suspected Glomerulonephritis*

Symptoms	Suspected Glomerulonephritis	Laboratory
History of preceding pharyngitis, URI, or impetigo	Acute postinfectious GN	C3, C4 complement (low C3, normal C4)
Arthralgia, purpura, pedal edema, abdominal pain, hematochezia	Henoch-Schönlein purpura	Skin biopsy
Arthritis, rash, fever, oral ulcers, weight loss, alopecia, weakness, central nervous system symptoms, other systemic symptoms	Systemic lupus erythematosus	C3, C4 (both low) ANA, anti-ds DNA (both high)
Family history of renal failure, hearing loss, hematuria	Familial nephritis–Alport syndrome	Audiogram, slit lamp exam, genetic testing
Recurrent, painless gross hematuria	IgA nephropathy	None (kidney biopsy)
Hemoptysis, cough, fevers	Goodpasture syndrome	anti-GBM Ab
Rash, sinus disease, hemoptysis, systemic symptoms	ANCA-associated vasculitis	ANCA

*All patients: serum creatinine, electrolytes, complete blood count, random urine protein:creatinine ratio, 24-hr urine collection for protein.
Ab, antibody; GN, glomerulonephritis; URI, upper respiratory infection; ANA, antinuclear antibody; anti-ds (native) DNA, anti-double stranded DNA antibody; anti-GBM, anti-glomerular basement antibody; ANCA, antineutrophil cytoplasmic antibody.

TABLE 20.3 **Causes of Gross Hematuria in Children**
Glomerular
Primary
Acute postinfectious glomerulonephritis
IgA nephropathy*
Mesangial proliferative glomerulonephritis
Membranoproliferative glomerulonephritis
Familial nephritis (Alport syndrome)
Benign familal hematuria - thin basement membrane disease
Rapidly progressive glomerulonephritis
Systemic
Henoch-Schönlein purpura
Systemic lupus erythematosus
Hemolytic uremic syndrome
ANCA-associated vasculitis
Goodpasture disease (rare in childhood)
Bacterial endocarditis
Interstitial Disease
Pyelonephritis
Acute interstitial nephritis
Polycystic kidney disease (autosomal dominant)
Vascular
Trauma
Sickle cell disease and trait
Renal artery/vein thrombosis
Arteriovenous malformation
Nutcracker syndrome
Sports- and exercise-induced hematuria
Hemangioma/hamartoma
Neoplastic
Wilms tumor
Renal cell carcinoma
Uroepithelial tumors
Rhabdoid tumors
Congenital mesoblastic nephroma
Angiomyolipoma
Urinary Tract
Cystitis
Bacterial
Viral (adenovirus)
Parasitic (schistosomiasis)
Tuberculosis
Cyclophosphamide
Urethritis
Urolithiasis
Idiopathic hypercalciuria without urolithiasis
Trauma
Hydronephrosis, severe
Foreign body
Bleeding Disorders
Hemophilia A or B
Platelet disorder
Thrombocytopenia
Coagulopathy, congenital or acquired

*Common cause of asymptomatic gross hematuria.

Benign familial hematuria and familial thin basement membrane nephropathy are also responsible for both microhematuria and gross hematuria. The primary difference in family history that separates benign familial hematuria from progressive hereditary nephritis is that members of sequential generations of the family with benign familial hematuria, either male or female, have persistent isolated hematuria that never progresses to significant renal disease. The genetics of benign familial hematuria due to thin basement membrane nephropathy has been defined and includes mutations that are identical to those seen in some patients with *autosomal* recessive forms of progressive hereditary nephritis. Patients with thin basement membrane nephropathy, or benign familial hematuria, may be carriers of genes that cause autosomal recessive Alport syndrome.

Patients with **autosomal dominant polycystic kidney disease (ADPKD)** may present initially with gross hematuria from spontaneous bleeding into the macrocysts. Because the course of ADPKD can vary widely from one generation to the next, with some members having very mild disease with minimal clinical features until late adulthood, the family history of the disease may not be apparent on presentation. Early onset of hypertension, during youth or young adulthood in a parent of an affected child, may be the only clue to a family member being affected by ADPKD.

Gross hematuria is a presenting complaint in 15% of children with **urolithiasis**. Kidney stone disease can be familial and in some cases related to specific genes, as in X-linked recessive nephrolithiasis (Dent disease) or primary hyperoxaluria. Therefore, family history of early-onset nephrolithiasis, especially in siblings, should be sought in children presenting with gross hematuria and symptoms or imaging that indicate kidney stone disease as the cause. A family history of a bleeding disorder such as hemophilia or platelet disorders should be sought.

◆ Physical Examination

The initial focus of the physical examination should be for evidence of systemic disease for which the hematuria is one manifestation, and for potential sequelae of renal disease. Accurate measurement and attention to blood pressure, recognizing age differences in blood pressure, is critical. **Hypertension** may be the sole feature on physical examination that indicates underlying acute glomerulonephritis, or chronic kidney disease from several causes. The finding of **edema** in this context is highly suggestive of underlying renal parenchymal disease, either acute or chronic, with likely accompanying renal insufficiency. **Poor growth** or failure to thrive may indicate chronic renal disease. Pallor, fever, rashes, or musculoskeletal findings suggest systemic vasculitis with renal involvement from diseases such as HSP, SLE, or less often, ANCA-associated disease. Examination of the abdomen may reveal abdominal or flank masses that could be tumors, cystic kidneys, or urinary obstruction. The most common renal tumor in childhood, typically seen in young children (ages 1-4 years), is Wilms tumor, though other types occur. Hydronephrosis or enlarged cystic kidneys may be palpable. Suprapubic tenderness may indicate bladder infection, stone, or other less common causes of bladder pathology as the source of blood. The genitalia may need to be inspected for blood at the urethral meatus that suggests a urethral source, tears or lacerations due to abuse or accidents such as from straddle injuries, or to look for a foreign body.

◆ Evaluation
Laboratory Tests

Macroscopic and microscopic examination of the urine is the first essential step in laboratory evaluation. If no heme is found on macroscopic examination, then other causes of urine discoloration need to be considered (see Table 20.1 and Fig. 20.1). If the urine is heme

STEP 1

Confirm hematuria with
• Urine dipstick
• Urine microscopic examination

Dipstick negative
No RBC seen

Evaluate for
pigment

Significant red blood cells (RBC) seen

STEP 2

Symptoms and signs of acute nephritic
syndrome, e.g., edema, hypertension, oliguria

Yes

Urine protein/creatinine
ratio, serum urea, creatinine,
electrolytes, albumin
Serum complements C3 and
C4, ASO or anti-DNAse B
ANA, anti-dsDNA
antibody, ANCA (if
pulmonary hemorrhage
present)

No

STEP 3

Macroscopic hematuria: exclude preceding
exercise.
Isolated microscopic hematuria: repeat
urinalysis weekly × 2 (without exercise).
Investigate if persistent hematuria.

STEP 4

Urine phase contrast microscopy
Urine protein/creatinine ratio

STEP 5

NON-GLOMERULAR
*Isomorphic RBC, no casts, no
proteinuria*

GLOMERULAR
*Dysmorphic RBC, RBC casts,
proteinuria*

• Urine calcium/creatinine ratio
• Urine culture
• Urine adenovirus culture
• Renal ultrasound and Doppler
• Coagulation screen (full blood count,
  PT, PTT)
• Abdominal X-ray (in cases of
  urinary tract calculi)
• 24-hr urine calcium, uric acid,
   oxalate, cystine (in cases of renal
   calculi)
• CT abdomen (in cases of trauma or
  tumor)
• Magnetic resonance angiography (if
  nutcracker syndrome is suspected)

• Serum urea, creatinine, electrolytes
• 24-hr urine protein and creatinine
  clearance
• Serum complements C3 and C4
• Serum IgA
• Renal ultrasound
• Test parents and siblings for
  hematuria
• Consider audiology
• Consider renal biopsy if indicated

Investigations normal
Intermittent hematuria

Follow up with yearly urinalysis

FIGURE 20.1 Algorithm for investigating hematuria. ANA, antinuclear antibody; ANCA, antineutrophil cyto-plasmic antibody; ASOT, antistreptolysin titer; CT, computed tomography; IgA, immunoglobulin A; PT, pro-thrombin time; PTT, partial thromboplastin time. (From Yap HK, Lau PYW. Hematuria and proteinuria. In: Geary DF, Schaefer F, eds. *Comprehensive Pediatric Nephrology.* Philadelphia: Elsevier; 2008:183.)

positive on macroscopic examination, but no red cells are found on microscopic examination of the urine sediment, then myoglobin-uria or hemoglobinuria need to be considered as the possible source, since **rhabdomyolysis** and **acute hemolysis** are both potential life-threatening diseases that require immediate attention. If urine is heme positive but no red cells are seen, and there is no evidence for rhab-domyolysis or acute hemolytic disease, then other reasons for the findings need to be considered. Urine test strips can on occasion be falsely positive for blood if the urine is infected with peroxidase-producing bacteria. More likely is that red cells were present but lysed in urine that either was very dilute or was held for an extended time before microscopic examination was performed. Finding red cell casts in a resuspended pellet of spun urine (centrifuged 3-5 minutes at 1500-2000 rpm) under high-power field is a clear indication that the source of hematuria is glomerular. While the specificity of this finding in localizing the source to the glomerulus is high, the sensitivity of finding red cell casts in the hands of clinical labs is low. When red cell casts have been found in the urine sediment by experienced nephrologists, clinical laboratory reports of finding RBC casts in the urine of the same patients is very low. Unless the urine is thoroughly examined by an experienced clinician, the lack of RBC casts in a lab report does not lower the chance the patient might have a glomerular source of the hematuria. Another finding on microscopic examination of the urine sediment that suggests a glomerular source is the pres-ence of a significant number of dysmorphic red cells (see Fig. 20.1). This finding requires careful inspection of erythrocyte morphology and is best done with a phase-contrast microscope. Clinical labs do not report the number of dysmorphic red cells present, in part because differentiating dysmorphic RBCs from simple crenated RBCs (a result of osmotic shrinkage of RBCs) takes an experienced eye. Keeping these caveats in mind, if an experienced clinician finds RBC casts or a significant number of dysmorphic RBCs in a patient with hematuria, subsequent testing can be focused on identifying potential glomerular causes of hematuria, avoiding unnecessary, costly, or potentially inva-sive imaging procedures.

An additional feature of urinalysi that may help guide to the source of the red cells include the presence of proteinuria. Gross hematuria from lower tract bleeding can result in urine positive for protein, particularly if any lysis of urinary red cells occurs, but usually is <2+ proteinuria by dipstick reading. *Anything greater than 2+ proteinuria should raise suspicion of glomerular disease, especially if the hematuria is only microscopic.* Bacteria and significant pyuria

suggest pyelonephritis or cystitis, but pyuria can also be a feature of acute suppurative glomerulonephritis. Quantification of the gross hematuria using a "urocrit," with a result >1% can indicate lower tract bleeding.

All patients with suspected glomerulonephritis or suspected chronic kidney disease should have prompt assessment of their renal function with a serum creatinine, and a complete blood count. Serologic studies for immune-mediated glomerulonephritis should be performed including complement levels (C3, C4), antinuclear antibody, and anti–double-stranded DNA antibody. Antineutrophil cytoplasmic antibody titers (ANCA) and anti–glomerular basement membrane antibody titers should also be obtained if vasculitis or pulmonary renal syndromes are suspected (see Table 20.2 and Fig. 20.1).

The diagnosis of most cases of postinfectious glomerulonephritis (GN) can be made clinically. The diagnosis of HSP is also made clinically, but skin biopsy of purpuric lesions demonstrating vasculitis with predominantly IgA deposits can be supportive evidence. A kidney biopsy is often needed to define other forms of glomerulonephritis, especially primary, idiopathic glomerulopathies. In addition, even if the diagnosis of vasculitis is made on clinical and serologic criteria, staging of the severity of renal disease with renal pathology, such as in SLE, HSP, or ANCA-positive disease, is important for guiding therapy. High levels of proteinuria are often an indication to obtain a kidney biopsy to provide a diagnosis or stage the severity of the lesion in several forms of glomerulonephritis. The degree of proteinuria can be assessed with a 24-hour urine collection, or with a spot urine protein : creatinine ratio (see Chapter 19).

A urine culture is indicated in patients with any bladder symptoms, fever, flank pain, or abdominal pain. Gross hematuria can also be seen with nonbacterial infections such as tuberculosis, adenovirus, or schistosomiasis. In immunocompromised patients, BK polyoma virus can cause prominent cystitis.

Idiopathic hypercalciuria can be a cause of gross hematuria. It is characterized by excessive urinary calcium excretion in the absence of hypercalcemia or other known causes of hypercalciuria (Table 20.4). The hematuria is thought to be secondary to calcium oxalate and phosphate crystals adhering to urothelium. The risk of developing kidney stones is not known. Although often asymptomatic, hypercalciuria is also implicated in causing urinary symptoms including abdominal and flank pain. Therefore, in a patient who has any such symptom concomitant with gross hematuria, especially if UTI and anatomic causes of hematuria are ruled out, urinary calcium should be measured.

Hypercalciuria is defined by a 24-hour urine for calcium excretion >4 mg/kg/day. A spot urine calcium : creatinine ratio of >0.22 is considered abnormal in the older child and adolescent, but normal values may be significantly higher in younger children, especially those less than 7 years of age.

Imaging and Cystoscopy

Renal imaging with noninvasive ultrasonography is recommended in all cases of gross hematuria, unless strong evidence for glomerulonephritis is found on clinical grounds as detailed earlier. Ultrasound is excellent in children to investigate potential urologic and congenital abnormalities, as well as certain genetic diseases including polycystic kidney disease and those causing nephrocalcinosis, such as Dent disease. The ultrasound should include imaging of the bladder, which can identify rare bladder tumors, as well as find evidence of obstructive urologic disease. Ultrasound can also provide some evidence for renal parenchymal disease. Enlarged, echogenic kidneys with poor corticomedullary differentiation may be seen in significant glomerular or interstitial nephritis. Nephrolithiasis or calcinosis may be found on ultrasound, as well as hydronephrosis secondary to urinary

obstruction from lower tract kidney stones. Urolithiasis may be missed on ultrasound; if the history and examination are highly suggestive of a stone as the source of the hematuria, a CT scan is then necessary.

Computed tomography (CT) imaging is most useful to identify kidney stones (using the helical technique) and is the primary indication to perform this study. CT also provides detailed images of the bladder, pelvis, and retroperitoneum when looking for masses. Angiogram of the kidney may be necessary to identify an arteriovenous malformation of the kidney.

Cystograms generally have no major role in the evaluation of gross hematuria unless there is ultrasound evidence of bladder outlet obstruction from unrecognized urethral valves, or an unusual mass such as a urothelial tumor, rhabdomyosarcoma, or fibromatous polyp. Cystoscopy is rarely indicated in the usual evaluation of hematuria in children. However, if passing blood clots is part of the presentation, or if renal and bladder ultrasound shows a bladder mass or an obstructive lesion, cystoscopy may then be definitive in diagnosing bladder and ureteral sources of bleeding and provides an opportunity to obtain tissue for diagnosis. Cystoscopy may also be helpful to look for unilateral bleeding from one ureter, which can be seen with renal papillary necrosis, or more uncommon lesions such as vascular malformations of the bladder or ureter, all of which can be difficult to define by radiologic methods.

MICROSCOPIC HEMATURIA

While thorough evaluation of gross hematuria is always warranted, how far to proceed with the evaluation of microscopic hematuria can

be a difficult question. Much depends on the context in which the microscopic hematuria was identified. Thorough evaluation of microscopic hematuria identified on a screening urinalysis at a well-child visit rarely reveals an etiology. One exception is when there is a **family history** of renal disease known or suggestive to be from hereditary nephritis. In that context, particularly if in a pattern indicative of Alport disease where there can be associated hearing loss, performing a screening urinalysis to determine whether a child may be affected is reasonable. The lack of any hematuria in an older child effectively rules out that child having hereditary nephritis. If microscopic hematuria is found, additional noninvasive study can help define whether a child has Alport disease, including audiometry to evaluate for subclinical high frequency hearing deficit and examination by an ophthalmologist who can identify retinal or lens abnormalities that are characteristic of Alport disease. If no hearing or ophthalmologic abnormalities are found, and if proteinuria accompanies microscopic hematuria in a child from a family affected by hereditary nephritis, further investigation may include collagen IV gene sequencing or kidney biopsy.

When microscopic hematuria is found on urinalysis performed because of symptoms or signs, further evaluation is then indicated. If the presentation was with urinary symptoms or abdominal or flank pain, urine culture and imaging of the urinary tract, first with ultrasound to include the bladder, is the first step. If those tests are not revealing, and particularly if abdominal or flank pain is colicky, abdominal CT scan with kidney stone protocol is then indicated. If imaging studies are normal and urine culture is negative, evaluation for idiopathic hypercalciuria may then be pursued.

Abnormalities on physical examination that led to a urinalysis being performed should drive further evaluation for underlying intrinsic kidney disease. Specifically, if hypertension, edema, or failure to thrive triggered the urinalysis, blood tests to assess kidney function and complete blood count should be performed. If acute glomerulonephritis is suspected because of prodromal illness, hypertension, or edema, blood complement C3 and C4 levels should also be measured. If other symptoms or signs suggest possible systemic vasculitis, testing for lupus or ANCA-associated disease should then be considered. If the patient has had poor growth suggesting a chronic process, or supportive evidence for acute nephritis is lacking, renal ultrasound may identify small kidneys indicating a chronic nephropathy, obstructive nephropathy, or cystic kidney disease as the etiology.

MORE COMMON CAUSES OF HEMATURIA

Postinfectious Glomerulonephritis

Gross hematuria appearing 5 days to 4 weeks after a febrile illness suggests a diagnosis of acute postinfectious glomerulonephritis (PIGN), the most common form of acute nephritis in childhood. The typical child with PIGN is school age. The classical findings are hematuria, oliguria, edema, some level of renal insufficiency, and hypertension. It is not uncommon for PIGN to be asymptomatic, and hypertension may not be a feature at initial presentation. The child with suspected PIGN requires close follow-up including monitoring for the development of hypertension, since severe symptomatic hypertension is a common sequela of acute PIGN.

PIGN is a self-limited disease that in the vast majority of cases resolves without the development of chronic kidney disease or established hypertension. Microscopic hematuria is present in virtually all cases; gross hematuria is present in about 30%. The urine is commonly described as smoky or tea- or cola-colored. The gross hematuria usually disappears in 3-5 days; proteinuria disappears in several weeks, and microscopic hematuria resolves in months to 1 year. Group A streptococcal (GAS) infection is the most well-defined cause, described

in up to 80% of patients with PIGN, with the triggering infection being either pharyngeal or impetiginous. Other infectious agents have also been implicated in causing PIGN, including several other bacteria and viruses.

The criteria for diagnosis of PIGN relies on defining the clinical picture, supported by finding glomerular hematuria (red cell casts or many dysmorphic RBCs) in the urine sediment by an experienced examiner, and a simple serologic pattern. Practitioners will commonly perform serologic testing for streptococcal infection, an old habit that is not typically informative. Serology positive for anti-streptococcal antibodies at presentation is neither necessary nor sufficient to confirm, nor does the absence of such antibodies rule out, the diagnosis of PIGN. Evidence of recent streptococcal infection can be helpful, and may be provided by positive culture for GAS in the correct time frame preceding onset of nephritis. Most important is testing C3 serum complement level at presentation. In nearly all cases of PIGN, C3 level is low at presentation, then returns to normal by 6-12 weeks after presentation, as the nephritis spontaneously resolves. If the serum C3 level does not return to normal, other causes of nephritis need to be considered, including lupus nephritis, membranoproliferative glomerulonephritis (MPGN), or C3 nephropathy. The complement pattern in active lupus nephritis often is a low C4 along with the low C3 level. In MPGN or C3 nephropathy, C4 is usually normal with persistently low C3. If C3 level is normal at presentation of glomerulonephritis, other etiologies need to be considered, including several idiopathic forms that may only be diagnosed by kidney biopsy (see Tables 20.2 and 20.3).

Therapy for postinfectious GN is symptomatic, with particular attention to hypertension. Early treatment of the streptococcal infection does not prevent development of nephritis. The acute complications from PIGN are principally from hypertension and may include seizures, hypertensive encephalopathy, and heart failure. The prognosis of PIGN is excellent. Mortality is low at ~0.5%. While some level of renal insufficiency is typical, fulminant renal failure is uncommon. Complete recovery occurs in over 95% of patients, with an occasional patient developing rapidly progressive, crescentic GN or indolent chronic GN that progresses to end-stage kidney disease. Recurrent hematuria and proteinuria can occur in patients who have a nonspecific upper respiratory tract illness within several months following the episode of PIGN, but it is unusual for the other features of acute nephritis (hypertension and renal insufficiency) to recur.

Immunoglobulin A (IgA) Nephropathy

Recurrent episodes of painless, gross hematuria are a common presentation of childhood IgA nephropathy. This form of glomerulonephritis is common in both children and adults, with the mean age of presentation in children being 9-10 years. Episodes of gross hematuria are triggered by upper respiratory illnesses, but in contrast to postinfectious GN where the illness precedes onset of hematuria, in IgA nephropathy the illness is concurrent with onset of gross hematuria. Serum complement is normal. Serum IgA levels have been found to be elevated in only 8-16% of affected children, so are not helpful in the diagnosis. Confirmation of the diagnosis is possible only by renal biopsy demonstrating immune deposits of primarily IgA in glomeruli, principally in the mesangium. A wide range of histologic glomerulopathy can be found in IgA nephropathy, ranging from mild mesangial proliferation to crescentic, rapidly progressive GN. Most cases of IgA nephropathy have a benign pattern, with recurrent episodes of gross hematuria during illnesses, followed by complete resolution of gross hematuria within days. Between episodes, the urine may be free of blood or may show persistent microscopic hematuria but lack of proteinuria. This benign pattern commonly does not progress nor require

(See *Nelson Textbook of Pediatrics,* Fig. 511-3.)

treatment. However, the disease is quite variable between patients, with some developing acute nephritic symptoms, acute renal failure, nephrotic syndrome, or progression to end-stage kidney disease in up to 10% of affected children. No specific therapy exists for IgA nephropathy, but an extended course of steroid therapy can be beneficial for patients with more severe forms of IgA nephropathy, including those with acute nephritic syndrome or nephrotic-range proteinuria.

Hereditary Nephritis

A family history of renal disease with progression to renal failure, restricted to male members of the family on the maternal side, suggests a diagnosis of Alport syndrome, an X-linked recessive nephropathy. Affected patients uniformly have some level of hematuria beginning at an early age, even in infancy. The majority of affected children develop hematuria in the school-age years. Initially the hematuria is an isolated finding, but as the disease progresses proteinuria develops. Often there is accompanying development of progressive deafness. Female members of the family who carry the gene usually have isolated microscopic and sometimes periodic macroscopic hematuria that does not progress to the other features of the syndrome. However, occasionally such individuals can develop progressive disease similar to male family members. The disease is caused by a mutation in a gene on the X chromosome that codes for a chain of collagen found in normal glomerular basement membranes; gene testing can help confirm the diagnosis. Renal biopsy provides a definitive diagnosis, which shows characteristic electron microscopic appearance of attenuation, disruption, and lamellation of the glomerular basement membrane. However, these findings may not occur until a later age when the nephropathy has progressed. Early findings may simply be thin glomerular basement membranes, which can be confused with the more benign entity, thin basement membrane nephropathy. No specific therapy exists, but treatment with an angiotensin-converting enzyme (ACE) inhibitor early in the course of the disease after proteinuria develops can slow the progression of the nephropathy.

There is also an autosomal recessive variant of hereditary nephritis that has been associated with mutations in genes that code for other chains of collagen found in the glomerular basement membrane. Progression of the nephropathy is similar to that of patients with the classical form of Alport disease. Individuals who carry a mutation in only one of these autosomal recessive genes may have simple, benign, thin basement membrane nephropathy that does not progress.

Some patients with a more common form of familial hematuria demonstrate persistent microscopic and recurrent gross hematuria *without* development of significant proteinuria or deterioration of renal function. This is called **benign familial hematuria**. Evidence of this cause of hematuria can be obtained when urinalyses are performed on other family members, finding isolated microscopic hematuria in other members of the family. Renal biopsy demonstrates normal light and immunofluorescent microscopic findings. Electron micrographs show uniformly thin basement membranes leading to it being termed "thin membrane nephropathy." It appears to be an autosomal dominant disorder; some such families have been reported to be carriers of mutations of collagen genes that are associated with autosomal recessive hereditary nephritis. This raises the possibility that benign familial hematuria is the hypomorphic state of progressive hereditary nephritis.

Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is a common disorder that mainly affects adults, but development of cysts may well begin in childhood, and in rare cases renal cysts may be present at birth. Usually the cysts are asymptomatic in childhood unless there is early and substantial cystic disease. Gross hematuria may be the first manifestation of this disorder and occurs in 50% of patients. It may occur spontaneously or be brought on by minimal trauma. The usual manifestations of the disease in adults (hematuria, hypertension, abdominal mass, and uremia) are seldom seen in children. Furthermore, adults tend to have associated problems not commonly seen in affected children, including acute and chronic pain (60%), urinary tract infection, and nephrolithiasis (20%). With the widespread use of ultrasonography and CT for routine evaluation of acute abdominal pain, it is more common to detect early evidence of the disease as an incidental finding, sometimes presenting as a single renal cyst during childhood. Diagnosis requires finding multiple bilateral renal cysts. Because the primary gene that causes ADPKD lies near the gene that causes tuberous sclerosis, the two diseases occasionally coexist as a contiguous gene deletion syndrome. Renal involvement in patients with tuberous sclerosis may be isolated to renal angiomyolipomas or may also manifest PKD as well, either of which can be a source of gross hematuria.

In contrast to ADPKD, **autosomal recessive polycystic kidney disease (ARPKD)** typically has early onset and evidence of renal disease is often found on prenatal ultrasound. If not discovered in the perinatal period, it may present later in infancy or early childhood as an abdominal mass with hypertension. Typically, the kidneys are significantly enlarged and have a cystic appearance different from ADPKD. However, it is not always possible to distinguish early-onset ADPKD from ARPKD on radiologic grounds.

Nephrolithiasis can occur at any age and may cause the symptoms of renal colic, manifested as intense, episodic flank pain that often radiates to the groin. In young infants, nephrolithiasis and thus renal colic is rare, and may manifest as generalized irritability or abdominal pain. Gross hematuria has been reported in ~25% of patients with nephrolithiasis. The physical examination may be unrevealing; the urinalysis may contain crystals in addition to red blood cells. A high-resolution CT scan is the best study to confirm the presence of a stone. Children with nephrolithiasis should have an evaluation for a metabolic cause of their kidney stones. This begins with a 24-hour urine collection for calcium, urate, citrate, oxalate, cystine, and creatinine. The determination of creatinine excretion is important to ensure that an adequate collection has been obtained (a minimum of 10-15 mg/kg/24 hr, depending on age and body habitus of the child). If an abnormality is found, specific therapy may prevent or delay subsequent complications, which can include frequently recurring stones and acute or chronic renal failure.

Hypercalciuria (defined as urinary calcium levels above 4 mg/kg/day) is the most common metabolic abnormality found in children with nephrolithiasis. Furthermore, hypercalciuria without an overt stone can manifest as gross hematuria with abdominal or flank pain. Hypercalciuria can be idiopathic or secondary to another disease, such as renal tubular acidosis. Therapy depends on the cause of the hypercalciuria or the specific type of stone.

Urinary tract infection is the most common identifiable cause of gross hematuria, with as many as 25% of children presenting with gross hematuria having a documented symptomatic urinary tract infection. Urine culture is essential for a diagnosis of urinary tract infection, and should be performed in all children with gross hematuria, especially if any urinary symptoms accompany.

UNCOMMON CAUSES OF HEMATURIA IN CHILDHOOD

Coagulation abnormalities and hemoglobinopathies are rarely found in patients with gross hematuria. **Sickle cell disease** is the most likely

(See *Nelson Textbook of Pediatrics,* p. 2497.)

(See *Nelson Textbook of Pediatrics,* p. 2515.)

(See *Nelson Textbook of Pediatrics,* p. 1065.)

cause in this category, and gross hematuria is one of the few manifestations of the carrier state that may develop in those with sickle cell trait. A combination of low oxygen tension, reduced blood flow, low pH, and high osmolality in the renal medulla makes a hostile environment that induces sickling and sludging of erythrocytes there. This results in areas of infarction and hemorrhage and can progress to renal papillary necrosis. While the gross hematuria often is asymptomatic, if papillary necrosis ensues or hemorrhage from the renal medulla is substantial with passage of clots, acquired ureteral obstruction can cause significant associated flank or abdominal pain. Therapy is hydration and rest.

Renal vascular thrombosis, particularly renal vein thrombosis, may present with isolated gross hematuria. Two groups of children are at highest risk for this problem. The first group is sick neonates. Renal vascular thrombosis in this group can originate from events associated with perinatal stress that cause hypotension and decreased perfusion to the kidney, umbilical vascular catheters, trauma, hypercoagulable states, dehydration, or disseminated intravascular coagulation. Infants of diabetic mothers are more prone to renal vein thrombosis, possibly because of polycythemia or other associated perinatal stress. The thrombosis in the neonate can be in the renal artery but most often is in the renal vein. Along with gross hematuria, accompanying clinical features may include a palpable enlarged kidney on the affected side, hypertension, and thrombocytopenia. The second group of children who are susceptible to renal vascular thrombosis are those with **nephrotic syndrome**, with the well described associated hypercoagulable state (see Chapter 19). The diagnosis of renal vein thrombosis can be suspected from the patient's history and can be confirmed with a Doppler flow study of the renal vasculature. Several treatment approaches have been advocated. In many cases, careful attention to hydration and hemodynamic status in the neonate, and administration of albumin in the patient with nephrotic syndrome stabilizes the patient with no further progression of the thrombus. With large thrombi that propagate to the vena cava or affect both kidneys, anticoagulation is considered. Renal vein thrombi, even with isolated supportive care, often resolve without late renal sequelae. However, late sequelae of hypertension and renal atrophy can occur. The less common renal artery thrombi more often result in significant renal injury and atrophy.

Renal and bladder **tumors** are rare causes of gross hematuria in children. Wilms tumor, the most common pediatric renal malignancy, usually manifests as a flank or abdominal mass, but on occasion can present with gross hematuria. Renal carcinoma is exceedingly rare in childhood, but can occur in older children and also may present as gross hematuria. Each of these tumors can be readily detected radiographically through ultrasonography or computed tomography, which is why imaging of the urinary tract to include the bladder is an important part of the evaluation of all children with gross hematuria unless the source of the blood has clearly been defined to be of glomerular origin.

Cyclophosphamide treatment can cause **hemorrhagic cystitis**, which can have accompanying severe bladder symptoms and hemorrhage. This results from prolonged contact of the toxic metabolites of cyclophosphamide with the bladder epithelium. Prevention is primarily with increased hydration to ensure high urine flow, and the use of mesna in patients receiving high-dose cyclophosphamide, a drug that prevents bladder mucosa toxicity from the metabolites.

High intensity or long-duration **physical exertion** can cause gross hematuria. Its pathophysiology is not known, but several mechanisms proposed include bladder or kidney trauma, hemolysis, dehydration, peroxidation of red cells, and renal ischemia.

Bleeding from **arteriovenous malformations** of the kidney, ureter, or bladder can manifest as asymptomatic gross hematuria, which often appears bright red. The blood can be localized to the bladder, one kidney, or ureter with cystoscopy. Endoscopic laser treatment can eliminate the source of bleeding. When bleeding from a vascular malformation is severe and not amenable to laser treatment, an angiograph and surgery are considered.

Nutcracker syndrome occurs when the left renal vein is compressed between the superior mesenteric artery and aorta, causing a rise in pressure and development of collateral veins with varicosities in the renal pelvis, ureter, and gonadal vein. It presents with left flank pain, hematuria, and occasionally a varicocele in males. Diagnosis can be difficult, but Doppler studies of the left renal vein, magnetic resonance angiography, and computed tomography may identify this entity.

Symptoms of urethritis with gross hematuria and a negative urine culture in boys suggest urethrorrhagia. The most common complaint is blood-stained underwear. Ultrasound including the bladder should be performed to rule out other lesions discussed earlier. Cystoscopy does not show a treatable lesion and may be contraindicated because of the possibility of producing a stricture. Low-dose, long-term antibiotic treatment may help in some cases. The condition appears to be benign and self-limited, so reassurance is the best approach.

Infections that are unusual in Western societies, but more common in other parts of the world can present with gross hematuria. *Schistosoma haematobium* causes bladder lesions, containing eggs and a surrounding granuloma, that may hemorrhage. Urinary symptoms of suprapubic pain, dysuria, or urgency are common. Chronic inflammation of the ureters may result in urinary obstruction. Diagnosis is made by biopsy of lesions found in the liver, rectum, or bladder, or by the detection of characteristic eggs in feces or urine.

Mycobacterium tuberculosis infection can involve the kidneys, resulting in formation of tuberculomas that may cavitate, rupture, and disseminate the bacterium throughout the urinary tract. Tuberculosis of the genitourinary tract most often occurs in young adults and is characterized by tubercles at the ureteral orifices.

Adenovirus is a common respiratory infection in children, which can cause a hemorrhagic cystitis. This complication occurs most often in immunocompromised patients, but on occasion can also affect normal, healthy children.

RED FLAGS

Blood visible in the urine commonly raises great concern in a child and the parents, and sometimes in the physician, but rarely heralds a serious disease. Parents frequently are concerned that hematuria is a manifestation of a malignancy, so this should be addressed initially with reassurance that it is very rare for the cause of hematuria in a child to be a tumor. The history of recent or current illness and the family history, as well as associated signs or symptoms, can usually direct the appropriate evaluation. The focus of testing initially should be on confirming the presence of hematuria, ruling out urinary infection with culture, assessing renal function with blood tests, and

exploring urinary tract anatomy with ultrasound. Invasive studies, such as cystoscopy or renal biopsy, are rarely indicated.

Features of the evaluation that require prompt attention include absence of red blood cells in the urine (which raises the concern for possible hemoglobinuria or myoglobinuria), hypertension, azotemia, pain, or a palpable mass. The presence of significant proteinuria suggests glomerular disease, which would require further evaluation by a nephrologist for consideration of renal biopsy.

Acute and Chronic Scrotal Swelling

John V. Kryger

The most serious causes of acute scrotal swelling are testicular torsion and incarcerated inguinal hernia, both of which necessitate immediate surgical correction. Consequently, a prompt, careful approach to a painful or inflamed scrotum is essential. The differential diagnosis of scrotal swelling is extensive and varies depending on the age of the patient (Tables 21.1 and 21.2). The most common causes include testicular torsion, torsion of the appendix testis, and epididymitis.

SCROTAL AND INGUINAL ANATOMY

Inguinal Region

The inguinal canal runs obliquely between the external and internal inguinal rings. The anterior wall of the canal is formed by the external oblique aponeurosis; the posterior wall is formed by the inguinal ligament and conjoined tendon. The oblique direction of the inguinal canal allows for the posterior and anterior walls to coapt with increases in intraabdominal pressure.

Testis Descent

The testes develop in the lumbar region of the abdominal cavity between the peritoneum and the transversalis fascia at approximately 7 weeks of gestation. By the 8th week of gestation, the gubernaculum extends from the caudal end of the epididymis through the inguinal canal to insert on the internal wall of the scrotum. The processus vaginalis, a finger-like outpouching of the peritoneum, extends adjacent to the gubernaculum to form the inguinal canal. As the processus vaginalis descends into the scrotum, it carries extensions of the abdominal wall layers.

The testis normally descends through the inguinal canal into the scrotum before birth. As the testis and spermatic cord descend through the inguinal canal, they are covered by the three concentric layers of the anterior abdominal fascia (Fig. 21.1). When the testis reaches the scrotum, the testis and surrounding layers of fascia and tunica vaginalis fuse to the dartos of the scrotum. The processus vaginalis is initially patent, leaving a connection between the scrotum and the peritoneal cavity. Normally, the processus vaginalis obliterates, leaving a residual tunica vaginalis surrounding the testis. Typically, the tunica vaginalis contains 1-2 mL of clear fluid.

Scrotum

The scrotum has 2 separate compartments, each containing a testis, epididymis, and distal spermatic cord. It comprises multiple layers that are continuous with the superficial layers of the anterior abdominal wall. The external location of the scrotum results in the temperature of the testes being 2-3°F below the core body temperature, which allows for normal spermatogenesis.

Testis

The testes are the male reproductive organs and are suspended in the tunica vaginalis of the scrotum by the spermatic cords. The epididymis, attached to the testis posteriorly, consists of the caput (upper pole), corpus (body), and cauda (tail) (Fig. 21.2). The vas deferens can be palpated as a narrow, firm, tubular structure in the spermatic cord. The epididymis is responsible for sperm maturation and storage. Each testis relies on 3 arteries for its blood supply: the testicular artery, the cremasteric artery, and the deferential artery. Each enters the scrotum through the spermatic cord. The testicle receives both sympathetic and parasympathetic innervation. These autonomic nerves carry impulses that, with testicular stimulation, produce symptoms of deep visceral pain and nausea.

DIAGNOSTIC STRATEGIES

◆ History

In evaluating acute or chronic scrotal swelling, the following historical elements should be established:

1. **Onset of pain**: Testicular torsion has a very sudden onset and can be precipitated by activity or can occur at rest or during sleep. Epididymitis or torsion of the appendix testis or other testicular appendage often has a more insidious onset over the course of days, with progressive pain and swelling.
2. **Duration of pain**: Episodic pain lasting seconds and abating is rarely pathologic, whereas severe pain, persistent pain, or episodes lasting more than 1 hour raise concern.
3. **Associated/radiation of pain**: If there is radiation of pain from the flank, then renal or ureteral pathologic processes, such as an obstructing ureteral calculus, should be considered. Inguinal discomfort may suggest hernia or other inguinal pathology.

Although sometimes nonspecific, associated manifestations are also important:

1. **General systemic**: Fever, chills, or rigors suggest an infectious cause.
2. **Abdominal signs/symptoms**: Nausea, vomiting, and abdominal or inguinal pain are common but nonspecific. They may indicate an intestinal process.
3. **Urologic signs/symptoms**: Dysuria, urinary frequency, hematuria, or penile discharge suggests an infectious process such as urinary tract infection, urethritis, or epididymitis.
4. **Unusual rashes**: Henoch-Schönlein purpura may result in vasculitis of the spermatic cord with associated scrotal pain and swelling.

In addition, a thorough medical history is imperative and should include the following:

1. History of urinary tract infections or renal calculi.
2. Prior sexual activity, which would raise the possibility of a sexually transmitted infection.
3. History of any surgical procedures on the groin, scrotum, or abdomen. Often an orchiopexy performed for an undescended testis places the testis in a dartos pouch, which would make testicular torsion unlikely in the future.

(See *Nelson Textbook of Pediatrics,* p. 2593.)

(See *Nelson Textbook of Pediatrics,* p. 2592.)

4. History of any previous episodes of testicular pain. Previous episodes of intermittent or severe pain in the same testis may be secondary to intermittent torsion of the testis.
5. Lower urinary tract pathologic processes, such as posterior urethral valves, neuropathic bladder, or urethral stricture (e.g., after trauma or hypospadias repair) may predispose to urinary tract infection, which could cause bacterial epididymitis.

TABLE 21.1 Differential Diagnosis of Scrotal Masses in Young and Adolescent Males

Painful	Painless*
Testicular torsion	Hydrocele
Torsion of testicular appendage (less common after adolescence)	Inguinal hernia (reducible)
	Varicocele
Epididymoorchitis	Spermatocele
Trauma: testicular rupture, hematocele	(postpubertal males)
Inguinal hernia (incarcerated)	Testicular tumor
Mumps orchitis	Paratesticular tumor
	Idiopathic scrotal edema
	Henoch-Schönlein purpura

*Occasionally associated with discomfort.

◆ **Physical Examination**

Examination of the scrotal contents should be performed in any male patient presenting with abdominal, inguinal, or scrotal pain. Essential components include inspection, palpation, and transillumination of any masses.

Pubertal development. In prepubertal males, torsion of the appendix testis is more common than testicular torsion (Table 21.3). Conversely, in the postpubertal male, testicular torsion and epididymitis (if the patient is sexually active) are more common.

Scars in the inguinal region. Scars may imply previous surgery for hernia, hydrocele, undescended testis, or varicocele.

Scrotal skin changes and fixation. Erythema suggests an underlying inflammatory process but is nonspecific. Duskiness or fixation of the skin over the testis is suggestive of testicular necrosis.

TABLE 21.2 Differential Diagnosis of Scrotal Swelling in Newborns

Hydrocele	Scrotal hematoma
Inguinal hernia (reducible)	Testicular tumor
Inguinal hernia (incarcerated)*	Meconium peritonitis
Testicular torsion*	Epididymitis*

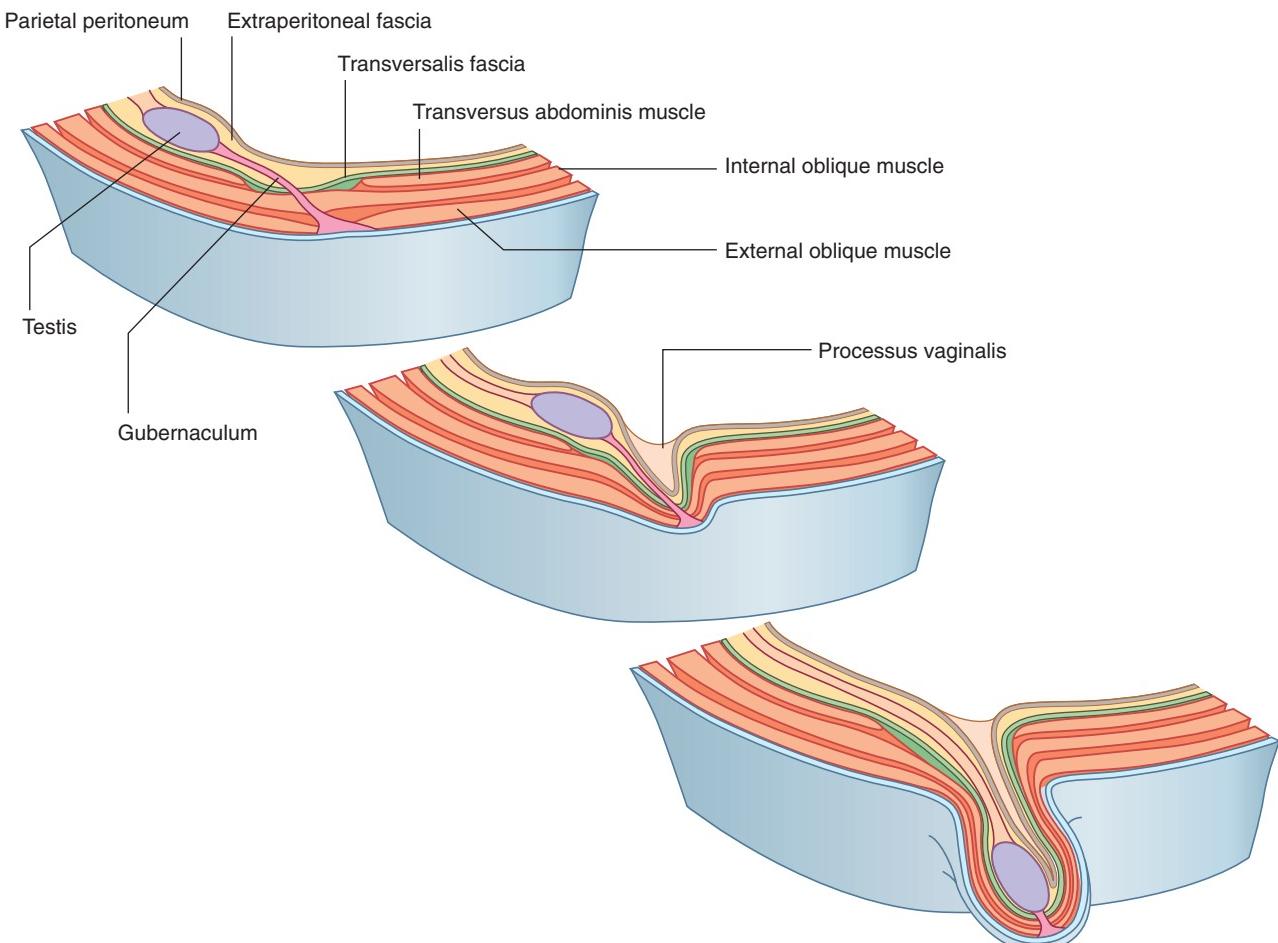
*May be associated with scrotal inflammation.


FIGURE 21.1 Descent of the testis from week 7 (postfertilization) to birth. As the testis and spermatic cord descend through the inguinal canal, they are covered by the three concentric layers of the anterior abdominal fascia. (From Drake RL, Vogl AW, Mitchell AWM, eds. *Gray's Anatomy for Students.* 3rd ed. Philadelphia: Churchill Livingstone; 2015:253-420.)

Testis position within the scrotum. A testis positioned high in the scrotum is suggestive of testicular torsion. The spermatic cord shortens as it twists. The affected testis should be compared with the contralateral testis with respect to size, consistency, and tenderness. Accurate localization of pain to the testis, epididymis, or both is important.

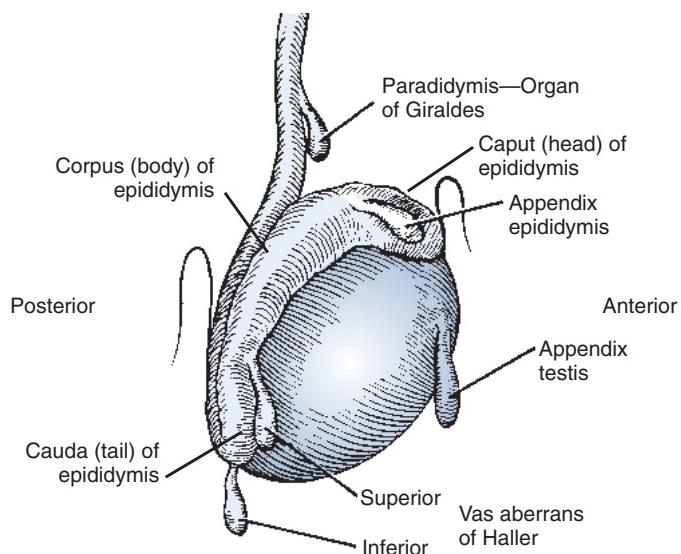
Cremasteric reflex. Stimulated by gently scratching the ipsilateral medial thigh, reflexive cremaster muscle contraction causes the scrotum to retract. The presence of a symmetric cremasteric reflex makes testicular torsion less likely. An absent cremasteric reflex is nonspecific. Sometimes with anxiety, the testis of a child will retract high into the inguinal canal. An important maneuver to relax the cremaster muscle is to examine the patient in a seated position with the legs crossed.


FIGURE 21.2 Lateral view of the testis showing the posterior location of epididymis and appendix testes. The appendix testis is present in almost all males, the appendix epididymis is present in approximately 50% of males, and the other appendages are rarely present. (From Kelalis PP, King LR, Belman AB, eds. *Clinical Pediatric Urology.* 2nd ed. Philadelphia: WB Saunders; 1985.)

◆ **Laboratory Data**

Basic laboratory evaluation of acute and chronic testicular swelling includes urinalysis, urine culture, and tests for *Chlamydia* and gonorrhea if the patient is sexually active (see Chapter 18).

◆ **Imaging Studies**

Imaging studies are often helpful in determining the cause of acute and chronic testicular or scrotal swelling. They should not be substituted for a thorough history and careful physical examination performed by a surgical specialist. The conditions necessitating immediate surgical treatment include testicular torsion, incarcerated inguinal hernia, and testicular rupture secondary to trauma; testicular tumor mandates urgent surgical attention. If the history and physical examination strongly support the diagnosis of testicular torsion, then prompt surgical exploration is recommended, without confirmation by an imaging study. If the history or physical findings are equivocal for testicular torsion, or if an alternate diagnosis requires investigation, **color Doppler ultrasonography** should be obtained. Sonography provides a relatively accurate image of the testis and epididymis, and color Doppler imaging assesses blood flow. It is performed by examining the uninvolved testis first and adjusting the color flow settings to detect normal flow. The affected testis is then examined for decreased or absent flow in comparison with the normal testis. Color flow Doppler imaging distinguishes between the increased collateral blood flow within the scrotal skin and the decreased blood flow to the testis in patients with testicular torsion. The sensitivity of Doppler ultrasonography for detecting testicular torsion ranges from 69-100%, and specificity ranges from 77-100%. Sonography can also help determine if a scrotal hematoma represents a testicular rupture. Color flow Doppler imaging accurately demonstrates increased flow resulting from torsion of the appendix testis or epididymitis, but is usually unable to distinguish these 2 entities. It also cannot distinguish viral from bacterial epididymitis. If a tumor is present, sonography can demonstrate whether the mass arises from the testis or paratesticular structures. It can also distinguish the presence of hydrocele, cyst, tumor, or varicocele. The test is quick, easy to perform, and noninvasive. There are several important limitations of color Doppler imaging:

TABLE 21.3 Differentiation of Acute Painful Scrotal Swelling in Childhood

	Testicular Torsion	Epididymoorchitis	Torsion of the Appendix Testis
Age	Usually perinatal and 12–18 yr, but any age possible	Usually adolescence, but any age possible	2–12 yr
Symptoms and signs	Abrupt onset; may have previous similar episodes	Gradual onset	Gradual onset
Pain	Localized to the testis and may radiate to groin and lower abdomen	Localization to epididymis; may involve entire testis after 24 hr	Localization to upper pole of testis; may involve entire testis after 24 hr
Fever	Rare	Common	Rare
Vomiting	Common	Rare	Rare
Dysuria	Rare	Common	Rare
Physical examination	Testis may be high riding, swollen, exquisitely tender; scrotal erythema may be present; cremasteric reflex absent	Testis and epididymis are firm, tender, swollen; scrotal erythema may be present; cremasteric reflex present	Testis is normal or enlarged; firm mass may be seen or felt at upper pole, distinct from epididymis; scrotal erythema may be present; cremasteric reflex present
Pyuria, urinary infection	Rare	Possible, particularly in bacterial epididymitis	Rare
Blood flow (color Doppler study)	Diminished or absent	Increased	Normal or increased

1. If the duration of torsion is brief and if the torsional rotation is incomplete, there may be venous congestion without impairment of arterial blood flow; color Doppler imaging may demonstrate normal or decreased blood flow.
2. In the prepubertal testis, blood flow may be difficult to demonstrate, even when the testes are normal, and absence of flow may be misinterpreted for testicular torsion.
3. The color Doppler aspect of the study is user dependent.

DIFFERENTIAL DIAGNOSIS

(Table 21.4; see also Table 21.3)

Testicular Torsion

Testicular torsion is a surgical emergency because of the risk of ischemic damage to the testis. The likelihood of testicular survival depends on the duration and severity of torsion. Consequently, testicular survival depends on accurate diagnosis and timely emergency management.

The incidence of spermatic cord torsion is 1 in 4000 among male patients younger than 25 years. The peak ages for testicular torsion are in the neonatal period, as well as from the ages of 12-18 years. The pathogenesis of torsion and the presentation in these two age groups are different.

In testicular torsion, the testis and spermatic cord rotate or twist within the tunica vaginalis (termed "intravaginal" torsion), resulting in obstruction of venous drainage, followed by compromise of arterial flow and subsequent infarction (Fig. 21.3). In many instances of

TABLE 21.4 Causes of Acute Scrotal Pain

Common
Testicular torsion
Torsion of testicular appendage
Epididymitis (gonorrheal and/or chlamydial infection in sexually active adolescents)*
Trauma*
Scrotal edema (Henoch-Schönlein purpura)
Pain referred to scrotum (nephrolithiasis, ureteropelvic junction obstruction, appendicitis, spinal cord tumor, IgA nephropathy)

Less Common
Orchitis (mumps, varicella, coxsackievirus, dengue)*
Abscess
Infarction
Malignancy: primary testicular neoplasm (e.g., seminoma), germ cell (usually painless mass)
Leukemia: primary or relapse (usually painless swelling)*

Uncommon
Granulomatous orchitis*
Drug-induced epididymitis (amiodarone)*
Behçet disease
Sarcoidosis
Polyarteritis nodosa*
Epididymitis (tuberculosis, brucellosis, actinomycosis, leprosy, *Salmonella* infection, fungal infection, parasitic infestation, *Nocardia* infection)
Orchitis (rickettsial, *Nocardia* infections, toxoplasmosis, cytomegalovirus)
Testicular pyocele
Fournier gangrene

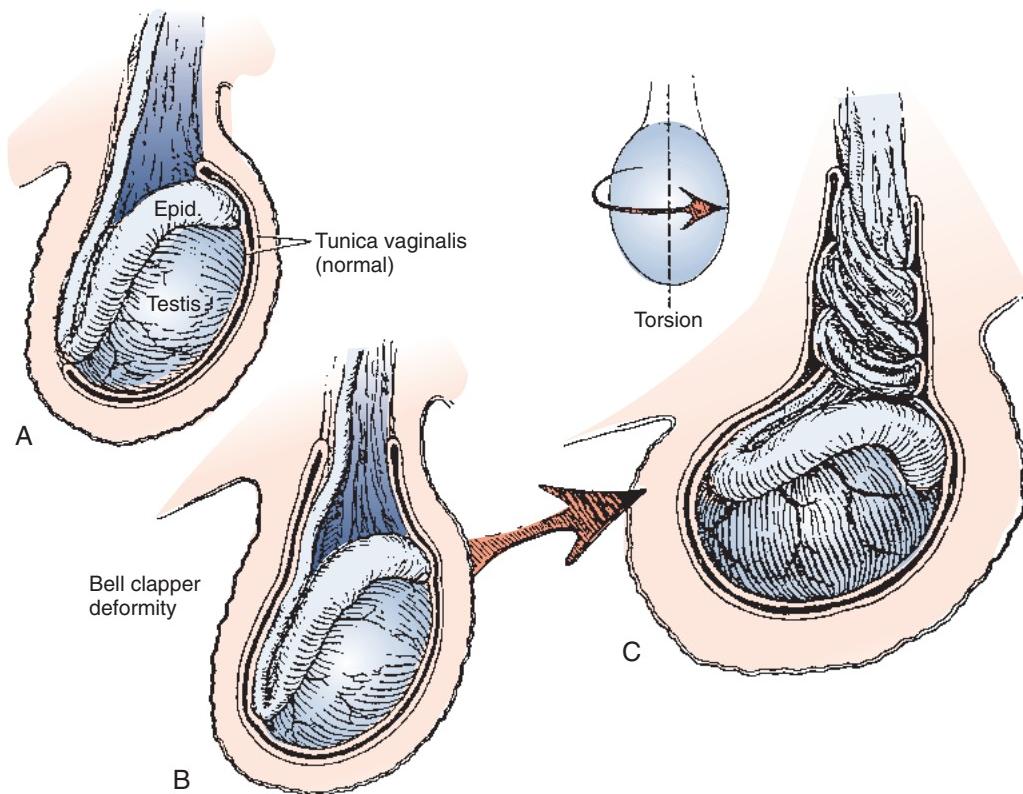
*Bilateral involvement possible.


FIGURE 21.3 *A* to *C,* Mechanism of testicular torsion associated with the bell clapper deformity. Epid, epididymis. (From Fleisher GR, Ludwig S. *Textbook of Pediatric Emergency Medicine.* 3rd ed. Baltimore: Williams & Wilkins; 1993.)

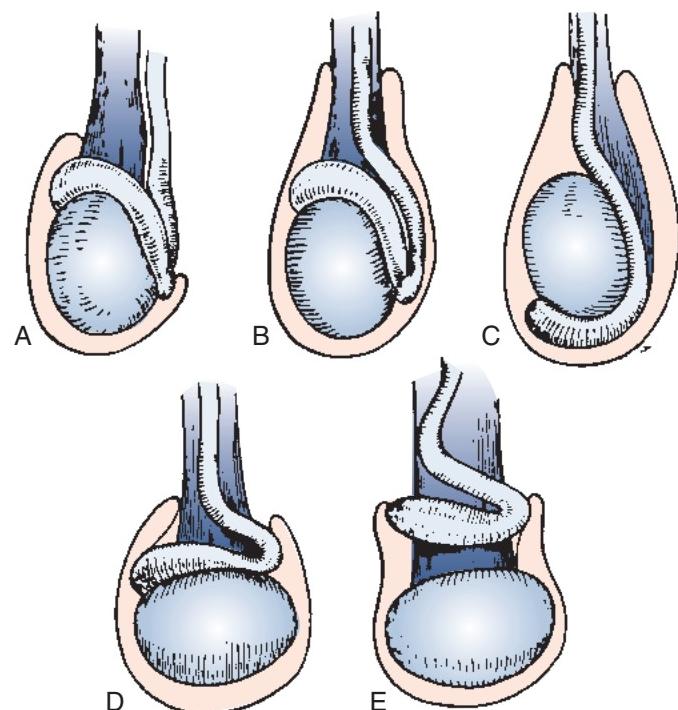
(See *Nelson Textbook of Pediatrics,* p. 2595.)

torsion occurring beyond the neonatal period, a preexisting anatomic abnormality termed the **bell clapper deformity** increases the likelihood of the testis rotating on the spermatic cord. The "bell clapper" refers to a redundant tunica vaginalis that inserts higher along the spermatic cord, allowing the testis to rotate freely within, and lie more transversely in the scrotum (Fig. 21.4). The deformity is common, present unilaterally in 17% and bilaterally in 40% of males.

The likelihood of irreversible testicular damage depends on the severity and duration of torsion. If the torsion results in complete ischemia, the testis may become necrotic within 6-12 hours; however, if testicular torsion is incomplete, there may be continued arterial perfusion for 24-48 hours. Because the viability of the testis cannot reliably be gauged based on the perceived duration of torsion, immediate surgical exploration should always be considered.

Patients with testicular torsion typically experience the sudden onset of severe testicular pain and swelling. The event is often incorrectly attributed to minor trauma or exercise, but pain may also occur independent of activity or suddenly awaken the patient from sleep. The pain is usually localized to the affected hemiscrotum, and patients may also report inguinal or abdominal pain. Associated symptoms may include nausea and vomiting. Up to half of patients describe previous episodes of severe scrotal pain that resolved spontaneously. Dysuria and other voiding symptoms are absent.

On examination, the scrotum is erythematous and edematous and the testis is enlarged and extremely tender. If the patient has been experiencing severe pain for more than 24 hours, there may be too much inflammation to delineate the scrotal contents. The cremasteric reflex is usually always absent, although this is not a perfectly reliable sign. The testis may be high in the scrotum with a transverse lie. Urinalysis results are negative. If testicular torsion has been present


for more than 48 hours, the scrotum is typically severely enlarged, erythematous, and edematous, and the testis is an enlarged and indurated mass. Color Doppler imaging typically reveals hyperemia in the scrotal wall and absent testicular blood flow.

In most cases, the diagnosis of testicular torsion can be made from the history and physical examination. If torsion is the likely diagnosis, scrotal exploration should proceed immediately and should not be delayed awaiting confirmatory imaging. If the diagnosis is uncertain, imaging should be obtained. Color Doppler ultrasonography typically demonstrates absent blood flow.

Some patients present with a history of severe testicular pain that resolved in the emergency room or on the way to the hospital. In these cases, **intermittent torsion** should be suspected. While immediate scrotal orchiopexy is not mandated under these circumstances, surgical fixation should still be considered, as the recurrence rate is high. Furthermore, some patients may fail to seek prompt medical evaluation in the event of recurrence because of fear of surgery or wishful thinking that the torsion will spontaneously resolve again.

Surgical management of testicular torsion consists of exploration, detorsion, and evaluation of testicular viability. An infarcted testicle is removed. If the testis is viable, orchiopexy is performed, in which the viable testis is fixed to the dartos layer of the scrotal wall with nonabsorbable sutures. Contralateral scrotal orchiopexy is also performed given the significant risk of contralateral torsion. If torsion is detected and treated within 4 hours of the onset of symptoms, the salvage rate approaches 100%; at 8-12 hours, it falls to 20%; and after 24 hours, infarction is likely.

Testicular torsion also occurs in the fetus and neonate. In these cases, torsion results from incomplete attachment of the gubernaculum and tunica vaginalis to the scrotal wall. The entire testis, epididymis, and tunica vaginalis twist in a process termed **extravaginal testicular torsion**. If torsion occurs prenatally, the testis is typically large and firm. The ipsilateral hemiscrotum may be ecchymotic if torsion occurred shortly prior to birth; although if torsion occurred more remotely, ecchymoses may have resolved by the time of delivery. Prenatal torsion always results in a nonviable testis. Postnatal extravaginal testicular torsion can occur up to 46 weeks corrected gestational age. Affected neonates typically have sudden onset of irritability with progressive enlargement of the testis, with associated scrotal erythema. Color Doppler ultrasonography in the neonate is fairly reliable in distinguishing testicular torsion from scrotal hematoma and testicular tumor. Although testicular salvage in neonates with in utero torsion is highly unlikely, urgent exploration is recommended to confirm the diagnosis and to perform a contralateral scrotal orchiopexy to protect the solitary remaining testis, which is also at risk for torsion. If there is a possibility that torsion occurred after birth, there is a chance of saving the testis, and immediate exploration is warranted.

TORSION OF THE APPENDIX TESTIS

The appendix testis, a vestigial remnant of the müllerian duct system, is attached to the upper pole of the testis and is present in approximately 90% of males. The appendix epididymis, a remnant of the wolffian ducts, is present in about 10% of males. When these appendages are long and pedunculated, they have a tendency to twist at their base, resulting in ischemia and eventual infarction. This type of torsion is most common between 2 and 12 years of age and is uncommon in adolescents. Torsion of the appendix testis results in progressive pain and inflammation of the epididymis and scrotum.

The onset of pain and swelling is typically gradual. Affected males often adopt a wide-based gait but otherwise appear comfortable. Constitutional symptoms are usually less severe than with testicular torsion,

FIGURE 21.4 Anomalies of suspension associated with intravaginal testicular torsion. *A,* Normal. *B,* Envelopment by the tunica vaginalis. *C,* Inversion of the epididymis. *D and E,* Horizontal lie. Bell clapper deformity is shown in *B* through *E.* (From Kelalis PP, King LR, Belman AB, eds. *Clinical Pediatric Urology.* 2nd ed. Philadelphia: WB Saunders; 1985.)

but may include nausea, vomiting, and pain referred to the lower abdomen. Physical examination reveals an erythematous and edematous scrotum. Palpation of the testis may reveal a 3- to 5-mm tender indurated mass on the upper pole. The torsed appendix testis may be visible through the scrotal skin; this finding is termed the **blue dot sign** and is present in approximately 20% of cases. As the duration of torsion increases, differentiation from testicular torsion becomes increasingly difficult as reactive inflammation of the testis and epididymis worsen. A clinical diagnosis of torsion of the appendix testis should not be made unless the appendix testis is palpated or visualized.

The natural history of torsion of the appendix testis is for the inflammation to resolve gradually after infarction of the appendage. In general, the process is complete within 10 days from the onset of symptoms. Scrotal exploration and excision of the torsed appendage is unnecessary unless there is uncertainty regarding the diagnosis and testicular torsion is possible. If the diagnosis of torsion of the appendix testis is highly likely, color Doppler ultrasonography is optional for confirmation. Management includes strict rest for 2-3 days and nonsteroidal antiinflammatory medications to reduce inflammation and pain. Vigorous activity such as sports should be restricted for at least 7 days, as activity may worsen and prolong pain and swelling. The patient should be instructed to seek prompt medical evaluation if pain does worsen, as such worsening may be indicative of testicular torsion.

EPIDIDYMITIS, EPIDIDYMOORCHITIS, AND ORCHITIS

The inflammation of **epididymitis** may be caused by an infectious process, or may be secondary to trauma, torsion of the appendix testis, or sterile reflux of urine down the vas deferens. Pain and swelling are typically insidious in onset. Patients may have associated dysuria, urgency, frequency, and urethral discharge, and some may report transient episodes of inguinal pain that preceded the onset of testicular symptoms and that were secondary to spermatic cord inflammation. The epididymis is tender, enlarged, indurated, and situated posterior to the testis; in **epididymoorchitis**, inflammation progresses to involve the testis, which also becomes enlarged and tender. A reactive hydrocele may be present, obscuring testicular examination. The cremasteric reflex is typically preserved. Isolated **orchitis** is less common, particularly in prepubertal males, though it may be seen in postpubertal males with mumps virus infection.

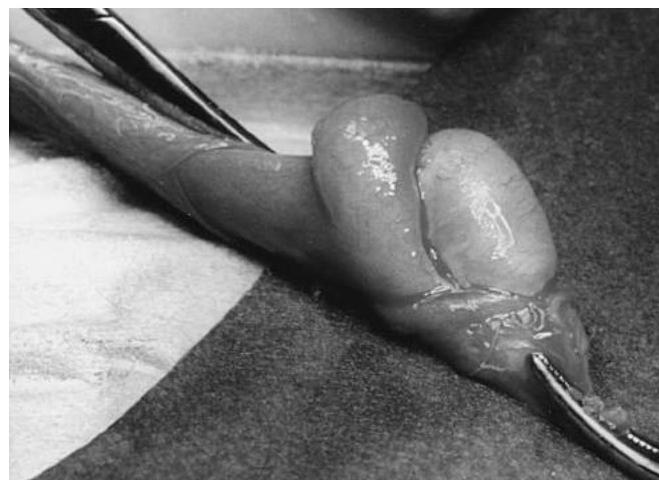
Bacterial epididymitis usually results from urethral infection passing retrograde through the vas deferens to the epididymis (Fig. 21.5). In prepubertal males, bacterial epididymitis is most frequently secondary to a structural abnormality of the lower genitourinary tract, such as ectopic ureter, ectopic vas deferens, or urethral stricture, or may be secondary to dysfunctional voiding. Urinalysis typically demonstrates pyuria, bacteriuria, or both, and bacterial culture of the urine may isolate the causative organism, usually a gram-negative coliform. Given the association with underlying urogenital abnormalities, further evaluation should include renal ultrasonography and voiding cystourethrography. In postpubertal males without underlying genitourinary abnormalities, bacterial epididymitis is most frequently caused by sexually transmitted infection, typically *Chlamydia trachomatis*, although *Neisseria gonorrhoeae* and *Ureaplasma urealyticum* may be causative as well. Additional causes of bacterial epididymitis include extension of urinary tract infection or infection with *Mycoplasma pneumoniae* or mycobacteria. Urinalysis and bacterial culture of the urine should be obtained, as should nucleic acid amplification tests for *C. trachomatis* and *N. gonorrhoeae* from urine or urethral swab specimens (see Chapter 18). Patients whose epididymitis is


FIGURE 21.5 Epididymitis in a 6-year-old male. Note the reactive orchitis as well as the significant enlargement of the epididymis.

related to a sexually transmitted infection should further be tested for syphilis and human immunodeficiency virus.

Viral epididymitis may be difficult to distinguish from non-infectious inflammatory causes of epididymitis. Enteroviruses and adenoviruses are typically implicated, either as a primary infection or as a postinfectious sequela. The inflammation of **orchitis** most commonly represents an extension of epididymitis; however, isolated orchitis may be seen in males with **mumps infection**. This manifestation is rare in prepubertal males, though may complicate infection in up to 35% of postpubertal males. The onset of orchitis usually occurs within 1 week of the onset of mumps parotitis and is more frequently unilateral. Diagnosis may be clinical, although given the markedly decreased incidence of mumps following the introduction of an effective vaccine and the possibility of alternate infectious etiologies, confirmatory testing may be obtained. Patients with parotitis may provide buccal swabs or saliva samples for nucleic acid amplification testing. Mumps-specific IgM antibody testing or acute and convalescent serum IgG antibody titer quantification may confirm the diagnosis. Up to a third of patients with mumps orchitis develop testicular atrophy and subfertility, although true infertility is rare, even with bilateral testicular involvement.

Noninfectious etiologies of epididymitis include torsion of the appendix testis, trauma, and medication exposure, particularly to amiodarone. Scrotal ultrasonography shows epididymal swelling and hyperemia consistent with epididymitis. Urinalysis and urine culture reveal no evidence of bacterial urinary tract infection.

TRAUMA AND HEMATOCELE

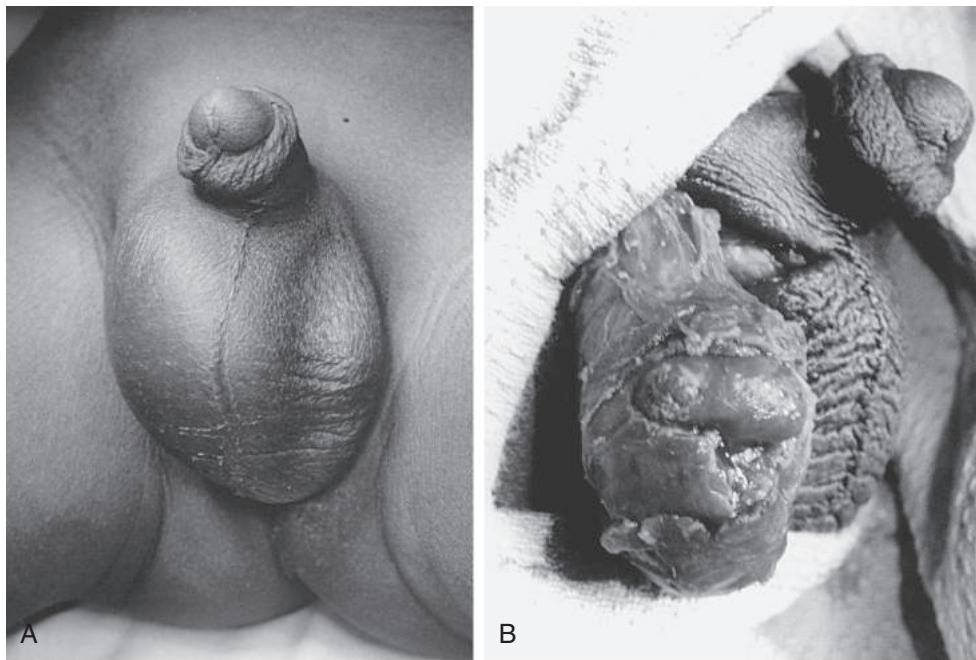
Blunt scrotal trauma can result in a spectrum of injuries ranging from testicular contusion to testicular rupture (Fig. 21.6). Testicular injuries usually result from a fall, kick, or direct blow from a blunt object that compresses the testis up against the pubic bone. A detailed history of the nature of the injury aids in recognizing the likelihood of serious testicular injury. With disruption of the tunica albuginea (capsule) of the testis, there is such significant painful scrotal swelling that the testis cannot be palpated. Often there is associated erythema or ecchymosis of the scrotal wall. In cases of suspected testicular injury, other diagnoses such as torsion and epididymitis should be considered. Scrotal ultrasonography should be performed to assess the integrity of the testis and to assess for torsion. Urinalysis should be performed to assess for bacterial epididymitis.


FIGURE 21.6 *A,* Appearance in an 8-year-old male kicked in the scrotum while performing karate with his brother. Note right scrotal swelling. An ultrasound study showed scrotal hematoma and a ruptured testis. *B,* Scrotal exploration shows a nonviable testis. Orchiectomy was performed.

VARICOCELE

A **varicocele** is an abnormal dilation of the veins of the pampiniform plexus in the scrotum. Varicoceles are rare under 10 years of age; however, approximately 10% of adolescent males and 15% of adult males have a varicocele. The increased prevalence among adolescents and adults is secondary to the increased testicular blood flow that occurs with puberty. More than 95% of varicoceles are left-sided, likely secondary to the higher venous pressure of the left internal spermatic vein and the absence of a venous valve at the insertion of the left internal spermatic vein into the renal vein. If a varicocele is detected on the right side or in a male younger than 10 years old, abdominal ultrasonography is indicated to ascertain whether an abdominal tumor is present.

A varicocele manifests as a painless, paratesticular mass often described as a "bag of worms." On occasion, patients describe a chronic, dull ache in or adjacent to the testis. Physical examination in both the supine and the upright positions, with and without the Valsalva maneuver, facilitates the diagnosis. Typically, the varicocele is decompressed while supine and is more prominent when standing. Measuring the volume of both testicles is important to document size discrepancies, as approximately one third of affected males have associated volume loss. Calipers, an orchiometer, or ultrasonography may be used.

Appropriate and timely diagnosis is essential, as an untreated varicocele may lead to degeneration of germinal centers, interstitial fibrosis, and impaired spermatogenesis and testosterone production. Up to 15% of adult males with a varicocele are infertile. The goal in treatment of a varicocele is preservation and restoration of spermatogenesis. Because the majority of testicular volume is composed of seminiferous tubules, if the left testis is significantly smaller than the right, the clinician may presume that the varicocele has affected testicular growth. Typically, after varicocelectomy in an adolescent, the testis shows catch-up growth. Surgical management does not guarantee paternity as an adult.

INGUINAL HERNIA

Hernias and hydroceles result from incomplete obliteration of the processus vaginalis. Indirect inguinal hernias result from a patent processus vaginalis that allows bowel or omentum to pass through the internal inguinal ring (Fig. 21.7). Patients usually present with inguinal swelling, scrotal swelling, or both. While swelling should reduce with gentle pressure, a hernia that cannot be reduced is called an **incarcerated hernia** and is a surgical emergency, as the vascular supply of the herniated bowel may become compromised. Physical signs of incarceration include inguinal or scrotal erythema, pain, signs of bowel obstruction, and inability to reduce the hernia. Infants with an incarcerated hernia have a 10% incidence of ipsilateral testicular infarction secondary to increased pressure on the spermatic cord.

If an incarcerated hernia is suspected, the child is hospitalized and sedated, and manual reduction of the hernia is attempted. Most incarcerated hernias can be reduced successfully and should be repaired promptly. Children with an easily reducible hernia should also undergo herniorrhaphy within a reasonable time to reduce the possibility of incarceration.

HYDROCELE

A **hydrocele** is an accumulation of fluid within the tunica vaginalis. Communicating hydroceles, defined by a patent processus vaginalis, are present in approximately 2% of newborn males, are more common in preterm infants, and tend to persist (see Fig. 21.7). The diameter of the patent processus vaginalis is much smaller than that seen with a hernia, allowing only peritoneal fluid to pass into the scrotum. Typically, affected males have painless scrotal swelling that progresses over the course of the day and resolves while sleeping or otherwise recumbent, as fluid returns to the peritoneal cavity. Noncommunicating hydroceles are characterized by the presence of an unobliterated portion of the processus vaginalis (see Fig. 21.7), and may be acquired following an inflammatory condition within the scrotum, such as

(See *Nelson Textbook of Pediatrics,* p. 2596.)

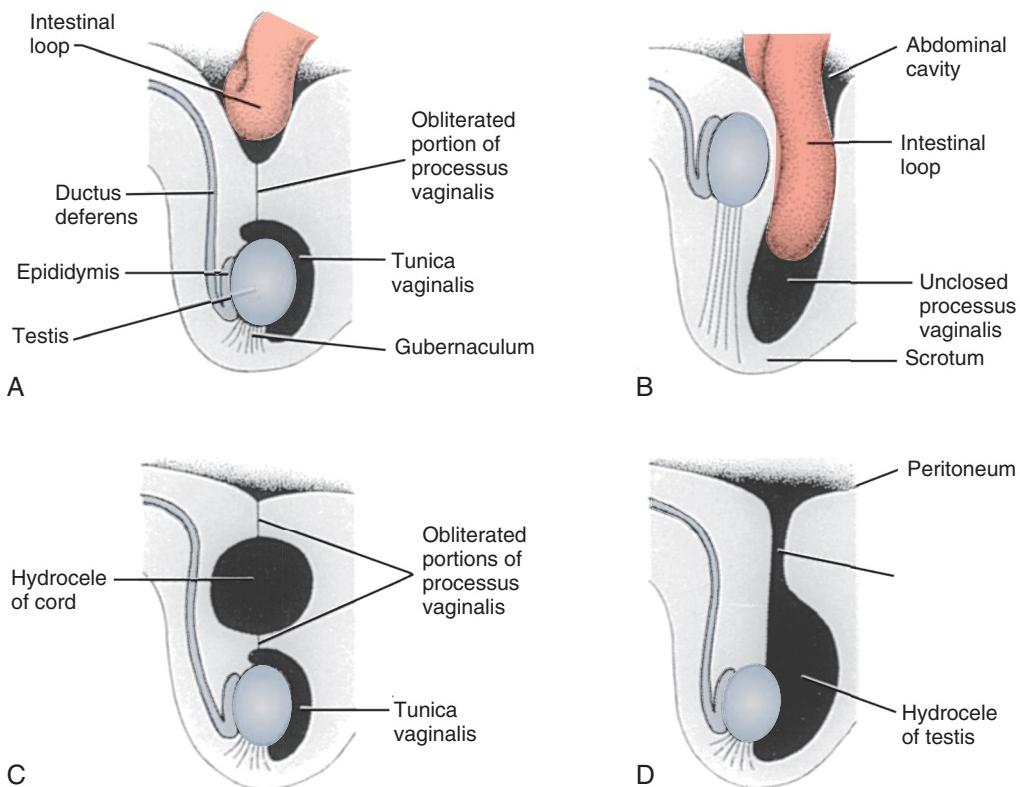
(See *Nelson Textbook of Pediatrics,* p. 1903.)


FIGURE 21.7 Diagrams of sagittal sections of the inguinal region. *A,* Incomplete indirect inguinal hernia, resulting from persistence of the proximal processus vaginalis. *B,* Indirect inguinal hernia into the scrotum, resulting from persistence of the entire processus vaginalis. Note the presence of an undescended testicle, which is a commonly associated malformation. *C,* Hydrocele of the cord, derived from an unobliterated portion of the processus vaginalis. *D,* Communicating hydrocele, resulting from peritoneal fluid passing through a patent processus vaginalis. testicular torsion, torsion of the appendix testis, epididymitis, or testicular tumor.

Physical examination reveals a smooth and nontender scrotal mass that is clear upon transillumination. Because hydroceles can be associated with testicular neoplasms in postpubertal males, testicular examination should be performed. If the size of the hydrocele precludes adequate testicular examination, scrotal ultrasonography is advised. Most communicating hydroceles resolve by 1 year of age and can be managed expectantly; however, large and tense masses may be difficult to distinguish from hernias, and may require ultrasonography. Large hydroceles or hydroceles persisting beyond the age of 2 years rarely regress spontaneously and may predispose to inguinal hernia.

A severe form of the hydrocele is the **abdominoscrotal hydrocele**, in which the hydrocele sac is tense with fluid and extends from the scrotum proximally through the inguinal canal into the abdominal cavity. On examination, these hydroceles are palpable in the inguinal canal, and an abdominal mass is often present. These hydroceles do not resolve and may cause extrinsic testicular compression. Early repair is recommended.

TESTICULAR TUMORS

Although testicular and paratesticular tumors are uncommon, testicular cancer is the most common solid malignancy in postpubertal males between the ages of 15 and 35 years, with a bimodal age distribution reflecting this age range, and another peak in the 1st 2 years of life. Most testicular cancers are germ cell tumors, representing

approximately 95% of testicular cancers, while the remaining 5% are stromal tumors derived from Leydig, Sertoli, and granulosa cells. Risk factors for testicular tumors include a history of cryptorchidism, a prior history of testicular cancer in the contralateral testicle, and a family history of testicular cancer.

Most patients with testicular tumors present with an incidentally noted nontender, hard mass that fails to transilluminate on examination. Pain is uncommon, although some patients may present with pain secondary to hemorrhage or infarction within the mass. Up to 15% of testicular tumors are associated with a noncommunicating hydrocele, prompting affected patients to seek medical evaluation. Stromal tumors may elaborate hormones that can lead to precocious pseudopuberty, gynecomastia, galactorrhea, or other endocrinologic manifestations.

Scrotal ultrasonography should be performed to confirm the finding of a testicular mass and may help delineate the type of testicular tumor. Serum tumor markers, such as α-fetoprotein and β-human chorionic gonadotropin, should be evaluated before surgical intervention. Partial orchiectomy is typically performed for prepubertal testis tumors with negative α-fetoprotein; radical orchiectomy is performed for postpubertal testis tumors and prepubertal testis tumors with elevated α-fetoprotein, given their higher metastatic potential. After radical orchiectomy, abdominal and chest computed tomography is obtained to evaluate the most common sites of metastatic disease, the retroperitoneum and lungs.

Leukemia and lymphoma are the most common secondary malignancies to affect the testis. These tumors can present bilaterally, and,

because the blood-testis barrier protects the intratesticular cells, the testis may be the site of residual tumor in children after chemotherapy. Paratesticular structures can give rise to various benign tumors, such as lipomas, leiomyomas, hemangiomas, and fibromas. Malignant paratesticular tumors are rare; rhabdomyosarcoma is the most common malignant paratesticular tumor.

MECONIUM PERITONITIS

Antenatal peritonitis may result from intestinal perforation. Although the intestinal perforation may heal, the intraabdominal meconium may track down the patent processus vaginalis into the scrotum, resulting in the formation of an inflammatory mass. This condition can manifest as bilateral neonatal hydroceles, which eventually regress into firm, nodular masses involving either or both testicles. Scrotal sonography demonstrates multiple areas of echogenic foci suggestive of calcification. In addition, a plain film of the scrotum shows calcification.

SCROTAL WALL SWELLING

Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a systemic vasculitis of unknown etiology that involves the skin, gastrointestinal tract, joints, and kidneys. Most affected patients are younger than 7 years. Genitourinary manifestations may include glomerulonephritis (see Chapter 20), ureteritis, renal pelvic bleeding, and acute swelling of the scrotum and spermatic cord. Scrotal wall and testicular involvement has been reported in up to a third of affected patients.

Palpable purpura (the characteristic skin finding in Henoch-Schönlein purpura) often begin in the lower extremities and buttock region. Later, the rash may spread to the scrotum; on occasion, the rash may begin on the scrotum. If scrotal swelling and pain precede the development of the characteristic rash, the presentation may be difficult to distinguish from testicular torsion. However, as these conditions may coexist, if there is any uncertainty regarding the diagnosis, color Doppler ultrasonography should be performed.

Acute Idiopathic Scrotal Wall Edema

Acute idiopathic scrotal wall edema is an uncommon entity that accounts for up to 5% of acute scrotal swelling. The average patient is between 4 and 7 years of age and typically presents with the sudden onset of unilateral or bilateral scrotal wall edema and mild tenderness. The overlying skin is erythematous, and the edema may extend anteriorly onto the abdominal wall or posteriorly into the perineum. The testicles are easily palpable, normal in size, and nontender. The origin of this syndrome is unknown, but allergic causes have been implicated. Most cases spontaneously resolve within 48-72 hours.

Idiopathic Fat Necrosis

Idiopathic fat necrosis is an uncommon cause of acute painful swelling of the scrotum, secondary to necrosis of the intrascrotal fat that is present in prepubertal males. Examination of the underlying testis may be hampered by inflammation within the scrotal wall. The etiology is unknown but may be related to trauma with physical activity. Ultrasonography demonstrates hyperechoic intrascrotal masses with posterior shadowing and a hyperechoic striated scrotal wall with normal-appearing testes and epididymi. Treatment is supportive.

Fournier Gangrene

Fournier gangrene of the scrotum usually affects adults, but rarely can afflict infants and children. In children, it occurs primarily as a result of genital insect bites, as a complication of circumcision, or from extension of perianal skin abscesses. Other predisposing factors include diabetes mellitus, trauma, instrumentation, urethral stricture, and inguinal or perineal surgery. Symptoms of this life-threatening infection include acute scrotal swelling with tenderness, erythema, skin necrosis, and systemic manifestations of fever, chills, and septicemia. The most common organisms identified include *Staphylococcus aureus*, *Bacteroides fragilis*, *Escherichia coli*, *Clostridium perfringens*, and streptococcal species. Despite aggressive treatment, mortality rates approach 50%.

REFERRED PAIN

Pain in the scrotum without inflammatory signs or abnormalities on physical examination may be referred pain. Sensory innervation to the scrotum includes the genitofemoral and ilioinguinal nerves. Most common causes include distal ureteral stones and constipation.

■ RED FLAGS

- Testicular torsion is a surgical emergency and acute scrotal pain should be evaluated promptly. Physical examination findings suggesting testicular torsion include marked tenderness, high-riding testis, and absent cremasteric reflex.
- Partial or intermittent torsion can present with persistent arterial blood flow on ultrasonography.
- A varicocele before puberty or on the right side is a red flag; abdominal ultrasonography is indicated.

Menstrual Problems and Vaginal Bleeding

Jessica Francis and Seema Menon

PREPUBERTAL VAGINAL BLEEDING

The source of abnormal bleeding during childhood is much more likely to be the vulva or vagina rather than the uterus. There are unique characteristics making history and physical examination effective in narrowing the diagnostic possibilities as seen in Table 22.1. Collecting information regarding recent trauma, medication exposure, rashes or irritation of the external genitalia, abdominal pain, chronic cough, constipation, and malodorous discharge are essential in making a diagnosis efficiently. A sensitive assessment regarding the possibility of sexual assault should be made, and an age-appropriate physical examination should be conducted noting the presence or absence of other pubertal signs, abnormalities of the vulva or urethra, vaginal discharge, and abdominal or vaginal masses.

Vaginal bleeding presenting within the first several days of life is most commonly due to estrogen withdrawal. Maternal estrogen enters fetal circulation stimulating growth of the endometrium. External genitalia examination typically reveals estrogenization, with thickened vulvar mucosa and leucorrhea. Several days after delivery, serum estrogen levels fall significantly, leading to a reduction of blood supply to the endometrium and the lining sheds as ischemia develops. If vaginal bleeding occurs within the 1st few days of life with a normal physical examination, a work-up is not needed provided the bleeding spontaneously resolves.

The presence of a **vaginal foreign body** is another common cause of vaginal bleeding in early childhood. This bleeding is often described as persistent, light in quantity, brown colored, and malodorous. The physical examination is unremarkable other than detection of a vaginal malodor. The most common foreign body in the vagina is toilet paper, although many other solid objects have been reported. Depending on the age and cooperation of the patient, lateral and downward traction of the labia majora may allow direct visualization of the foreign body. Toilet paper can be retrieved in the office by gently irrigating the vagina with water using a small, flexible pediatric feeding tube. In cases where the patient is not able to cooperate, a vaginoscopy under sedation should be performed. One technique is to place an 8 French Foley catheter in the vagina. A 5-mm laparoscope is simultaneously placed in the vagina. Saline is then flushed into the vagina using the Foley catheter while the labia majora are manually held together. The vagina is then distended allowing for complete visualization of the vaginal cavity including the cervix and any foreign body present. Simply removing the foreign body will adequately treat the symptoms; no antibiotic therapy is needed. A vaginal foreign body should not automatically trigger a full sexual assault evaluation; this investigation should be conducted if there is indication by history, or if suspicious scarring of the posterior fourchette is noted.

Prepubertal **vaginal infection** may present with bleeding and discharge, but unlike foreign body, the bleeding is typically red in color and nonmalodorous. Vaginal infection is also associated with complaints of external genital irritation. Mucosal erythema on physical examination is notable, particularly when the pathogen is group A β-hemolytic streptococcus. The diagnosis is confirmed with culture of the vaginal canal. A specimen for culture can be collected using the gentle irrigation technique described previously if vaginal swab placement is not possible. In addition to group A β-hemolytic streptococcus, other pathogens that are commonly identified include *Haemophilus influenzae*, *Escherichia coli*, *Shigella,* and *Salmonella* species with the latter 2 being particularly associated with vaginal bleeding. Notably, *Candida* infections of the vagina are uncommon in this population. A recent history of an upper respiratory infection should raise suspicion of this diagnosis as the majority of vaginal infections arise from autoinoculation.

Vulvar dermatoses can also present with vaginal bleeding and significant irritation or pain of the external genitalia. In this case, the bleeding is minimal, typically related to trauma from scratching. While vulvar dermatosis in the prepubertal population is relatively uncommon, **lichen sclerosus** and **psoriasis** are the most commonly described conditions. Suspicion for either condition should be raised if extragenital skin findings are noted, or if a positive family history is elicited. The typical appearance of lichen sclerosus is white parchment paper-like appearance in an hourglass distribution. Obliteration of the labia minora and clitoris can occur with long-standing disease. The treatment involves short courses of high-potency topical steroids and usually resolves as serum estrogen levels rise with maturation. Psoriasis typically appears as an erythematous plaque or papule marked by fissures, erosions, or scales. Treatment includes topical steroids, fluorinated ointments, and emollients. In both cases, biopsy is needed to confirm the diagnosis; however, if clinical suspicion is high and symptoms are severe, empiric treatment prior to biopsy is reasonable. Other vulvar lesions that can produce bleeding include hemangiomas and genital warts.

Urethral prolapse is another cause of prepubertal vaginal bleeding associated with a classic physical examination finding. The only complaint is bleeding; there is no coexisting pain or irritation. The limited estrogen levels in childhood leave the urethra vulnerable to prolapse, especially in the setting of frequent valsalva maneuvers from chronic cough or constipation. On physical examination, the urethra appears prominent, erythematous, and tubular "doughnut shaped," protruding well beyond the urethral meatus. Topical estrogen therapy for 1-2 weeks is typically effective in resolving this condition. Rarely, urethral necrosis can occur in which conservative therapy with estradiol can still be effective; however, surgical resection may be needed.

While the vast majority of lesions of the external genitalia causing prepubertal bleeding are benign, malignancy has been reported. **Sarcoma botryoides**, a variant of rhabdomyosarcoma, is the most common vaginal tumor in childhood. The classic description of this tumor is a protruding vaginal mass with grapelike vesicles. Other malignant tumors of the lower genital tract that have been reported include mesencymal tumors, neural ectodermal tumors in the Ewing family, and mixed müllerian tumors. Any abnormal-appearing vaginal

(See *Nelson Textbook of Pediatrics,* p. 2613.)

TABLE 22.1 Causes of Prepubertal Bleeding

	Pain or Irritation	Associated Characteristics	Family History
Estrogen withdrawal	No	Within 1st wk of life	No
Foreign body	No	Malodorous	No
Vaginal infection	Yes	Recent upper respiratory infection	No
Vulvar dermatoses	Yes	Vulvar discoloration or lesion Extragenital skin findings	Yes
Urethral prolapse	No	Chronic cough or constipation Red, beefy, protuberant urethra	No
Straddle injury	Yes	Provoking injury Visible laceration	No
Precocious puberty	No	Cyclic pattern of bleeding Secondary sexual characteristics present	Yes
Vaginal malignancy	Possible	Visible mass	No

TABLE 22.2 Comparison of GnRH-Dependent and GnRH-Independent Precocious Puberty

	GnRH-Dependent Precocious Puberty	GnRH-Independent Precocious Puberty
Prevalence	More common	Less common
Family history of early puberty	Positive	Negative
Unique characteristics	History or symptoms of CNS lesions, tumors, or infections	Symptoms of hypothyroidism, café-au-lait lesions, known Peutz-Jeghers syndrome
GnRH stimulation test	Positive	Negative

CNS, central nervous system; GnRH, gonadotropin-releasing hormone.

mass should raise concern for malignancy and should prompt a referral to an appropriate specialist for evaluation.

Bleeding secondary to a **perineal injury** presents acutely with pain and is associated with a clear provoking event unlike the other causes of childhood vaginal bleeding. Straddle injuries are the most common childhood injury to the genitalia and can lead to a bleeding laceration. This injury is caused by a nonpenetrating blunt force to the perineum when the legs are apart. Classic activities associated with straddle injuries include bike riding, playing on a seesaw, and gymnastics. An examination must be done to determine whether the laceration requires primary closure with suture. Conscious sedation or examination under anesthesia is appropriate for straddle injury evaluations as pain may prohibit a thorough evaluation. If the history does not substantiate the injury, a sensitive interview should be conducted prior to the examination. Co-examination with the sexual assault team is important should there be any suspicion.

Prepubertal vaginal bleeding presenting with breast development and growth acceleration should raise concern for **precocious puberty**. Pubertal changes before age 8 is precocious, and important historical cues that are helpful in making a diagnosis include symptoms of, or known existing central nervous system (CNS) abnormalities, symptoms of hypothyroidism, family history of early puberty, Peutz-Jeghers syndrome or neurofibromatosis, type 1. Height, Tanner staging of the breast and pubic hair, and external genital changes consistent with estrogen exposure, such as elongation of the labia minora and thickening of vulvar mucosa, should be specifically evaluated during physical examination. Café-au-lait spots, presence of an abdominal mass, and thyroid gland abnormalities should also be assessed. Radiographic imaging of the left wrist showing advanced bone age signifies elevated serum estrogen levels and is a good, initial screening test. Laboratory

evaluation confirming precocious puberty includes elevated serum estradiol, androgen panel, and gonadotropins.

Early elevated serum estrogen most commonly occurs because of maturation of the hypothalamic-pituitary-ovarian (HPO) axis, termed gonadotropin-releasing hormone (GnRH)–dependent precocious puberty. In this condition, the pathology is simply the early timing of maturation. Administration of a GnRH analog is effective in temporarily stopping anterior pituitary production of gonadotropins, ultimately preventing sex hormone production from the ovary. The purpose of halting early puberty is to avoid age-inappropriate social contact, and to preserve height, which is particularly effective when treating patients 6 years of age or younger. Rarely, GnRH pulsatile release is stimulated by CNS abnormalities such as infection, tumors, hydrocephaly, meningomyelocele, neonatal encephalopathy, or cranial radiation. Type 1 neurofibromatosis and tuberous sclerosis are also associated with GnRH-dependent precocious puberty. Imaging of the CNS should be aggressively pursued if there is suspicion of a CNS lesion, if pubertal progression is rapid, or if the child is under age 6.

GnRH-independent precocious puberty is a much less common cause of precious puberty. In this condition, the hypothalamus is not driving ovarian sex steroid hormone production. Conditions such as malignant granulosa cell tumors of the ovary, benign ovarian cysts, or tumors of the pituitary or adrenal gland are responsible for the elevated serum estrogens. McCune-Albright syndrome, Peutz-Jeghers syndrome, and hypothyroidism are associated with GnRH-independent precocious puberty as well.

GnRH-dependent and -independent precocious puberty are associated with different history and physical examination cues (Table 22.2). A GnRH stimulation test is effective in differentiating these 2 processes. A rise in gonadotropins after exogenous administration of GnRH

TABLE 22.3   **Causes of Abnormal Bleeding in Adolescents**

	Cycle Length	Intermenstrual Bleeding	Heavy Menses	Unique Characteristics	Family History
Coagulopathy	Prolonged	No	Yes	Bruising Epistaxis Gingival bleeding	Yes

Leiomyoma	Prolonged	No	Yes	Asymmetrically enlarged uterus	Yes
Polyp	Prolonged	Yes	No	None	No

HPO, hypothalamic-pituitary-ovary; PCOS, polycystic ovary syndrome.

suggests that the HPO axis is active, confirming GnRH-depending precocious puberty.

ABNORMAL BLEEDING IN ADOLESCENCE

Establishment of the menstrual cycle is a major hallmark of adolescence. The menstrual cycle serves as a marker of health, so much so, it has been heralded as a "vital sign" during adolescence. Irregular menstrual bleeding may simply be related to the maturation of the complex physiologic process leading to puberty. In other cases, irregular menstrual bleeding may be a symptom of a significant medical condition (Table 22.3). A basic understanding of the menstrual cycle is helpful when trying to understand the many causes of abnormal bleeding.

REVIEW OF THE MENSTRUAL CYCLE

Complex interaction between the hypothalamus, pituitary, ovary, and uterus leads to ovulatory menstrual cycles (Fig. 22.1). The hypothalamus releases pulses of gonadotropin-releasing hormone (GnRH) into a portal system to the pituitary gland. The anterior pituitary is stimulated to release the gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), when exposed to GnRH pulses. LH acts on the theca cells of the ovary leading to androgen production; these hormones are aromatized to estrogens in the granulosa cells of the ovary under the influence of FSH. This drives development of the dominant follicle.

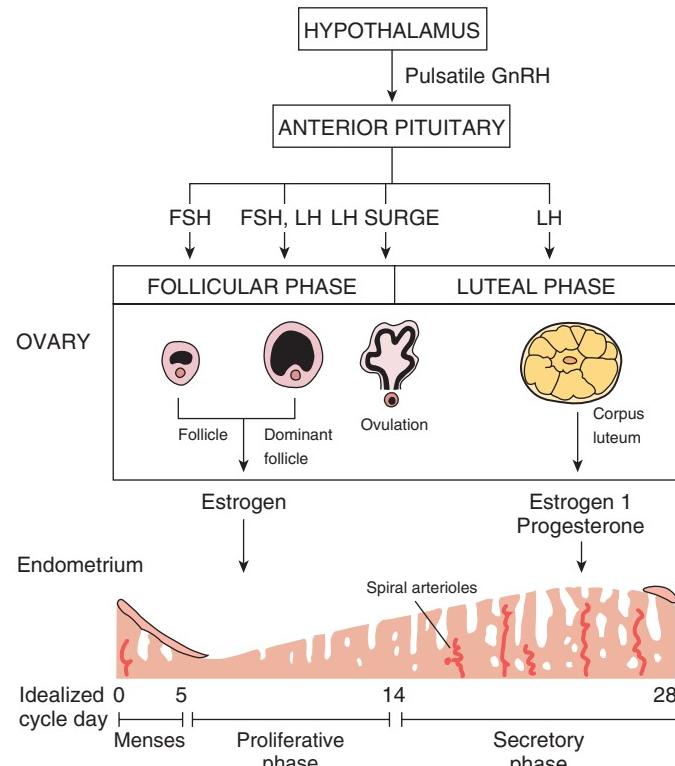
Interaction between the anterior pituitary and ovary is complex in that it is bidirectional. Gonadotropin release is stimulated by GnRH, and modulated by ovarian hormones, both the sex steroid hormones and the peptide hormones, activin and inhibin. In the first half of the cycle, the dominant follicle grows in size leading to increased estradiol production. A positive feedback relationship is seen between the ovary and the anterior pituitary with higher levels of estradiol stimulating gonadotropin release. This ultimately leads to the LH surge, triggering ovulation.


FIGURE 22.1 Hypothalamic-pituitary-ovarian endometrial axis: changes over time. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Postovulation, the dominant follicle transforms into a progesterone secreting corpus luteum. During this phase of the cycle, estradiol inhibits gonadotropin release preventing the development of another dominant follicle. The corpus luteum sustains progesterone secretion for 14 days; beyond this point, continued progesterone secretion is

(See *Nelson Textbook of Pediatrics,* p. 963.)

TABLE 22.4 New Classification System for Abnormal Bleeding

Malignancy	Endometrial causes
	Not otherwise specified

dependent on β-human chorionic gonadotropin (β-hCG) signaling from a pregnancy. If no pregnancy occurs, the corpus luteum regresses, and progesterone levels drop.

The endometrium is a mucosal surface lining the uterine cavity. Its thickness and composition are under the control of estradiol and progesterone. During the preovulatory estradiol-dominant phase, termed the *proliferative phase,* the endometrium rapidly grows. The endometrial lining undergoes glandular differentiation to optimize implantation during the postovulatory progesterone-dominant phase, termed the *secretory phase.* If no pregnancy occurs, the spiral arterioles supplying the endometrium undergo spasm secondary to waning estradiol and progesterone levels. The endometrium becomes ischemic and sheds, producing menstrual bleeding. The amount of menstrual blood directly correlates with the thickness of the endometrium, the activity of the coagulation cascade directing the clotting of the vessels, and the re-exposure to estrogen with the start of the new cycle. Any abnormality in these processes can lead to an abnormal bleeding pattern.

Normal parameters of the menstrual cycle should be understood to correctly identify abnormal patterns of bleeding. The cycle interval describes the number of days between the first day of 1 period and the 1st day of the next period. A normal cycle *interval* in adolescents is between 21-45 days, with the most common upper limit of 35 days. The cycle *length* describes the number of days menstrual bleeding lasts. A normal cycle length is conventionally described as between 3 and 7 days. The amount of bleeding is much harder to quantify. Greater than 80 mL of menstrual blood loss during a cycle is considered pathologically heavy, with the average blood loss being 30 mL. The clinical impracticality of obtaining this information is obvious; subjective clinical interview is used to determine heavy blood flow.

Information regarding the start of menarche, cycle interval, cycle length, bleeding between menses, and questions detailing the quantity of blood flow are essential in the assessment of abnormal bleeding. The Federation of Gynecology and Obstetrics Menstrual Disorders Group has recommended a classification system to categorize the causes of abnormal uterine bleeding. The acronym PALM-COEIN has been devised to categorize the multiple causes of abnormal uterine bleeding (Table 22.4). The conditions falling under the PALM group describe structural abnormalities and are much less common in the adolescent population than the nonstructural conditions falling under the COEIN group.

PREGNANCY

Pregnancy evaluation is an important early step in the assessment of abnormal bleeding in the adolescent. Bleeding in pregnancy, particularly in the 1st trimester is common and can occur with a normal or abnormal intrauterine pregnancy or an ectopic pregnancy. Pregnancy-associated bleeding can be light or heavy; similarly, it may be painless or associated with uterine cramping. A thorough history is helpful in understanding the heaviness of the current bleeding episode, the date of the last normal menstrual cycle, and assessing sexual and contraceptive activity. Physical examination can be helpful if the patient is beyond the 1st trimester as the uterus may be palpable on abdominal examination. A pelvic examination to assess the size of the uterus is helpful in the 1st trimester, but may not be appropriate for all adolescent patients. If a pregnancy is diagnosed by urine β-hCG testing, the viability of the pregnancy may be determined with ultrasound or serial β-hCG measurements 48 hours apart early in pregnancy. This hormone will increase by at least 53% over a 48-hour time period. β-hCG levels that drop or plateau are typically diagnostic of an abnormal intrauterine or ectopic pregnancy.

COAGULOPATHY

Bleeding dyscrasias, particularly platelet dysfunction, is associated with heavy and prolonged menstrual bleeding. In the adolescent population, menstrual cycles consistently lasting more than 7 days with a gushing sensation, or the need to change pads 8 or more times a day have been associated with a bleeding dyscrasia. Capturing information related to the cycle length, saturation of pads and frequency of change, frequency of menstrual blood leakage onto clothing, and the number of school days or social activities missed are effective in assessing heavy bleeding in the adolescent. Patients who report easy bruising, gingival bleeding, or frequent epistaxis should raise suspicion for a platelet function defect. The American College of Obstetricians and Gynecologists recommends testing adolescent patients for dyscrasia if they have one of the following: menses lasting >7 days with flooding, gushing, or leakage through pads in 2 hours, a history of anemia, a family history of a bleeding disorder, or heavy bleeding after a hemostatic challenge such as tooth extraction, surgery, or child birth. A reasonable basic approach to testing involves evaluating the platelet count, prothrombin time/international normalized ratio and partial thromboplastin time, and von Willebrand disease panel. Hematology referral is advisable in patients with severe, heavy and prolonged bleeding, and for those patients whose bleeding is not controlled with standard hormone therapy. Although not as common as platelet function disorders, coagulation factor deficiencies may present with heavy uterine bleeding during adolescence.

OVULATORY DYSFUNCTION

The complex feedback relationship between estrogen and the anterior pituitary is the last part of the menstrual cycle to mature. Before positive feedback is established, FSH may actually decrease with rising estrogen levels. This stunts dominant follicle development and ovulation does not occur. Without ovulation, the corpus luteum does not develop; consequently, progesterone secretion from the ovary is limited. The endometrial lining is unstable without progesterone influence leading to an abnormal bleeding pattern. This scenario is often termed *immaturity of the HPO axis.* The associated **anovulatory bleeding** pattern can present as frequent, absent, or heavy uterine bleeding. The abnormal bleeding associated with HPO immaturity is typically seen within the first 3 years of menarche, but can persist for 5 years after menarche. While this is the most common cause of irregular bleeding in early adolescence, other causes should be considered because immaturity of the HPO axis is a diagnosis of exclusion.

Polycystic ovary syndrome (**PCOS**) is a complex endocrinopathy that is likely the result of a heterogeneous combination of influences including genetics, the intra- and extrauterine environment, insulin resistance, steroid hormone metabolism, and other metabolic abnormalities. The presenting clinical pattern can include hyperandrogenemia causing hirsutism and acne, infrequent or absent ovulation leading to amenorrhea, oligomenorrhea, and subfertility, polycystic

ovaries on ultrasound, and eventual development of metabolic syndrome (obesity, type 2 diabetes, hypertension). The bleeding pattern most commonly associated with PCOS is infrequent or absent menses, although prolonged and heavy bleeding may occur. Diagnosis of PCOS typically relies on a variable presentation of 3 key features: hyperandrogenism, oligomenorrhea, and polycystic-appearing ovaries. The hormonal changes and physical symptoms associated with PCOS overlap greatly with early adolescence, making the evaluation particularly difficult in this age group. A stricter criterion for diagnosis includes hyperandrogenemia and progressive hirsutism, cycle length of 45 days or more, and polycystic ovaries with a size greater than 10 cm by sonogram. The diagnostic work-up of PCOS also involves the exclusion of mimicking causes such as late-onset congenital adrenal hyperplasia, androgen-secreting tumors, and Cushing disease. Normal early adolescence should also be considered as a mimicking condition. Therefore, considering this diagnosis within the 2 years of menarche should be done with caution, and only in the case of obvious pathology. Given the association of PCOS with future morbidity, these adolescents should be monitored closely and retested if the abnormal bleeding pattern persists.

Thyroid dysfunction can lead to an abnormal uterine bleeding pattern by disrupting ovulation. Similar to PCOS, the bleeding pattern most commonly associated with thyroid dysfunction is absent or infrequent menses, but heavy, prolonged bleeding can develop. In this case, severe hypothyroidism leads to significantly elevated levels of thyroid-stimulating hormone. This hormone, also from the anterior pituitary, has FSH-like activity and stimulates the stromal cells of the ovary to produce high levels of estrogen. The dysregulated production of estrogen leads to a thickened endometrial lining that eventually outgrows its blood supply, leading to ischemia and shedding. Bleeding is heavy and prolonged because this shedding is asynchronous, and the volume of endometrium is high.

Ovulatory dysfunction often presents as absent menses or amenorrhea. The **amenorrhea presentation** has an extremely wide range of diagnostic possibilities, some of which are associated with significant morbidity and even mortality if not recognized. Significant anatomic abnormalities, male karyotype, tumor of the anterior pituitary gland, significant malnutrition, and premature ovarian insufficiency illustrate the complexity of diagnostic possibilities (Table 22.5).

The 1st step in accurate diagnosis is determining when amenorrhea is actually pathologic. A work-up for absent menses should be done for adolescents who show no signs of secondary sexual maturation by age 13, no menses with other sexual characteristics by age 15, or if more than 3 months pass between menstrual cycles. Starting with a thorough history to identify any risk factors such as known renal anomalies, childhood exposure to chemotherapy or radiation, exercise and nutrition imbalance, galactorrhea, or family history of early menopause is important. A physical examination, including assessment of height, body mass index, acne and hirsutism, Tanner staging of breast and pubic hair development, and confirmation of a patent vagina if appropriate can help to further narrow the diagnostic possibilities. Ultrasound evaluation is a reasonable early test if the patient is not amenable to an examination, particularly if there is high risk of an anatomic abnormality. Laboratory assessment should include a pregnancy test, and serum thyroid-stimulating hormone, FSH, and prolactin.

If the thyroid or pregnancy testing is abnormal, the diagnosis is clear. If the prolactin level is elevated and there is no evidence of hypothyroidism, magnetic resonance imaging of the anterior pituitary is warranted. Over 50% of the time, an elevated prolactin level is secondary to an anterior pituitary tumor. Other CNS lesions that irritate the pituitary stalk are also associated with elevated prolactin levels. A thorough medication review should also be conducted in the case of hyperprolactinemia as this is a common side effect of antipsychotic medications that competitively bind to dopamine receptors, effectively

TABLE 22.5 Characteristics of the Causes of Amenorrhea

	FSH	Karyotype	Family History	Classic Unique Findings
Turner syndrome	Elevated	45,X	Fragile X syndrome	Short stature Webbed neck Lymphedema of hands and feet Low neck hairline
XY gonadal dysgenesis	Elevated	46,XY	No	No secondary sexual development
Hypothalamic amenorrhea	Low or normal	46,XX	No	Low body mass index Poor dentition
Imperforate hymen	Normal	46,XX	No	Pain Bulging hymen
PCOS	Normal	46,XX	Yes	Acne Hirsutism Central obesity
Mullerian anomalies	Normal	46,XX	Possible	Normal breast development Absent vagina
AIS	Normal	46,XY	No	Normal breast development Scant or no body hair Absent vagina
Premature ovarian insufficiency	Elevated	46,XX	Yes	Variable presence of secondary sexual characteristics
Kallman syndrome	Low or normal	46,XX	Yes	Inability to smell Absent secondary sexual characteristics

AIS, androgen insensitivity syndrome; PCOS, polycystic ovary syndrome.

lowering dopamine activity leading to an elevation of prolactin secondary to the inhibitory relationship between dopamine and prolactin.

An elevated FSH is associated with complex diagnoses such as premature ovarian insufficiency and gonadal dysgenesis. Immediate karyotype evaluation should be performed with the intent of making an early diagnosis of **Turner syndrome** or **gonadal dysgenesis** involving an XY karyotype. Both of these conditions are associated with significant morbidity if early treatment is not initiated. XY karyotype is associated with malignancy requiring gonadectomy; Turner syndrome is associated with left-sided cardiac abnormalities (bicuspid aortic valve, coarctation of aorta) in 50% of patients. Certainly emotional support, with both individual and family therapy, and referral to a support group should be considered in patients with the elevated FSH, as natural fertility is compromised and to support any gender identity concerns that might be raised.

In many cases of amenorrhea, the hormone evaluation and physical examination will be largely normal. Functional hypothalamic amenorrhea, most likely caused by immaturity of the HPO axis, is a diagnosis of exclusion and presents with either normal or low FSH levels. Identification of excessive stress related to either the social environment or a medical condition, sports or exercise activity not supported with sufficient calories, physical examination findings confirming poor nutrition based on low body mass index percentile, or poor dentition from frequent vomiting are important to identify. Amenorrhea and anosmia is suspicious for Kallmann syndrome, which is associated with GnRH deficiency. In the case of functional hypothalamic amenorrhea, magnetic resonance imaging of the central nervous system should be considered when the history interview does not produce any suspicion for stress or nutrition abnormalities, and particularly when symptoms such as nausea, headaches, and vision changes are present.

ENDOMETRIAL CAUSES

Infection and inflammation of the endometrium can lead to an abnormal uterine bleeding pattern. The bleeding pattern can range from light, intermenstrual bleeding to prolonged menstrual bleeding. Infection of the upper genital tract, pelvic inflammatory disease (PID), is a common diagnosis in adolescents and is directly linked to the high prevalence of gonorrhea and chlamydia infections in this population. Treating gonorrhea and chlamydia infections of the lower genital tract has been shown to reduce the risk of PID, which has clinical implications much more severe than abnormal bleeding. Testing for gonorrhea and chlamydia infections is recommended at least annually in sexually active women 25 years of age or younger, regardless of symptoms. Nucleic acid amplification test (NAAT) is the most sensitive and clinically useful as testing can be done on urine specimens and vaginal swabs as well as endocervical specimens. An infectious source of bleeding should be considered when evaluating a sexually active teenager.

IATROGENIC CAUSES

The most common group of medications that lead to abnormal uterine bleeding prescribed to adolescents is hormonal contraceptives. This bleeding is referred to as **breakthrough bleeding** and is typically described as prolonged or intermenstrual and is rarely heavy. Combination contraceptives (pills, transvaginal ring, and transdermal patch) are designed to provide 21 days of hormones for the purpose of blocking ovulation, and 7 days of placebo triggering the endometrium to shed, leading to a menstrual cycle. If pills are missed, or if the transdermal patch or ring are left in place longer than prescribed, or removed too early, endometrial bleeding will be triggered. In some

cases, breakthrough bleeding may occur even if the contraceptive method is being used correctly. Some follicular development has been described particularly with the very low dosage ethinyl estradiol contraceptive pills. While this is not associated with lower contraceptive efficacy, it may be associated with more ovarian cyst development and irregular bleeding. All progestin-only contraceptive methods are particularly troublesome for the breakthrough bleeding side effect. The majority of women using progesterone-only contraception report abnormal bleeding pattern after 1 year of use; however, the longer these methods are used, the more acceptable the bleeding pattern becomes. The actual mechanism causing breakthrough bleeding when using progesterone-only contraception is not clear; endometrial evaluation shows abnormal, enlarged, thin-walled fragile blood vessels. The intrauterine device (IUD), both the progestin-releasing and the nonhormonal device, can be associated with an abnormal bleeding pattern after initial insertion; the abnormal bleeding pattern will improve over time. The majority of hormonal IUD users ultimately experience a decrease in monthly menstrual bleeding, while the majority of nonhormonal IUD users report no change from their preinsertion menstrual pattern after 1 year of use.

Abnormal bleeding in adolescents can be associated with nonhormonal medications as well. Anticoagulation medications can lead to a heavy and prolonged bleeding pattern, especially when supratherapeutic anticoagulation occurs. In some cases, the bleeding associated with anticoagulation is quite heavy and requires acute, aggressive therapy to prevent significant anemia. A strategy to avoid heavy menstrual bleeding from anticoagulation is to start a safe hormonal contraceptive method with the purpose of limiting menses altogether.

NOT YET CLASSIFIED

Persistent abnormal bleeding sometimes requires multiple evaluations over time to identify the cause. In many cases, the initial evaluation, even when complete, may not identify the abnormality. PCOS is a good example of a condition that evolves over time and sometimes requires multiple evaluations to confirm. If the bleeding pattern is causing anemia or significant quality-of-life disruption, treatment should not be withheld simply because a clear diagnosis has not been established.

STRUCTURAL CAUSES: PALM

The structural causes of abnormal bleeding are much less common in the adolescent population. Gynecologic malignancy and hyperplasia in adolescence are rare conditions. In the case of the rare vaginal or cervical malignancy, the abnormal bleeding is typically prolonged or intermenstrual; endometrial malignancies and uterine sarcomas, also exceedingly rare, typically present with heavier bleeding. **Ovarian germ cell** tumors are the most common gynecologic malignancy during adolescence, most commonly presenting in the 15-19 year age group. Abnormal uterine bleeding is not a common presenting symptom of germ cell tumors; however, malignant stromal cell tumors of the ovary, specifically juvenile granulosa cell tumors, classically present with heavy and prolonged uterine bleeding. Ultrasound evaluation should be immediately performed if an adolescent presents with abnormal uterine bleeding and an abdominal mass.

In addition to malignancy, ultrasound evaluation is effective in diagnosing leiomyomas (fibroids) and polyps. Both represent a benign overgrowth of uterine tissue, and, again, are extremely uncommon in the adolescent population. A **leiomyoma** is a smooth muscle tumor of the myometrium that loses growth regulation and often presents with heavy and prolonged uterine bleeding. A **polyp** is typically an

overgrowth of the endometrium or the endocervix and classically presents as intermenstrual bleeding. This structural abnormality is not well reported in the adolescent population. **Adenomyosis** is another abnormality where islands of endometrial tissue are embedded in the myometrium of the uterus. While this condition is rare in the adolescent population, it typically presents with heavy and prolonged bleeding, similar to a leiomyoma. Adenomyosis is also a benign condition, but unlike leiomyoma, the sensitivity of ultrasound diagnosis is low; magnetic resonance imaging is more sensitive and reliable for diagnosis.

CONGENITAL ANOMALIES

Müllerian anomalies are another important structural cause of abnormal bleeding. The müllerian ducts, embryonically called the paramesonephric ducts, appear 37 days post fertilization and undergo a process of invagination, elongation, fusion, and resorption with canalization to become the fallopian tubes, uterus, cervix and upper vagina. Müllerian anomalies result from agenesis, failed resorption, or failed lateral fusion. Absent menstrual bleeding is the most common abnormal bleeding pattern associated with müllerian anomalies, although most anomalies, such as bicornuate, didelphys, and septate uterus do not result in abnormal bleeding. Anomalies presenting with amenorrhea are associated with an absence of the vagina, uterus and/or cervix, or a complete obstruction such as a transverse vaginal septum.

Anomalies involving a transverse vaginal septum are actually quite rare and may present with prolonged irregular bleeding as well as with amenorrhea. If spontaneous perforation of the vaginal septum occurs, a prolonged, irregular bleeding pattern is produced. Similarly, an obstructed hemivagina that spontaneously ruptures leads to a similar bleeding pattern. This müllerian anomaly describes uterine didelphys and bicollis, with a partial vaginal septum obstructing the outflow of one of the müllerian tracts. If an abnormality of the upper genital tract is suspected, magnetic resonance imaging is indicated for confirmation.

A simple external genital examination should always be done during the evaluation of amenorrhea as imperforate hymen, a structural anomaly much more common than müllerian anomalies, is easily diagnosed by inspection. An imperforate hymen is the complete obstruction by the hymenal membrane at the level of the vaginal introitus preventing the passage of menstrual bleeding. Pain is a key complaint. Diagnosis by examination is reliable as the hymenal tissue is often bulging from the pressure resulting from the hematocolpos. In this case, a simple surgical procedure to remove the redundant hymen can be done to achieve normal anatomy.

Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome and androgen insensitivity syndrome (AIS) are 2 other diagnostic possibilities that present with absent vagina and amenorrhea. In both of these conditions, the müllerian structures are absent, and both external genitalia and breast development are consistent with a female phenotype. Karyotype and testosterone level differentiates the 2 disorders, as MRKH individuals are 46,XX with serum testosterone in the female range whereas AIS individuals are 46,XY with testosterone levels in the male range. In AIS, the absent androgen activity leads to female external genitalia development and limited body hair, as well as no wolffian structure development. Peripheral conversion of androgens to estrogens leads to estrogenization, specifically breast development, during puberty. The gonads are at risk for malignancy and removal after achievement of adult height is recommended. After gonadectomy, estrogen replacement is needed until natural age of menopause is reached for optimal health. AIS is significantly less common than MRKH (2-

5/100,000 vs 4/1500) and is associated with an X-linked recessive inheritance pattern, whereas MRKH appears to be more sporadic.

TREATMENT

Progestins alone, or in combination with estradiol, are the most effective medical therapy to treat abnormal bleeding in adolescents. Hormones should be considered 1st-line therapy even when managing adolescents with bleeding dyscrasias or structural abnormalities such as adenomyosis or leiomyomas. When given cyclically, especially in the combination contraceptive formulation, bleeding becomes regular and light. If progestin-only therapy is given continuously, menstrual bleeding will theoretically be suppressed, although breakthrough bleeding, as described previously, can occur.

Selecting the best method for abnormal bleeding management should first focus on safety considerations, particularly if an estrogen-containing treatment is selected. Contraindications to estrogen therapy are listed in Table 22.6. After a determination of safety is made, a detailed discussion should be held to determine any potential compliance concerns as improper use of hormone therapy can lead to irregular bleeding and ultimately treatment failure.

Antifibrinolytics, specifically tranexamic acid, are effective nonhormonal medications that can be considered for those adolescents who are not comfortable taking hormonal medications or who have significant contraindications or side effects to hormone therapy. These medications can also be used adjunctively with hormone therapy if bleeding control is suboptimal, but the risk for venous thromboembolism should be discussed with the patient. A platelet transfusion, factor replacement, desmopressin, intravenous immune globulin, or oral corticosteroids may be appropriate adjunctive therapy depending on the etiology. Hormone therapy is effective in controlling bleeding secondary to all of these conditions and should be concurrently administered. In the rare case of a malignancy, polyp, or a resectable partial anatomic blockage, surgical management is required.

If abnormal uterine bleeding is profound, producing significant anemia, hormonal therapy remains the mainstay of medical treatment, but with different dosing regimens (see Table 22.7). Both estrogens and progestins alone or in combination are effective. High-dose progestin therapy leads to endometrial atrophy. High-dose estradiol therapy is effective by inducing endometrial vascular vasospasm, regenerating denuded epithelium, and increasing clotting factors. Both intravenous and oral high-dose estradiol preparations are available and the intravenous route may be preferable in patients who are unable to tolerate

TABLE 22.6 Contraindications to Estrogen Therapy

Poorly controlled hypertension, or coexisting vascular disease
Current/history of ischemic heart disease
Liver dysfunction: severe cirrhosis, adenoma, hepatocellular carcinoma
History of venous thromboembolism/known thrombophilia
Complicated valvular heart disease
Migraine with aura
Active cancer or within 6 mo of treatment
<6 mo since diagnosis of peripartum cardiomyopathy
Diabetes with vascular complication
Major surgery with prolonged immobilization
Moderate to severe impairment of cardiac function
Solid organ transplant complicated by graft failure, rejection, cardiac allograft vasculopathy

TABLE 22.7	**Hormone Treatment Regimens for Acute Heavy Bleeding**	
IV Estrogen	**Combination Oral Contraceptives**	**Oral Progesterone**
Conjugated estrogen 25 mg every 4-6 hr	30-50 µg of ethinyl estradiol–containing tablets every 4-8 hr Taper dosage over several days when bleeding subsides	Medroxyprogesterone 20 mg orally bid to tid or norethindrone 5-10 mg orally bid

oral medication secondary to nausea. Regardless of which high-dose hormone regimen is used, once cessation of bleeding has been achieved, transitioning to a progestin-dominant therapy is imperative. If this is not done, sudden stoppage of the high dosage of hormone therapy will lead to withdrawal bleeding. Specific factor replacement, particularly factor VII replacement, may also be effective in controlling profound heavy bleeding, regardless of the cause.

GnRH agonist therapy is another option to acutely control heavy uterine bleeding. The mechanism of action involves decreased expression of GnRH receptors of the anterior pituitary secondary to receptor saturation, which leads to decreasing sex hormone production from the ovaries. This medication should be used with caution as a flare in bleeding may initially occur. Traditional dosing involves an intramuscular injection of either 11.25 mg given at 3-month intervals, or monthly dosing of 3.75 mg. GnRH agonist therapy is limited to 12 months of use secondary to the significant lowering of bone mineral density as a result of decreased circulating ovarian estrogens. Vasomotor symptoms are also a common side effect of decreased estrogens; treatment low-dose progestins or estradiol is typically effective in relieving symptoms.

Management of acute bleeding may require surgical therapy. Placement of a Foley balloon into the endometrium filled with 30 mL of saline is effective by tamponading the bleeding endometrium and reducing the blood supply to the uterus by partially compressing the uterine arteries. The balloon is deflated gradually over 2-3 days while hormone therapy is ongoing. A dilation and curettage is often performed with Foley balloon placement. This procedure leads to endometrial thinning and can be effective in controlling heavy bleeding on its own. Again, hormone therapy should be ongoing. The final 2 surgical options impair fertility and should be reserved as a last resort: uterine artery embolization and hysterectomy. Hysterectomy is the last resort when all other conservative management fails.

MENSTRUAL PAIN IN ADOLESCENTS

Dysmenorrhea, defined as pain during the menstrual cycle, is the most common reason adolescent patients seek gynecologic care. Pain is most commonly in the pelvis secondary to uterine cramping, but can also be reported in the back and upper thighs. Sixty to seventy percent of adolescents report pain during menses, and 15% report significant quality-of-life dysfunction leading to a disruption of normal activities. Dysmenorrhea is associated with ovulatory cycles; therefore, this symptom typically presents in the later adolescent years. Dysmenorrhea, unlike chronic pelvic pain, presents with cyclic pain beginning within 48 hours of the 1st day of the menstrual cycle, and resolves by menstrual cycle day 2 or 3. Primary dysmenorrhea is significantly more common in adolescents. In this condition, high levels of prostaglandin E_2 and $F_{2\alpha}$, produced by the endometrium, cause painful uterine cramping. Secondary dysmenorrhea is the result of an anatomic abnormality causing uterine cramping. About 10% of adolescents with menstrual pain have secondary dysmenorrhea.

If the physical examination is normal, and there are no factors in the medical history raising suspicion for an anatomic abnormality, empirical treatment without laboratory or radiologic evaluation is a reasonable approach. Nonsteroidal antiinflammatory drugs (NSAIDs) are effective therapy as prostaglandin production is directly reduced. This therapy is most effective when started 24-48 hours prior to the onset of pain. Contraceptive agents that block ovulation and limit the growth of the endometrial lining lead to a decreased in prostaglandin production and, therefore, are also effective in treating dysmenorrhea. Although NSAIDs are traditionally considered 1st-line therapy for primary dysmenorrhea, starting a contraceptive agent without an NSAID trial is acceptable given the inherent administration difficulty associated with proper NSAID use. Nontraditional therapies such as vitamin E, magnesium supplementation, acupuncture, transcutaneous electrical nerve stimulation, and dietary supplements are not well studied.

If menses are reported to be painful, and if there is some persistence of pain between cycles, or if empirical therapy for primary dysmenorrhea is unsuccessful after 3-6 months of treatment, a diagnosis of secondary dysmenorrhea should be considered. Uterine leiomyomas, adenomyosis, and outflow tract abnormalities that block the egress of menstrual blood can cause significant pain during menses and discomfort between menstrual cycles. The most common cause of **secondary dysmenorrhea** during adolescence is **endometriosis.** The prevalence of endometriosis in the adolescent population has not been established, but 60% of adult women with endometriosis report symptoms prior to age 20, and 45-70% of adolescents undergoing laparoscopy for pain are found to have endometriosis. Confirmation of endometriosis is challenging as no blood test or imaging study is diagnostic. Laparoscopic surgical evaluation of the pelvis can be helpful, but the lesions are often subtle and heterogeneous in appearance and consequently can be missed. The hormonal therapies effective in treating primary dysmenorrhea are also effective in the treatment of secondary dysmenorrhea, with the exception of outflow tract obstruction abnormalities, which always require surgical management. The levonorgestrel intrauterine device has been particularly effective in controlling symptoms of endometriosis and leiomyomas.

While dysmenorrhea is a common premenstrual symptom, it is a different entity than **premenstrual syndrome (PMS)**. The basic diagnostic strategy for PMS involves confirming the presence of at least 1 somatic complaint (breast tenderness, abdominal bloating, headache, or swelling of extremities) and 1 affective complaint (depression, angry outbursts, irritability, anxiety, confusion, or social withdrawal) during the 5 days preceding menses for 3 consecutive menstrual cycles. The symptoms must be resolved by the 4th day of the menses, and should not recur until at least 13 days have passed from cycle day 1 of the last menses. For diagnostic purposes, these symptoms should also negatively impact social or school participation.

Premenstrual dysphoric disorder (PMDD) is often grouped with PMS but the diagnostic criteria differ. The American Psychiatric Association requires at least 5 of the following symptoms: marked depressed mood, marked anxiety, marked emotional lability, persistent and marked anger, decreased interest in usual activities, difficulty concentrating, lethargy, marked change in appetite, sleep disturbance, loss of control sensation, and physical symptoms of breast tenderness, swelling, headaches, joint pain, muscle pain, bloating, or weight gain. For diagnosis, the symptoms must interfere with activities and relationships, and the symptoms cannot be an exacerbation of a mood or personality disorder. These criteria must be confirmed by daily

prospective ratings over 2 consecutive cycles. The pathophysiology of PMS and PMDD have been linked to the fluctuation of ovarian sex steroid hormones after ovulation. While no difference in hormonal levels have been confirmed in women with PMS/PMDD compared to those that do not have these conditions, there may be a different serotonin activity or γ-aminobutyric receptor activity response to the hormone fluctuations during the luteal phase.

Treatment options include hormonal suppression of ovulation to prevent the luteal phase fluctuation of hormones. Hormonal agents containing the 4th-generation progestin drospirenone have been effective in controlling affective and somatic symptoms. The possible small increased risk of venothromboembolic events associated with this particular progestin preparation warrants a careful risk-benefit analysis. NSAIDS and spironolactone have been shown to be helpful in the alleviation of the physical symptoms. Selective serotonin reuptake inhibitors (SSRIs) have been put forth as a 1st-line treatment option in adult women with severe PMS and PMDD as improvement in both somatic and affective symptoms have been documented. However, the efficacy of these medications in adolescents with PMS/PMDD is unclear, and the association of these medications with increased suicidality has blunted widespread use. Nonpharmacologic therapies that have been utilized include exercise, stress management, cognitive-behavioral therapy, education about the syndrome, supplementation with calcium, magnesium, vitamin B_6, and vitamin E, and chasteberry, ginkgo biloba, and St. John's wort herbal remedies. Data supporting these therapies are promising, but limited for conclusions of efficacy. Red flags include a mass, extragenital bleeding, anemia, a positive family history, and the possibility of an abnormal pregnancy.

SUMMARY AND RED FLAGS

Menstrual concerns and abnormal bleeding are common complaints in childhood and adolescence with a wide range of diagnostic possibilities. At first, the work-up may appear overwhelming. However, a thorough history and physical examination helps to quickly identify the more likely underlying causes, narrowing the laboratory and imaging evaluation that may be needed to efficiently make an accurate diagnoses. Red flags in the evaluation include prolonged bleeding, anemia, or fevers. For the vast majority of adolescents presenting with menstrual concerns, treatment can be initiated with limited evaluation secondary to the likelihood of the underlying cause being a benign, transient process. Abnormal bleeding in childhood typically warrants more of a diagnostic work-up, although most often, the underlying cause is also benign.

Disorders of Sex Development

Patricia A. Donohoue

The term *disorders of sex development (DSD)* replaces the former terms *intersex* and *hermaphroditism* (Table 23.1). The most common presenting symptom of DSD is **atypical (ambiguous) genitalia** at birth. Other presenting signs and symptoms include lack of some or all aspects of pubertal development, postnatal virilization of a phenotypic female, or infertility. The classification of DSD is based on broad categories related to blood sex chromosome composition and gonadal structure. These categories include 46,XX DSD, 46,XY DSD, ovotesticular DSD, and sex chromosome DSD (Table 23.2).

The terms *atypical,* or *ambiguous genitalia,* in a broad sense, refer to any case in which the external genitalia do not appear completely male or completely female. Although there are standards for genital size dimensions, variations in size of these structures do not always constitute ambiguity.

Development of the external genitalia begins with the potential to be either male or female (Fig. 23.1 and Table 23.3). Virilization of a female, the most common form of DSD, results in varying phenotypes (Fig. 23.2) that develop from the basic bipotential genital appearances of the embryo (see Fig. 23.1). Degrees of virilization at birth are often classified using the **Prader stages** (Fig. 23.3).

OVERVIEW OF SEX DIFFERENTIATION

In typical differentiation from the sexually undifferentiated early fetus, the final phenotype of the external and internal genitalia is consistent with a normal sex chromosome complement (either XX or XY). The process of sex differentiation and development follows a consistent timeline (Fig. 23.4). The control of sex development is vast in its complexity and timing. A 46,XX complement of chromosomes as well as genetic factors, including DAX1, the signaling molecule WNT-4, CTNNB1 and R-spondin 1, are among the many factors needed for the development of normal ovaries and müllerian (paramesonephric) ducts (uterus, fallopian tubes, and upper vagina). Development of the male phenotype requires the product of a Y chromosome gene called *SRY* (Sex-determining Region on the Y chromosome), which, in concert with products of other genes such as *SOX9, SF1, WT1, FGF9* and others, directs the undifferentiated gonad to become a testis. SRY acts as a transcriptional regulator to increase cellular proliferation, attract interstitial cells from adjacent mesonephros into the genital ridge, and stimulate testicular Sertoli cell differentiation. Sertoli cells act as an organizer of steroidogenic and germ cell lines and produce antimüllerian hormone (AMH) that causes the female (paramesonephric) duct system to regress. Aberrant genetic recombinations may result in X chromosomes carrying *SRY,* resulting in XX males (46,XX testicular DSD), or Y chromosomes that have lost *SRY,* resulting in XY females (46,XY DSD due to gonadal dysgenesis). Epigenetic causes of abnormal sex differentiation have been shown in plants, invertebrates, and vertebrates and will likely be shown to contribute to human DSD as well.

Antimüllerian hormone (AMH) from the ipsilateral fetal testis causes the müllerian (paramesonephric) ducts to regress. In its absence, they persist as the uterus, fallopian tubes, cervix, and upper vagina. By about 8 weeks of gestation, the Leydig cells of the testis begin to produce testosterone. During this critical period of male differentiation, testosterone secretion is stimulated by placental human chorionic gonadotropin (hCG), which peaks at 8-12 weeks. In the latter half of pregnancy, lower levels of testosterone are maintained by luteinizing hormone (LH) secreted by the fetal pituitary. **Testosterone** produced locally initiates development of the ipsilateral wolffian (mesonephric) duct into the epididymis, vas deferens, and seminal vesicle. Development of the external genitalia also requires **dihydrotestosterone (DHT)**, the more active metabolite of testosterone. DHT is produced largely from circulating testosterone and is necessary for fusion of the genital folds to form the penis and scrotum. DHT is also produced via an alternative biosynthetic pathway from androstanediol, and this pathway must also be intact for normal and complete prenatal virilization to occur. A functional **androgen receptor**, produced by an X-linked gene, is required for testosterone and DHT to produce the androgen effects.

In the XX fetus with normal long and short arms of the X chromosomes, the bipotential gonad develops into an ovary by about the 10th-11th week. This occurs only in the absence of *SRY,* testosterone, and AMH and requires a normal gene in the DSS (Dosage Sensitive Sex reversal) locus of DAX1 (DSS Adrenal hypoplasia congenital region on X, also known as NROB1), the WNT-4 molecule, and R-spondin 1. A female external phenotype will develop even in the absence of fetal gonads. Unlike development of the male external phenotype, which requires androgen production and its action, estrogen is unnecessary for normal female prenatal sex differentiation. This is demonstrated by 46,XX patients who lack estrogen due to a deficiency of aromatase, the enzyme required for conversion of androgen to estrogen. Development of the ovary was once thought to be a passive process in the absence of SRY. Although the morphologic changes in the developing ovary are less marked than in the testis, there are a number of sequentially expressed genes and pathways that are required for complete ovarian development as well as maintenance of ovarian integrity postnatally. One of these genes is R-spondin 1 which, if mutated, can result in testicular or ovotesticular development in 46,XX individuals. Once developed, the ovary requires FAX12 to preserve its differentiation and stability.

Several genes important to the pathoetiology of DSD are listed in Table 23.4.

OVERVIEW OF GONADAL FUNCTION

Testes

Levels of placental hCG peak at 8-12 weeks of gestation and in males hCG stimulates the fetal Leydig cells to secrete testosterone, the main

hormonal product of the testis. In the classical androgen biosynthetic pathway (Fig. 23.5), testosterone is then converted by the enzyme 5α-reductase to its more potent metabolite, DHT. This early period is critical for virilization of the XY fetus including fusion of the midline to form the scrotum and extension of the urethral meatus to distal penile opening (see Fig. 23.1). Defects in this process lead to various deviations from typical male development. After virilization, fetal levels of testosterone decrease but are maintained at lower levels in the latter half of pregnancy by luteinizing hormone (LH) secreted by the fetal pituitary. This LH-mediated testosterone secretion is required for continued penile growth and to some degree, for testicular descent.

As part of the normal transition from intrauterine to extrauterine life, perhaps related to the sudden withdrawal of maternal and placental hormones, newborns and young infants experience a transient surge of gonadotropins and sex steroids. This is the so-called minipuberty.

In males, LH and testosterone peak at 1-2 months of age and then decline to reach prepubertal levels by 4-6 months of age. Follicle-stimulating hormone (FSH), along with inhibin B, peaks at 3 months and declines to prepubertal levels by 9 and 15 months, respectively. The LH rise is more dominant than that of FSH.

TABLE 23.2 Etiologic Classification of Disorders of Sex Development

46,XX Disorders of Sex Development (DSD)

Androgen Exposure

Fetal/Fetoplacental Source

    Congenital Adrenal Hyperplasia
      21-Hydroxylase (CYP21A2) deficiency
      11β-Hydroxylase (CYP11B1) deficiency
      3β-Hydroxysteroid dehydrogenase II (HSD3B2) deficiency
    Cytochrome P450 oxidoreductase (POR)
    Aromatase (CYP19) deficiency
    Glucocorticoid receptor gene mutation

Maternal Source

    Virilizing ovarian tumor
    Virilizing adrenal tumor
    Androgenic drugs

Disorders of Ovarian Development

XX gonadal dysgenesis
Testicular DSD

Undetermined Origin/Associated with Genitourinary and Gastrointestinal Tract Defects

Cloacal exstrophy
MURCS association
Mayer–Rokitansky–Küster–Hauser syndrome

46,XY DSD

Defects in Testicular Development

WT-1 Defects

    Denys–Drash syndrome
    Fraser syndrome
    WAGR syndrome

Campomelic syndrome and SOX9 mutation
SF1 mutation
Mutation in *SRY*-gene (XY pure gonadal dysgenesis, Swyer syndrome)
XY gonadal agenesis (Embryonic testicular regression syndrome)

Deficiency of Testicular Hormone Production

Leydig cell aplasia/hypoplasia

    Mutation in LH receptor

Congenital adrenal hyperplasia

    Lipoid adrenal hyperplasia (CYP11A1) deficiency; mutation in StAR
      (steroidogenic acute regulatory protein)
    3β-Hydroxysteroid dehydrogenase type II (HSD3B2) deficiency
    17-Hydroxylase/17,20-lyase (CYP17A1) deficiency

17β-Hydroxysteroid dehydrogenase (17β-HSD) or 17-ketosteroid reductase deficiency
Smith-Lemli-Opitz syndrome (defect in conversion of 7-dehydrocholesterol to cholesterol [DHCR7])

Persistent Müllerian Duct Syndrome Due to Antimüllerian Hormone Gene Mutations, or Receptor Defects for Antimüllerian Hormone

Defect in Androgen Action

Dihydrotestosterone (DHT) deficiency

    5α-Reductase II (SDR5A2) mutations
    3α-Reductase (AKR1C2/AKR1C4) mutations

Androgen receptor defects

    Complete androgen insensitivity syndrome (CAIS)
    Partial androgen insensitivity syndrome (PAIS)

Undetermined Causes, Including Those Associated with Other Congenital Defects

Ovotesticular DSD

XX
XY
XX/XY chimeras

Sex Chromosome DSD

45,X (Turner syndrome and variants)
47,XXY (Klinefelter syndrome and variants)
45,X/46,XY (mixed gonadal dysgenesis, sometimes a cause of ovotesticular DSD)
46,XX/46,XY (chimeric, sometimes a cause of ovotesticular DSD)

TABLE 23.3 **Embryologic Origins of Female and Male Reproductive Structures**

Precursor	Female	Male
Undifferentiated bipotential gonad	Ovary	Testis
Internal ducts		
Wolffian (mesonephric)	Involution	Epididymis, vas deferens, seminal vesicles
Mullerian (paramesonephric)	Fallopian tubes, uterus, cervix, upper vagina	Involution, prostatic utricle
Urogenital sinus	Lower vagina, urethra	Urethra
External genitalia		
Genital tubercle	Clitoris	Penile corpora cavernosa
Labioscrotal folds	Labia majora	Scrotum
Labiourethral folds	Labia minora	Penile urethra

The neonatal surge may be important for postnatal maturation of the gonads, stabilization of male external genitalia, and perhaps also for gender identity and sexual behaviors. The postnatal surge in LH and testosterone is absent or blunted in infants with hypopituitarism, cryptorchidism, and complete androgen insensitivity syndrome (CAIS). The development of nocturnal pulsatile secretion of LH marks the advent of puberty.

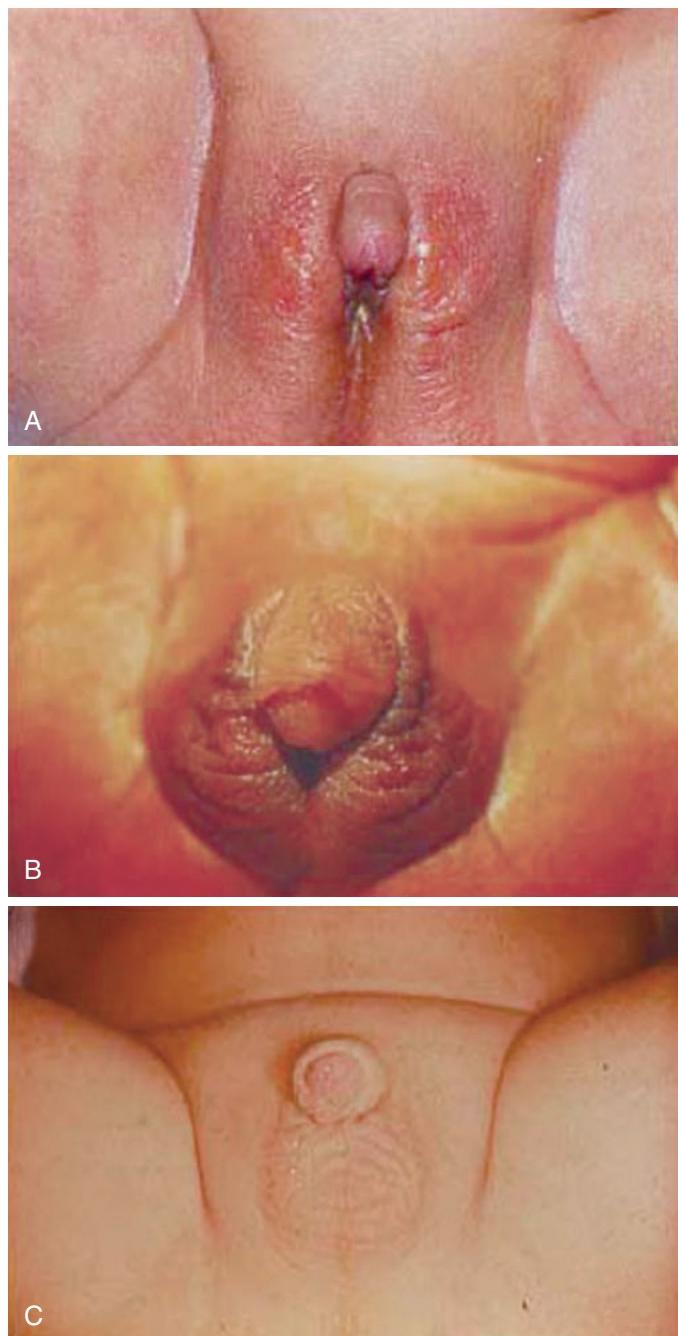
Antimüllerian hormone (AMH), inhibin, and activin are members of the transforming growth factor-β (TGF-β) superfamily of growth factors. AMH is the earliest secreted product of the Sertoli cells of the fetal testis. The AMH receptor is expressed in Sertoli cells. In the female it is present in fetal müllerian duct cells, and in granulosa cells (fetal and postnatal). During sex differentiation in males, AMH causes involution of the müllerian ducts. AMH is secreted in males by Sertoli cells during both fetal and postnatal life. In females, it is secreted by ovarian granulosa cells from 36 weeks of gestation to menopause, but at lower levels. The serum concentration of AMH in males is highest at birth, whereas in females it is highest at puberty. After puberty, both sexes have similar serum concentrations of AMH. Its role in postnatal life is not yet fully characterized.


FIGURE 23.2 Examples of atypical genitalia in 46,XX DSD due to CAH (21-OH deficiency) with varying degrees of virilization. *A,* 2-week-old infant; positive newborn screen: abnormal genitalia missed; serum 17-OH progesterone = 30,690 ng/dL; electrolytes: Na = 133 meq/L, K = 7.1 meq/L. *B,* 12-day-old "male with perineal hypospadias and crypt-orchidism"; newborn screen: 17-OH progesterone was normal; urology consultant suggested endocrine evaluation; high-dose steroids for respiratory problems on days of life 1-12; day 12: 17-OH progesterone = 169 ng/dL, karyotype 46,XX; day 14: 17-OH progesterone = 37,400 ng/dL. *C,* 3-week-old infant; discharged after circumcision as bilateral crypt-orchid male with follow-up appointment in urology clinic; presented near death with salt-losing crisis; karyotype 46,XX. (From Kim MS, Donohoue PA. Adrenal disorders. In: Kappy MS, Allen DB, Geffner ME, eds. *Pediatric Practice Endocrinology.* 2nd ed. New York: McGraw-Hill; 2014.)

Inhibin is another glycoprotein hormone secreted by testicular Sertoli cells and ovarian granulosa and theca cells. Inhibin A consists of an α subunit disulfide linked to the β-A subunit, whereas inhibin B consists of the same α subunit linked to the β-B subunit. Activins are dimers of the B subunits, either homodimers (BA/BA, BB/BB) or heterodimers (BA/BB). Inhibins selectively inhibit, whereas activins stimulate pituitary FSH secretion. Inhibin A is absent in males and is present mostly in the luteal phase in women. Inhibin B is the principal form of inhibin in males, and in females during the follicular phase. *Inhibin B is useful as a marker of Sertoli cell function in males.* FSH stimulates inhibin B secretion in females and males, but only in males is there also evidence for gonadotropin-independent regulation. Levels of inhibin B are currently being studied in children with various forms of gonadal and pubertal disorders. In males with delayed puberty, inhibin B may be a useful screening test to differentiate between constitutional delay of puberty and hypogonadotropic hypogonadism (HH). In HH the serum inhibin B level has been shown to be very low to undetectable.

Like inhibin and activin, follistatin (a single-chain glycosylated protein) is produced by gonads and other tissues such as the hypothalamus, kidney, adrenal gland, and placenta. Follistatin inhibits FSH secretion principally by binding activins, thereby blocking the effects of activins at the level of both the ovary and pituitary.

Many additional peptides act as mediators of the development and function of the testis. They include neurohormones such as growth hormone-releasing hormone, gonadotropin-releasing hormone, corticotropin-releasing hormone, oxytocin, arginine vasopressin, somatostatin, substance P, and neuropeptide Y; growth factors such as insulin-like growth factors (IGFs) and IGF-binding proteins, TGF-β, and fibroblast, platelet-derived, and nerve growth factors; vasoactive peptides; and immune-derived cytokines such as tumor necrosis factor and interleukins IL-1, IL-2, IL-4, and IL-6.

Testicular development is marked by major maturational changes at puberty (see Chapter 42). Clinical patterns of pubertal changes vary widely. In 95% of boys, enlargement of the genitals, which is typically the first sign of puberty, begins between 9.5 and 13.5 years, reaching maturity at 13-17 years. In a minority of normal boys, puberty begins after 15 years of age. In some boys, pubertal development is completed in less than 2 years, but in others it may take longer than 4.5 years. Pubertal development and the adolescent growth spurt occur at an older age in boys than in girls.

The median age of sperm production (spermarche) is 14 years. This event occurs in mid-puberty as judged by pubic hair, testis size, evidence of growth spurt, and testosterone levels. Nighttime levels of FSH are in the adult male range at the time of spermarche; the first conscious ejaculation occurs at about the same time.

Ovaries

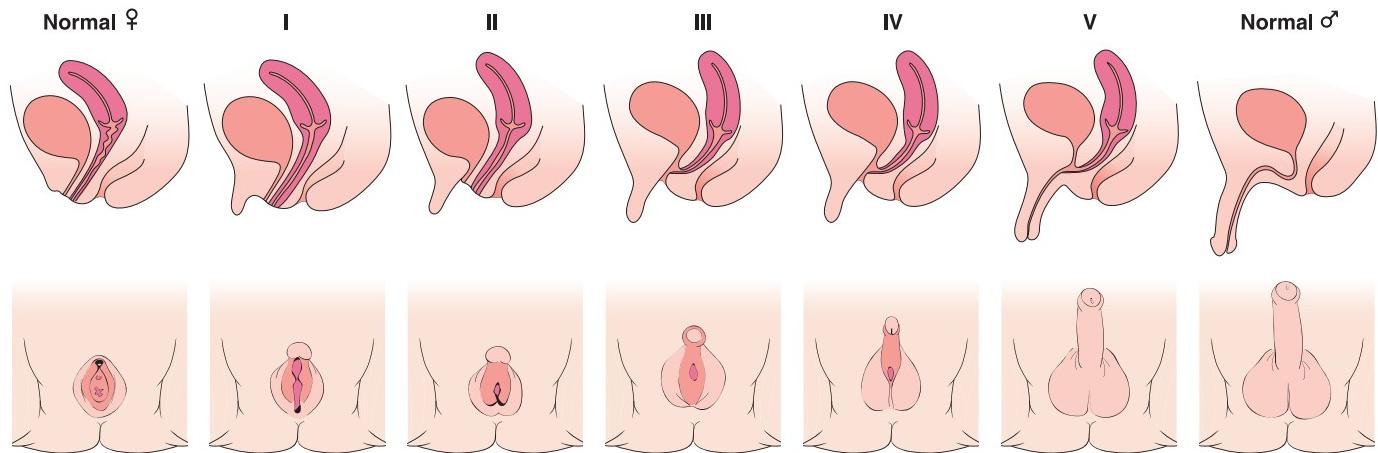
In the normal female, the undifferentiated gonad can be identified histologically as an ovary by 10-11 weeks of gestation (see Fig. 23.4), after the upregulation of R-spondin 1. Oocytes are present from the 4th month of gestation and reach a peak of 7 million by 5 months of gestation. For normal maintenance, oocytes need granulosa cells to form primordial follicles. Functional FSH (but not LH) receptors are present in oocytes of primary follicles during follicular development. Two normal X chromosomes are needed for maintenance of oocytes. In contrast to somatic cells, in which only one X chromosome is active, both Xs are active in germ cells. At birth, the ovaries contain about 1 million active follicles, which decrease to 0.5 million by menarche. Thereafter, they decrease at a rate of 1000/mo, and at an even higher rate after the age of 35 years.


FIGURE 23.3 Method of staging the degree of virilization of the external genitalia of females as proposed by Prader (1958). In type I, the only abnormality is a slight enlargement of the clitoris. In type V, there is a markedly enlarged phallus with a penile urethra. (Redrawn from Prader A. Vollkommen männliche äussere gentialentwicklung und salzverlustsyndrom bei madchen mit kongenitalem adrenogenitalem syndrom. *Helv Paediat Acta.* 1958;13:5.)

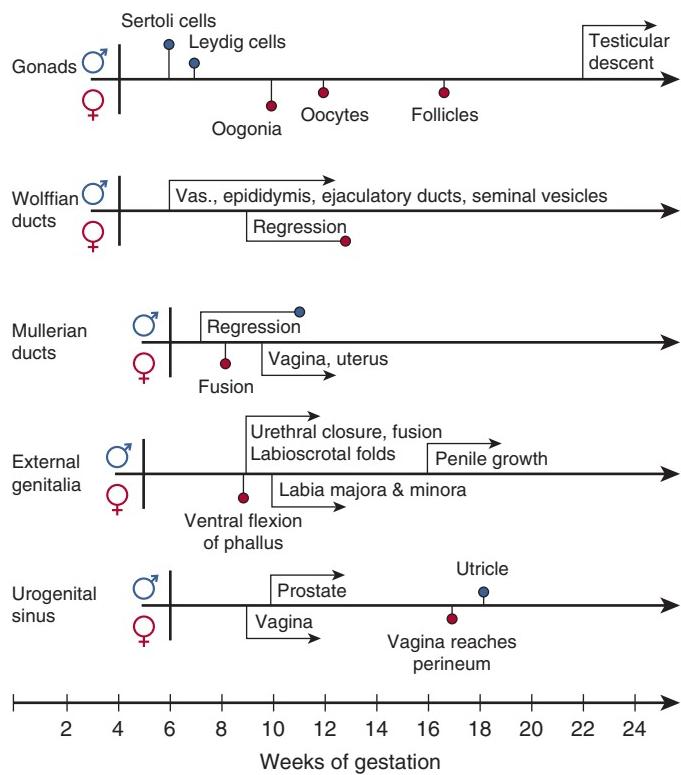

FIGURE 23.4 Timing of Development of External and Internal Genitalia. The *solid dot* shows the age at onset of the various developmental changes. Male differentiation is shown above each line, with female differentiation below. (From White PC, Speiser PW. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency. *Endocr Rev.* 2000;21:245-291.)

The hormones of the fetal ovary are provided mostly by the feto-placental unit. As in males, peak gonadotropin secretion occurs in fetal life and then again at 2-3 months of life, with the lowest levels at about 6 years of age. In contrast to males, the FSH surge predominates over LH in females. FSH peaks around 3-6 months of age, declines by 12 months, but remains detectable for 24 months. Under LH influence, estradiol peaks at 2-6 months of age. The inhibin B response is variable, peaking at between 2-12 months and remaining above prepubertal levels until 24 months. In both infancy and childhood, gonadotropin levels are higher in females than in males.

The most important estrogens produced by the ovary are estradiol-17β (E2) and estrone (E1); estriol is a metabolic product of both, and all 3 estrogens may be found in the urine of mature females. Estrogens arise from androgens produced by the adrenal glands, the ovaries, or the testes (see Fig. 23.5). This conversion explains why in certain types of 46,XY DSD, feminization occurs at puberty. In HSD17B3 deficiency (see later), for example, the enzymatic block results in markedly increased secretion of androstenedione, which is converted in the peripheral tissues to estradiol and estrone. These estrogens, in addition to those directly secreted by the testis, result in breast development. Estradiol produced from testosterone in the complete androgen insensitivity syndrome causes complete feminization in these XY individuals.

Plasma levels of estradiol increase slowly but steadily with advancing sexual maturation and correlate well with clinical progression of pubertal development, skeletal age, and rising levels of FSH. Levels of LH do not rise measurably until secondary sexual characteristics are present. Estrogens, like androgens, inhibit secretion of both LH and FSH (negative feedback). In females, estrogens also provoke the surge of LH secretion that occurs in the mid-menstrual cycle and results in ovulation. The capacity for this positive feedback is another maturational milestone of puberty.

The average age at menarche in Caucasian American girls is about 12.5-13 years, but the range of "normal" is wide, and 1-2% of normal girls have not menstruated by 16 years of age (see Chapter 42). The age at onset of pubertal signs is about 2 years before menarche. This age varies, with some studies suggesting earlier ages than previously thought, especially in the U.S. African-American population. Menarche generally correlates closely with skeletal age. Maturation and closure of the epiphyses is partially estrogen dependent, as demonstrated by a very tall 28-year-old normally-masculinized male with continued growth due to incomplete closure of the epiphyses, who proved to have complete estrogen insensitivity due to an estrogen-receptor defect.

TABLE 23.4 Genes Mutated in Disorders of Sex Development

Gene	Protein	OMIM #	Locus	Inheritance	Gonad	Müllerian Structures	External Genitalia	Associated Features/ Variant Phenotypes
46,XY DSD								
Disorders of Gonadal (Testicular) Development: Single Gene Disorders								
WT1	TF	607102	11p13	AD	Testicular dysgenesis	±	Female or ambiguous	Wilms tumor, renal abnormalities, gonadal tumors (WAGR, Denys-Drash, and Frasier syndromes)
SF1 (NR5A1)	Nuclear receptor TF	184757	9q33	AD/AR	Testicular dysgenesis	±	Female or ambiguous	More severe phenotypes include primary adrenal failure; milder phenotypes have isolated partial gonadal dysgenesis; mothers who carry SF1 mutation have premature ovarian insufficiency
SRY	TF	480000	Yp11.3	Y	Testicular dysgenesis or ovotestis	±	Female or ambiguous	
SOX9	TF	608160	17q24-25	AD	Testicular dysgenesis or ovotestis	±	Female or ambiguous	Campomelic dysplasia (17q24 rearrangements; milder phenotype than point mutations)
DHH	Signaling molecule	605423	12q13.1	AR	Testicular dysgenesis	+	Female	The severe phenotype of 1 patient included minifascicular neuropathy; other patients have isolated gonadal dysgenesis
ATRX	Helicase (?chromatin remodeling)	300032	Xq13.3	X	Testicular dysgenesis	−	Female, ambiguous or male	α-Thalassemia, developmental delay
ARX	TF	300382	Xp21.13	X	Testicular dysgenesis	−	Ambiguous	X-linked lissencephaly, epilepsy, temperature instability
Disorders of Gonadal (Testicular) Development: Chromosomal Changes Involving Key Candidate Genes								
DMRT1	TF	602424	9p24.3	Monosomic deletion	Testicular dysgenesis	±	Female or ambiguous	Developmental delay
DAX1 (NR0B1)	Nuclear receptor TF	300018	Xp21.3	dupXp21	Testicular dysgenesis or ovary	±	Female or ambiguous	
WNT4	Signaling molecule	603490	1p35	dup1p35	Testicular dysgenesis	+	Ambiguous	Developmental delay
Disorders in Hormone Synthesis or Action								
LHGCR	G-protein receptor	152790	2p21	AR	Testis	−	Female, ambiguous or micropenis	Leydig cell hypoplasia
DHCR7	Enzyme	602858	11q12-13	AR	Testis	−	Variable	Smith-Lemli-Opitz syndrome: coarse facies, 2nd-3rd toe syndactyly, failure to thrive, developmental delay, cardiac and visceral abnormalities

TABLE 23.4   Genes Mutated in Disorders of Sex Development—cont'd

Gene	Protein	OMIM#	Locus	Inheritance	Gonad	Müllerian Structures	External Genitalia	Associated Features/ Variant Phenotypes
StAR	Mitochondrial membrane protein	600617	8p11.2	AR	Testis	–	Female	Congenital lipoid adrenal hyperplasia (primary adrenal failure), pubertal failure
CYP11A1	Enzyme	118485	15q23-24	AR	Testis	–	Female or ambiguous	Congenital adrenal hyperplasia (primary adrenal failure), pubertal failure
HSD3B2	Enzyme	201810	1p13.1	AR	Testis	–	Ambiguous	CAH, primary adrenal failure, partial androgenization due to ↑ DHEA
CYP17	Enzyme	202110	10q24.3	AR	Testis	–	Female ambiguous or micropenis	CAH, hypertension due to ↑ corticosterone and 11-deoxycorticosterone (except in isolated 17,20-lyase deficiency)

Enzyme activities include 20-hydroxylase, 22-hydroxylase, and 20,22-lyase; CYP17A1: activities include 17α-hydroxylase and 17,20-lyase; HSD3B2: activities include 3β-hydroxysteroid dehydrogenase type II and D5D4-isomerase; CYP21A2: activity is 21-hydroxylase; CYP11B1: activity is 11β-hydroxylase; CYP11B2: activities include 18-hydroxylase (CMOI) and 18-dehydrogenase (CMOII); SRD5A1: activity is 5α-reductase type I; SRD5A2: activity is 5α-reductase type II; HSD17B2: activity is 17β-hydroxysteroid dehydrogenase type II; HSD17B3: activity is 17β-hydroxysteroid dehydrogenase type III; AKR1C2/4 *(blue):* activities are 3α-reductase types I and III; AKR1C2/ToDH 9ox): activities are 3α-reductase and 3-hydroxyepimerase. ARO, aromatase; DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone; 5αDHP, 5α-dihydroprogesterone; DOC, deoxycortico-sterone; POR, P450 oxidoreductase. (Data from Kim MS, Donohoue PA. Adrenal disorders. In: Kappy MS, Allen DB, Geffner ME, eds. *Pediatric Practice Endocrinology.* 2nd ed. New York: McGraw-Hill; 2014; and Flück CE, et al. Why boys will be boys: two pathways of fetal testicular androgen biosynthesis are needed for male sexual differentiation. *Am J Hum Genet.* 2011;89:201-218.)

DIAGNOSTIC APPROACH TO THE PATIENT WITH ATYPICAL OR AMBIGUOUS GENITALIA

Infants with ambiguous or atypical genitalia should be evaluated and treated at a center with multidisciplinary experience in DSD. The appearance of the external genitalia is rarely diagnostic of a particular disorder, and thus does not often allow distinction among the various forms of DSD. The most common causes of 46,XX DSD are virilizing forms of **congenital adrenal hyperplasia (CAH)**. It is important to note that in 46,XY DSD, the specific diagnosis is not found in up to 50% of cases. At 1 experienced center, the etiologies of DSD in 250 patients over 25 years were compiled. The 6 most common diagnoses accounted for 50% of the cases. These included virilizing CAH (14%), androgen insensitivity syndrome (10%), mixed gonadal dysgenesis (8%), clitoral/labial anomalies (7%), hypogonadotropic hypogonad-ism (6%), and 46,XY small-for-gestational age males with hypospadias (6%). The etiology in cases of 46,XY DSD without a known diagnosis can be further delineated using exome sequencing technologies.

The relative lack of established diagnoses in 46,XY DSD and the resulting lack of specific management emphasizes the need for thor-ough diagnostic evaluations. These include biochemical characteriza-tion of possible steroidogenic enzymatic defects, imaging studies to characterize internal genitalia, and determination of genetic sex as well as other genetic studies as determined by each individual patient with atypical genitalia. The parents need counseling about the potentially complex nature of the baby's condition, and guidance as to how to deal with the curiosity of their well-meaning friends and family members. The evaluation and management should be carried out by a multidis-ciplinary team of experts that include practitioners in pediatric endo-crinology, pediatric surgery/urology, pediatric radiology, newborn medicine/neonatology, genetics, and psychology. *On occasion, the sex of rearing will need to be uncommitted until the diagnostic evaluation is completed.* Once the sex of rearing has been agreed on by the family and team, treatment can be organized. Genetic counseling should be offered when the specific diagnosis is established.

After a complete history and physical exam, the common diagnostic approach includes multiple steps as described in the following outline. These steps are usually performed simultaneously rather than waiting for results of 1 test prior to performing another, in order to expedite the diagnosis. Careful attention to the presence of physical features other than the genitalia is crucial to determine if a diagnosis of a par-ticular multisystem syndrome is possible (Table 23.5 and Fig. 23.6). A summary of many features of commonly encountered causes of DSD is provided in Table 23.6.

(See *Nelson Textbook of Pediatrics,* p. 2752.)

TABLE 23.5	**Potential Investigations for Disorders of Sex Development**	
Approach	**Test**	**Uses**
Genetics	FISH* (X- and Y-specific probes)	Rapid analysis of sex chromosome complement on cells
	qfPCR*	Rapid analysis of sex chromosome signal in DNA
	Karyotype*	Analysis of sex chromosomes and autosomes in cells with ability to look for mosaicism by screening multiple cells, as well as detection of major deletions, duplications, and balanced translocations
	Array CGH or SNP microarray*	Analysis of chromosome signal across the genome, with ability to detect smaller copy number variants but not balanced translocations, using DNA
	Multiple ligation probe-dependent amplification	Analysis of the loss of gain of specific exons or whole genes on a predefined panel of probes, such as for DSD genes, using DNA
	Single-gene analysis	Sanger sequencing and analysis of individual genes that are highly likely to be the cause of DSD based on incidence and clinical and biochemical features (e.g., *CYP21A2*)
	Targeted panel sequencing	Analysis of large numbers of known DSD-causing genes using high throughput sequencing of DNA
	Whole exome sequencing	Analysis of all the coding exons in the DNA, which may show changes in known, putative, or novel DSD-associated genes, using high-throughput sequencing
Endocrine	Routine serum biochemistry*; urinalysis*	May reveal a salt-losing crisis or associated renal disorder (e.g., WT1)
	17-Hydroxyprogesterone,* 11-deoxycortisol, 17-hydroxypregnenolone	May help to diagnose CAH or reveal a specific block in an adrenal pathway relevant to DSD
	Renin, ACTH	May show a salt-losing state or primary adrenal insufficiency
	Testosterone,* androstenedione, DHT	Indicates the degree of androgen production and ratios of androgens in the basal state or following hCG stimulation and may help to diagnose a block in androgen production consistent with a specific diagnosis (e.g., 17β-HSD or 5α-reductase deficiencies); can also reveal androgen production in ovotesticular DSD
	Gonadotropins	May indicate an underlying block in steroidogenesis or androgen insensitivity (LH), or impaired Sertoli cell function (FSH)
	AMH, inhibin B	Can be useful markers of testicular integrity: AMH is detectable throughout childhood and is reduced in testicular dysgenesis or absent if streak gonads or anorchia occur; AMH may be high in AIS or reduced androgen production due to steroidogenic defects; AMH may help to reveal the presence of testicular tissue in 46,XX ovotesticular DSD
	Urinary steroids by GC–MS	Can be used to diagnose specific steroidogenic defects in the newborn period (e.g., 21-hydroxylase deficiency, 11β-hydroxylase deficiency, 3β-hydroxysteroid dehydrogenase deficiency, P450 oxidoreductase deficiency, 17α-hydroxylase deficiency); can reveal 5α-reductase deficiency only after 3-6 mo of life
	Dynamic tests: ACTH stimulation	Used to assess the adrenal gland stress response (quantitative) and can be coupled with measurement of steroid metabolites or poststimulation urine steroid analysis to study ratios of metabolites (diagnostic)
	hCG stimulation	Used in short (3 days) or prolonged (3 wk) formats to assess androgen production (quantitative) and androgen biosynthesis pathways (diagnostic); can also be used to assess for the presence of testicular tissue (e.g., anorchia, ovotestis), although AMH is now more often used initially
	FSH stimulation test	Rarely used to investigate the presence of ovarian tissue by measuring inhibin A and estradiol response
Imaging	Abdominopelvic and renal ultrasound*	Can reveal the size, position, and structure of gonads (especially testes), the presence of müllerian structures, and associated changes (such as renal size or anomalies)
	MRI	Sometimes used to assess internal structures, especially in adolescence
	Cystourethroscopy, sinogram	Can reveal the structure of the bladder, vagina, and common channel
Surgical	Laparoscopy	Can reveal internal structures by direct visualization, such as gonads and müllerian structures
	Gonadal biopsies	Can be used to determine the nature of gonads, especially if testicular dysgenesis or ovotestes are suspected

*Indicates first-line investigations for which results are available within days. For images of G-banded karyotypes and FISH analysis, see Fig. 23.6.

ACTH, adrenocorticotropic hormone; AIS, androgen insensitivity syndrome; AMH, antimüllerian hormone; CAH, congenital adrenal hyperplasia; CGH, comparative genomic hybridization; DHT, dihydrotestosterone; DSD, disorders of sex development; FISH, fluorescent in situ hybridization; FSH, follicle-stimulating hormone; GC–MS, gas chromatography–mass spectrometry; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; qfPCR, quantitative fluorescent polymerase chain reaction; SNP, single-nucleotide polymorphism. From Achermann JC, Hughes IA. Pediatric disorders of sex development. In: Melmed S, Polonsky KS, Larsen PR, et al., eds. *Williams Textbook of Endocrinology.* 13th ed. Philadelphia: Elsevier; 2016:949.

Initial karyotype
(FISH, qfPCR)

46, XX

If CAH suspected (common):
PRIOR TO TREATMENT:
glucose, electrolytes, cortisol, PRA, aldosterone, 17-OHP, A4, DHEAS, USP; consider ACTH stimulation test (after day 3)

Ovotesticular DSD (rare):
AMH, inhibin B, testosterone, consider early EUA and laparoscopy

Aromatase deficiency (very rare):
also clitoromegaly of prematurity and structural variants

46, XY

Ensure **adrenal function** adequate (rarely insufficient): glucose, electrolytes, ACTH, cortisol; consider ACTH stimulation test

Is it **testicular dysgenesis, steroidogenic defect or androgen resistance?**
AMH, inhibin B, testosterone, LH/FSH, USP; consider 3 day/ 3 week hCG stimulation test

46, XX/46, XY (very rare)
Individualized approach; consider early EUA/ laparoscopy if uncertainty about assignment

45, X/46, XY
AMH, inhibin B, testosterone, LH/FSH; consider hCG stimulation test, or early EUA/laparoscopy if uncertainty about assignment; ECHO, TFTs, renal USS, Turner syndrome screening, audiology, etc.

FIGURE 23.6 Overview of potential investigations for a newborn with atypical genitalia or disorders of sex development (DSD) once the initial karyotype or assessment of sex chromosome complement has been made. A4, androstenedione; ACTH, adrenocorticotropic hormone; AMH, antimüllerian hormone; CAH, congenital adrenal hyperplasia; DHEAS, dehydroepiandrosterone sulfate; ECHO, echocardiogram; EUA, examination under anesthetic; FISH, fluorescent in situ hybridization; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; 17-OHP, 17-hydroxyprogesterone; PRA, plasma renin activity; qfPCR, quantitative fluorescent polymerase chain reaction; TFT, thyroid function test; USP, urine steroid profiling; USS, ultrasound screening. (From Achermann JC, Hughes IA. Pediatric disorders of sex development. In: Melmed S, Polonsky KS, Larsen PR, et al., eds. *Williams Textbook of Endocrinology.* 13th ed. Philadelphia: Elsevier; 2016:948.)

Diagnostic tests include the following:
1. Blood karyotype, with rapid determination of sex chromosomes (in many centers this is available within 24-48 hours) (see Fig. 23.6).
2. Other blood tests (see Table 23.5)
   a. Screen for congenital adrenal hyperplasia: cortisol biosynthetic precursors and adrenal androgens, particularly serum levels of 17-hydroxyprogesterone and androstenedione for 21-hydroxylase deficiency, the most common form. In the United States, all 50 states have a newborn screen for 21-hydroxylase deficiency.
   b. Screen for androgen biosynthetic defects with serum levels of androgens and their precursors.
   c. Assess for gonadal responsiveness to gonadotropin to screen for testicular gonadal tissue: measure serum levels of testosterone and dihydrotestosterone before and after intramuscular injections of hCG.
   d. Molecular genetic analyses for SRY (sex-determining region of the Y chromosome), other Y-specific loci, and when needed, other single-gene defects associated with DSD (see Table 23.4).

   e. Gonadotropin levels (LH and FSH).
   f. AMH and inhibin B levels.
3. The internal anatomy of patients with ambiguous genitalia can be defined with 1 or more of the following studies:
   a. Voiding cystourethrogram (VCUG).
   b. Endoscopic examination of the genitourinary tract.
   c. Pelvic ultrasound; renal and adrenal ultrasound.
   d. Pelvic MRI.
   e. Exploratory laparoscopy to locate and characterize/biopsy the gonads.

BASIC APPROACHES TO THE DIAGNOSIS AND MANAGEMENT OF DISORDERS OF SEX DEVELOPMENT

In the neonate, the presence of atypical genitalia requires immediate attention to determine the etiology and then if necessary, decide on the sex of rearing. In some cases, DSD is associated with other abnormalities that adversely impact the child's health, particularly the salt-losing forms of CAH, adrenal insufficiency related to SF1 defects, and renal abnormalities associated with WT-1 defects.

The family of the infant needs to be informed of the child's condition as early, completely, compassionately, and honestly as possible. Caution must be used to avoid feelings of guilt, shame, and confusion. Guidance needs to be provided to alleviate both short-term and long-term concerns and to allow the child to grow up in a completely supportive environment. The initial care is best provided by the aforementioned team of professionals who remain focused foremost on the needs of the child. Management of the potential emotional and psychologic effects that these disorders can generate in the child and the family is of paramount importance and requires the involvement of physicians, psychologists, and other health care professionals with sensitivity, training, and experience in this field.

While awaiting the results of blood tests, imaging with pelvic ultrasonography and/or MRI is used to determine the presence of a uterus and ovaries. Presence of a uterus and absence of external palpable gonads often suggest a virilized XX female. A search for the source of virilization includes studies of adrenal hormones to rule out varieties of CAH, and studies of androgens and estrogens may be necessary to rule out aromatase deficiency. Virilized XX females with CAH are generally (but not always) reared as females even when Prader 4 or 5 (see Fig. 23.3).

The absence of a uterus, with or without palpable external gonads, may indicate an undervirilized XY male. Measurements of blood levels of gonadotropins, testosterone, AMH, and DHT are necessary to determine whether testicular production of androgen is present and is normal. Undervirilized males who are totally feminized may be reared as females. Certain significantly undervirilized infants, such as those with 5α-reductase deficiency, may be reared as males because these children virilize normally at puberty. Sixty percent of individuals with 5α-reductase deficiency assigned as female in infancy will identify as males as adults. An infant with a comparable degree of undervirilization resulting from an androgen receptor defect, such as androgen insensitivity syndrome (AIS), may be successfully reared as a female, depending on androgen responsiveness.

In some mammals, the female exposed to androgens prenatally or in early postnatal life exhibits nontraditional sexual behavior in adult life. Most, but not all, girls who have undergone fetal masculinization from CAH have female sexual identity, although during childhood they may appear to prefer male typical play activities over female typical play activities.

TABLE 23.6   Atypical/Ambiguous Genitalia: Features Associated with the Most Common Diagnoses

	21-OH* Deficiency	Testicular Dysgenesis with Y Chromosome	Ovo-Testicular DSD	Partial Androgen Insensitivity	Dihydrotestosterone (DHT) Deficiency	Block in Testosterone (T) Synthesis
Clinical Feature						
Palpable gonad(s)	–	+/–	+/–	+	+/–	+
Uterus present[†]	+	+	Usually	–	–	–
Increased skin pigmentation	+/–	–	–	–	–	–
Sick baby	+/–	–	–	–	–	+/–
Dysmorphic features	–	+/–	–	–	–	–
Diagnostic Test Results						
Serum 17-OHP	Elevated	Normal	Normal	Normal	Normal	Normal
Electrolytes	Possibly abnormal	Normal	Normal	Normal	Normal	Possibly abnormal
Karyotype	46,XX	45,X/46,XY or others	46,XX	46,XY	46,XY	46,XY
Testosterone response to hCG	NA	Positive	Normal or reduced	Positive	Positive	Reduced or absent
Gonadal biopsy	NA	Dysgenic gonad	Ovotestis	Normal testis with +/– Leydig cell hyperplasia DNA screening for AR[‡] or post-receptor mutations positive in many cases	Normal testis Elevated T : DHT ratio	Normal testis Levels of testosterone precursors elevated Testosterone level low

*21-Hydroxylase.
[†]As determined by ultrasound or rectal examination.
[‡]Androgen receptor.
hCG, human chorionic gonadotropin; NA, not applicable; 21-OH, 21-hydroxylase; 17-OHP, 17-hydroxyprogesterone.

In the past it was thought that surgical treatment of ambiguous genitalia to create a female appearance, particularly when a vagina was present, was more successful than construction of male genitalia. Considerable controversy has developed regarding these decisions. Sexual functioning is to a large extent more dependent on neurohormonal and behavioral factors than the physical appearance and functional ability of the genitalia. Similarly, controversy exists regarding the timing of the performance of invasive and definitive procedures, such as surgery. Whenever possible, without endangering the physical or psychologic health of the child, an expert multidisciplinary team should consider deferring elective surgical procedures and gonadectomies until the child can participate in the informed consent for the procedure. One study of 59 boys and 18 girls with gender dysphoria but without DSD or documentation of genomic or enzymologic abnormalities indicated that most of these children no longer have gender dysphoria after completion of puberty. Among those who do, homosexuality and bisexuality are the most frequent diagnoses.

For patients with DSD who have Y-chromosome material and intraabdominal gonads, gonadectomy is generally recommended due to the risk of gonadal tumors developing with increasing age, many of which are malignant.

The pediatrician, pediatric endocrinologist, and psychologist, along with the appropriate additional specialists, should provide ongoing compassionate, supportive care to the patient and the patient's family throughout childhood, adolescence, and adulthood. Active support groups are available for families and patients with many of the conditions discussed.

SPECIFIC TYPES OF DISORDERS OF SEX DEVELOPMENT

46,XX Disorders of Sex Development

In 46,XX DSD, the sex chromosomes are XX, but the external genitalia are virilized. If the gonads are ovaries, there is no significant AMH production. Thus the uterus, fallopian tubes, cervix, and upper vagina will develop. The varieties and causes of this condition are relatively few. Most cases result from exposure of the female fetus to excessive exogenous or endogenous androgens during early intrauterine life (see Fig. 23.4 and Table 23.2). The changes consist principally of virilization of the external genitalia (clitoral hypertrophy and labioscrotal fusion).

Androgen Exposure/Fetoplacental Source

Congenital adrenal hyperplasia. CAH is the most common cause of genital ambiguity and of 46,XX DSD. CAH is caused by an enzymatic defect in the biosynthesis of cortisol. This results in compensatory ACTH excess, which stimulates hyperplasia of the adrenal cortex in an attempt to normalize cortisol secretion. There is overproduction of adrenal androgen precursors in the forms of CAH that cause genital ambiguity in 46,XX infants. Females with 21-hydroxylase and 11-hydroxylase deficiency are the most highly virilized (see Fig. 23.2).

Minimal virilization also occurs with the type II 3β-hydroxysteroid dehydrogenase (HSD3B2) defect (see Fig. 23.5 for enzymatic pathways). The androgen precursors are converted in extra-adrenal tissues into testosterone and DHT, the potent androgens that bind to the androgen receptor (AR). The treatment for all forms of CAH is cortisol replacement therapy, which reduces ACTH secretion and reverses the androgen excess. Mineralocorticoid replacement may be needed in 21-hydroxylase and HSD3B2 deficiency. The surgical treatment of virilized genitalia in affected females is usually recommended during infancy. However, this remains a controversial topic. Surgical outcomes have improved in the past decades.

CAH due to 21-hydroxylase deficiency (mutations in the *CYP21A2* gene) is one of the most common inherited diseases associated with DSD. It accounts for more than 95% of cases of adrenal steroidogenic defects and is estimated to occur in about 1 in 14,000 live births. In some genetically isolated populations such as Yupik Eskimos, the incidence is much higher. CYP21A2 deficiency usually presents as 1 of 2 clinical syndromes in neonates or very young infants, both of which are associated with glucocorticoid deficiency. If not diagnosed in the 1st couple of weeks, the **salt-wasting form** is associated with dehydration, hyponatremia, hyperkalemia, acidosis, and hypotension with elevated plasma renin activity (PRA) due to mineralocorticoid deficiency. Symptoms of this renal salt loss include lethargy, vomiting, and poor feeding. Adrenal androgen excess results in ambiguous genitalia in affected females. The simple virilizing form also causes prenatal virilization in females but without postnatal salt wasting. In some infants, the distinction between the 2 forms is not clear due to early detection by newborn screening. Female patients with salt-losing CAH tend to have more virilization than do non–salt-losing female patients. Masculinization may be so intense that a complete penile urethra results, and the patient may appear to be a male with bilateral cryptorchidism. Affected males have normal genitalia. **Late-onset forms** of CYP21A2 deficiency present with early pubarche in both sexes, or with hirsutism and menstrual irregularities in older females. These late-onset forms are not causes of DSD.

CAH due to 11β-hydroxylase deficiency (mutations in the *CYP11B1* gene) is the second most common cause of CAH, and accounts for less than 5% of CAH cases. As with other causes of CAH, cortisol synthesis is reduced; however, there is excessive mineralocorticoid (deoxycorticosterone [DOC]) secretion accompanying adrenal androgen overproduction. As a result, patients become hypertensive after infancy because of increased sodium retention.

CAH due to 3β-hydroxysteroid dehydrogenase type II deficiency (mutations in the *HSD3B2* gene) is a rare form of CAH in which synthesis of all steroid hormones is impaired (see Fig. 23.5). Thus, there are deficiencies of glucocorticoids, mineralocorticoids, and potent androgens. Most patients present as neonates or in early infancy. Clinical manifestations are because of both cortisol and aldosterone deficiency as seen in 21-hydroxylase deficiency, including feeding difficulties, vomiting, volume depletion, and subsequent hyponatremia, hyperkalemia, and high PRA. Affected females have mild virilization (an indirect effect of oversecretion of dehydroepiandrosterone [DHEA]). This form of CAH may also cause 46,XY DSD.

P450 oxidoreductase (POR) deficiency is also known as apparent combined CYP21A2 and CYP17A1 deficiency. The underlying defect is a mutation in the *POR* gene that encodes cytochrome P450 oxidoreductase, a mitochondrial cofactor that transfers electrons to CYP21A2 and CYP17A1 during steroidogenesis. This results in a partial deficiency of the enzymes 21-hydroxylase and 17-hydroxylase. Affected girls are born with ambiguous genitalia, suggesting intrauterine androgen excess; however, as opposed to classic CAH, after birth serum androgen concentrations are low, and virilization does not progress. Boys may have undervirilization. Mothers may have virilization during pregnancy with an affected fetus. Bone malformations affecting primarily the head and limbs (**Antley-Bixler syndrome**) may be seen in both boys and girls with POR deficiency.

Aromatase deficiency. In 46,XX females, the rare condition of aromatase deficiency during fetal life leads to 46,XX DSD and results in hypergonadotropic hypogonadism at puberty because of ovarian failure to synthesize estrogen from androgen. Examples of this condition include 2 46,XX infants who had enlargement of the clitoris and posterior labial fusion at birth. In 1 instance, maternal serum and urinary levels of estrogen were very low and serum levels of androgens were high. Cord serum levels of estrogen were also extremely low, and those of androgen were elevated. The 2nd case also had virilization of unknown cause since birth, but the aromatase deficiency was not diagnosed until 14 years of age, when she had further virilization and failed to go into female puberty. At that time, she had elevated levels of gonadotropins and androgens but low estrogen levels, and ultrasonography revealed large ovarian cysts bilaterally. Two siblings with aromatase deficiency have also been described. The 28-year-old XX proband was 177.6 cm tall (+2.5 SD) after having received estrogen replacement therapy. Her 24-year-old brother was 204 cm tall (+3.7 SD), and had a delayed bone age of only 14 years due to failure of epiphyseal fusion, which is estrogen-mediated.

Cortisol resistance due to glucocorticoid receptor gene mutation. A 9-year-old girl with 46,XX DSD and a history of ambiguous genitalia, thought to be due to 21-hydroxylase deficiency CAH, had elevated cortisol levels both at baseline and after dexamethasone, along with hypertension and hypokalemia, suggestive of the diagnosis of generalized glucocorticoid resistance. A novel homozygous mutation in exon 5 of the glucocorticoid receptor was demonstrated. Virilization occurs due to excess ACTH stimulation of adrenal steroid production, as the glucocorticoid receptor defect is also present in the pituitary gland, which senses inadequate cortisol effect to provide negative feedback.

Androgen Exposure: Maternal Source

Virilizing maternal tumors. Rarely, a female fetus can be virilized by a maternal androgen-producing tumor. In a minority of cases, the lesion is a benign adrenal adenoma, but the majority are ovarian tumors, particularly androblastomas, luteomas, and Krukenberg tumors. Maternal virilization may be manifested by enlargement of the clitoris, acne, deepening of the voice, decreased lactation, hirsutism, and elevated levels of androgens. In the infant, there is enlargement of the clitoris of varying degrees, often with labial fusion if the tumor produced excess androgen during the 1st trimester. Mothers of children with unexplained 46,XX DSD should undergo physical examination and measurements of their own levels of plasma testosterone, dehydroepiandrosterone sulfate (DHEAS), and androstenedione.

Administration of androgenic drugs to women during pregnancy. Testosterone and 17-methyltestosterone have been reported to cause 46,XX DSD in some instances. The greatest number of cases has resulted from the use of certain progestational compounds for the treatment of threatened abortion. These progestins have been replaced by nonvirilizing ones.

Disorders of Ovarian Development

46,XX testicular DSD. In this condition, also called XX male, the gonads are testicular, and virilization is typically incomplete. Infertility and/or gonadal failure may develop after childhood. Many cases are due to translocation of SRY sequences onto one of the X chromosomes, often paired with duplication of SOX9. The appropriate sex of rearing may be difficult to determine.

46,XX gonadal dysgenesis. These girls typically present at puberty with lack of breast development and hypergonadotropic

hypogonadism. Normal müllerian structures are present, but ovaries are absent or streaks.

Undetermined/unknown. Rarely, 46,XX DSD can be associated with other congenital anomalies, especially those of the genitourinary or gastroenteric tract, and are thus multifactorial in origin. These include cloacal exstrophy and MURCS association (müllerian hypoplasia, renal agenesis, and cervicothoracic somite abnormalities). Isolated deficiency of müllerian development is known as **Mayer-Rokitansky-Küster-Hauser syndrome.**

46,XY Disorders of Sex Development

In 46,XY DSD, the genotype is XY, and the external genitalia are either not completely virilized, ambiguous (atypical), or completely female. When gonads are found, they typically contain testicular elements; their development ranges from rudimentary to normal. Because the process of normal virilization in the fetus is so complex, it is not surprising that there are many varieties and causes of 46,XY DSD. *The etiology of 46,XY DSD is not identified in up to 50% of cases.*

Defects in Testicular Development

The first step in male differentiation is development of the bipotential gonad into a testis. In the XY fetus, if there is a deletion of the short arm of the Y chromosome or mutation of the *SRY* gene, male gonadal differentiation does not occur. The phenotype is female; müllerian (paramesonephric) ducts are well developed because of the absence of AMH, and gonads consist of undifferentiated streaks. By contrast, even extreme deletions of the long arm of the Y chromosome (Yq-) have been found in normally developed males, most of whom have short stature and azoospermia. This indicates that the long arm of the Y chromosome normally has genes that prevent these manifestations. In many syndromes in which the testes fail to differentiate, Y chromosomes appear morphologically normal on karyotyping.

Wilms tumor suppressor gene (WT1) *mutations: Denys-Drash, Fraser and WAGR syndromes.* The constellation of nephropathy with atypical genitalia and bilateral Wilms tumor typify Denys-Drash syndrome. Müllerian ducts are often present, indicating deficiency of multiple fetal testicular functions. Affected patients with a 46,XX karyotype have normal external genitalia. There is onset of proteinuria in infancy that progresses to nephrotic syndrome and end-stage renal failure by 3 years of age, with focal or diffuse mesangial sclerosis being the most consistent histopathologic finding. Wilms tumor usually develops in children younger than 2 years of age and is frequently bilateral. Gonadoblastomas have also been reported.

A variety of mutations of *WT1* have been found in **Denys-Drash syndrome**. *WT1* functions as a tumor suppressor gene and a transcription factor, and is expressed in the genital ridge and fetal gonads. One report found a zinc finger domain mutation in the *WT1* alleles of a patient with no genitourinary abnormalities, suggesting that some cases of sporadic Wilms tumor may carry the *WT1* mutation. Different mutations of the *WT1* gene, heterozygous mutations at intron 9, have been described in **Fraser syndrome**, a condition of nonspecific focal and segmental glomerulosclerosis, 46,XY gonadal dysgenesis, and frequent gonadoblastoma, but without Wilms tumor.

WAGR syndrome is a contiguous gene deletion syndrome causing Wilms tumor, aniridia, genitourinary malformations, and retardation. These children have a deletion of 1 copy of chromosome 11p13, which may be visible on karyotype analysis. The deleted region encompasses the aniridia gene *(PAX6)* and *WT1*. Only the 46,XY males have genital abnormalities, ranging from cryptorchidism to severe undervirilization. Gonadoblastomas have developed in the dysgenic gonads. Wilms tumor usually occurs by 2 years of age. Some cases also had unexplained obesity, raising the question of an

obesity-associated gene in this region of chromosome 11 and naming the syndrome **WAGRO.**

Campomelic syndrome. This form of short-limbed skeletal dysplasia is characterized by anterior bowing of the femur and tibia; small, bladeless scapulae; small thoracic cavities and 11 pairs of ribs, along with malformations of other organs. It is usually lethal in early infancy. About 75% of reported 46,XY patients exhibit a completely female phenotype with the external and internal genitalia both being female. Some 46,XY patients have atypical genitalia. The gonads appear to be ovaries but histologically may contain elements of both ovaries and testes.

The gene responsible for the condition is *SOX9* (SRY-related HMG-box gene). This gene is structurally related to *SRY* and also directly regulates type II collagen gene *(COL2A1)* development. The same mutations may result in different gonadal phenotypes. Gonadoblastoma was reported in a patient with this condition. The inheritance is autosomal dominant.

Steroidogenic Factor 1 *(SF1)* Gene Mutations

Adrenal insufficiency and 46,XY DSD have been described in patients with mutations of the *SF1* gene. In some patients, *SF1* mutations occur without causing adrenal insufficiency. In a number of these families, if the mother shares the *SF1* mutation she has premature ovarian insufficiency.

Other Known Genetic Causes of 46,XY DSD

46,XY DSD has been described in patients with other single gene mutations, as well as deletions of parts of autosomal loci on chromosomes 2q, 9p, and 10q. Examples of a number of these genetic conditions are shown in Table 23.4. The use of exome sequencing of targeted genes has enhanced the detection of specific genetic defects in patients with 46,XY DSD.

XY pure gonadal dysgenesis (Swyer syndrome). The designation *pure* distinguishes this condition from forms of gonadal dysgenesis that are of chromosomal origin and associated with somatic anomalies such as 45,X Turner syndrome and 47,XXY Klinefelter syndrome. Affected patients have normal stature as adults and a completely female phenotype at birth, including vagina, uterus, and fallopian tubes. At pubertal age, breast development and menarche fail to occur, and hypergonadotropic hypogonadism is present. None of the other phenotypic features associated with 45,X are present. Familial cases suggest an X-linked or a sex-limited dominant autosomal transmission. Most of the patients with a known genetic cause have had mutations of the *SRY* gene. The gonads consist of almost totally undifferentiated streaks despite the presence of a cytogenetically normal Y chromosome. The primitive gonad cannot accomplish any testicular function, including suppression of müllerian ducts. There may be hilar cells in the gonad capable of producing some androgens; accordingly, some virilization, such as clitoral enlargement, may occur at the age of puberty. The streak gonads may undergo neoplastic changes, such as **gonadoblastomas** and **dysgerminomas**, and should be removed as soon as the diagnosis is established, regardless of the age of the patient.

XY gonadal agenesis syndrome (embryonic testicular regression syndrome). In this rare syndrome, the external genitalia are slightly atypical but more nearly female. Hypoplasia of the labia; some degree of labioscrotal fusion; a small, clitoris-like phallus; and a perineal urethral opening are present. No uterus, no gonadal tissue, and usually no vagina can be found. At the age of puberty, no sexual development occurs and gonadotropin levels are elevated. Most children have been reared as females. In several patients with XY gonadal agenesis in whom no gonads could be found on exploration, significant rises in testosterone followed stimulation with hCG, indicating Leydig cell function somewhere. Siblings with the disorder are known.

It is presumed that testicular tissue was active long enough during fetal life for AMH to inhibit development of müllerian ducts but not long enough for testosterone production to result in virilization. Testicular degeneration seems to occur between the 8th and the 12th fetal week. Regression of the testes before the 8th week of gestation results in Swyer syndrome; between the 14th and the 20th week of gestation, it results in the rudimentary testis syndrome; and after the 20th week, it results in anorchia with otherwise normal external genitalia.

In **bilateral anorchia**, sometimes referred to as *vanishing testes syndrome*, testes are absent, but the male phenotype is complete; it is presumed that fetal testicular function was active during the critical period of genital differentiation but that sometime later it was damaged. Bilateral anorchia in identical twins and unilateral anorchia in identical twins and in siblings suggest a genetic predisposition. Coexistence of anorchia and the gonadal agenesis syndrome in a sibship is evidence for a relationship between the disorders.

Deficiency of Testicular Hormone Production

Genetic defects have been delineated in the enzymatic steps required for the synthesis of testosterone by the fetal testicular Leydig cells, and a defect in Leydig cell differentiation has also been described. These defects produce 46,XY males with incomplete masculinization. Because levels of testosterone are normally low before puberty except during the period of "minipuberty" at 1-2 months of age, an hCG stimulation test may be needed in children to assess the ability of the testes to synthesize testosterone.

Leydig cell aplasia. Patients with aplasia or hypoplasia of the Leydig cells usually have a female phenotype, but there may be mild virilization. Testes, epididymis, and vas deferens are present; the uterus and fallopian tubes are absent due to normal production of müllerian-inhibiting substance. There are no secondary sexual changes at puberty, but pubic hair may be normal. Plasma levels of testosterone are low and do increase with hCG stimulation; luteinizing hormone (LH) levels are elevated. The Leydig cells of the testes are absent or markedly deficient. The defect may involve a lack of receptors for LH. In children, hCG stimulation is necessary to differentiate the condition from the androgen insensitivity syndromes (AISs), as older children with AIS have low testosterone levels when prepubertal. There is male-limited autosomal recessive inheritance. The human LH receptor is a member of the G protein–coupled superfamily of receptors that contains 7 transmembrane domains. Several inactivating mutations of the LH receptor have been described in males with hypogonadism suspected of having Leydig cell hypoplasia or aplasia.

Congenital adrenal hyperplasia (CAH). **CAH due to lipoid adrenal hyperplasia:** This is the most severe form of congenital adrenal hyperplasia and it derives its name from the appearance of the enlarged adrenal glands resulting from accumulation of cholesterol and cholesterol esters. The rate-limiting process in steroidogenesis is the transport of free cholesterol through the cytosol to the inner mitochondrial membrane, where the P450 side-chain cleavage enzyme (CYP11A1) acts. Cholesterol transport into mitochondria is mediated by the steroidogenic acute regulatory protein (StAR) (see Fig. 23.5). Most patients with lipoid CAH have genetic mutations of StAR. A minority have mutations in CYP11A1.

All serum steroid levels are low or undetectable, and ACTH and PRA levels are very elevated. The phenotype is female in both genetic females and males. Genetic males have no müllerian structures because the testes can produce normal AMH but no steroid hormones. These children present with acute adrenal crisis and salt wasting in infancy. Most patients are 46,XY. In 46,XX patients with StAR defects, ovarian steroidogenesis can occur at puberty, as ovarian estrogen production does not require StAR. These 46,XX patients do not have DSD. All

patients have a lifelong requirement for glucocorticoid and mineralocorticoid replacement therapy. Some patients will need estrogen replacement therapy, such as all 46,XX individuals with CYP11A1 mutations, as well as all 46,XY lipoid CAH patients. Intraabdominal testes should be removed.

CAH due to 3β-hydroxysteroid dehydrogenase type II (HSD3B2) deficiency. 46,XY infants with this form of CAH have various degrees of hypospadias, with or without bifid scrotum and cryptorchidism and, rarely, a complete female phenotype. Affected infants usually develop salt-losing manifestations shortly after birth due to an inability to synthesize biologically potent steroid hormones (see Fig. 23.5). Incomplete defects, occasionally seen in infants without salt loss and in boys with premature pubarche, as well as late-onset nonclassic forms have been reported, but these forms do not cause DSD. As described earlier, patients with HSD3B2 deficiency have point mutations of the gene encoding type II 3β-hydroxysteroid enzyme, resulting in impairment of steroidogenesis in the adrenals and gonads. The impairment may be unequal between adrenals and gonads. Normal pubertal changes in some boys could be explained by the normally present type I 3β-hydroxysteroid dehydrogenase present in many peripheral tissues. Infertility is frequent. There is no correlation between degree of salt wasting and degree of phenotypic abnormality. Replacement therapy with adrenal steroids is required from infancy on, and with sex steroids at puberty. In 46,XY patients with intraabdominal testes who are being raised as females, gonadectomy is recommended.

CAH due to deficiency of 17-hydroxylase/17,20-lyase. A single enzyme (CYP17A1) encoded by a single gene has both 17-hydroxylase and 17,20-lyase activities in adrenal and gonadal tissues (see Fig. 23.5). Genetic males with CYP17A1 deficiency usually have a complete female phenotype or, less often, various degrees of undervirilization from labioscrotal fusion to perineal hypospadias and cryptorchidism. Pubertal development fails to occur in both genetic sexes.

In the classic disorder, there is decreased synthesis of cortisol by the adrenals and of sex steroids by the adrenals and gonads. Levels of the mineralocorticoid DOC and corticosterone are markedly increased and lead to the hypertension and hypokalemia characteristic of this form of 46,XY DSD. Although levels of cortisol are low, the elevated ACTH and corticosterone levels prevent symptomatic cortisol deficiency. The renin-aldosterone axis is suppressed because of the strong mineralocorticoid effect of elevated DOC. Virilization does not occur at puberty; levels of testosterone are low, and those of gonadotropins are increased. Because fetal production of AMH is normal, no müllerian duct remnants are present. In 46,XY phenotypic females, removal of intraabdominal testes and replacement therapy with hydrocortisone and estrogenic sex steroids are indicated.

CYP17A1 deficiency has autosomal recessive inheritance. Affected 46,XX females are usually not detected until young adult life, when they fail to experience normal pubertal changes and are found to have hypertension and hypokalemia. This condition should be suspected in patients presenting with primary amenorrhea and hypertension whose chromosomal complement is either 46,XX or 46,XY.

Deficiency of 17-ketosteroid reductase. This enzyme, also called 17β-hydroxysteroid dehydrogenase (17β-HSD), catalyzes the final step in testosterone biosynthesis. It is necessary to convert androstenedione to testosterone and also DHEA to androstenediol, and estrone to estradiol (see Fig. 23.5). Enzymatic defects in the fetal testis give rise to males with complete or near-complete female phenotype in 46,XY patients. Müllerian ducts are absent, and a shallow vagina is present. The diagnosis is based on the ratio of androstenedione to testosterone; in prepubertal children; an hCG stimulation test may be necessary to make the diagnosis.

The inheritance is autosomal recessive. At least 4 different types of 17β-HSD are recognized, each encoded by different genes on different chromosomes. Type III (HSD17B3) is the enzyme defect that is especially common in a highly inbred Arab population in Gaza. The gene for the disorder is expressed only in the testes, where it converts androstenedione to testosterone. Most patients are diagnosed at puberty because of virilization and the failure to menstruate. Testosterone levels at puberty may approach normal, presumably as a result of peripheral conversion of androstenedione to testosterone. Some patients spontaneously adopt a male gender role at puberty.

Type I 17β-HSD converts estrone to estradiol and is found in placenta, ovary, testis, liver, prostate, adipose tissue, and endometrium. Type II, whose gene is on chromosome 16q24, reverses the reactions of types I and III (convert testosterone to androstenedione and estrone to estradiol, respectively). Type IV is similar in action to type II. A late-onset form of 17β-HSD deficiency presents as gynecomastia in young adult males.

Persistent müllerian duct syndrome. In this disorder, there is persistence of müllerian duct derivatives in otherwise completely virilized males. Cases have been reported in siblings and identical twins. Cryptorchidism is present in 80% of affected males; during surgery for this or inguinal hernia, the condition is uncovered when a fallopian tube and uterus are found. The degree of müllerian development is variable and may be asymmetric. Testicular function is normal in most, but testicular degeneration has been reported. Some affected males acquire testicular tumors after puberty. In a study of 38 families, 16 families had defects in the AMH gene. They had low blood AMH levels. In 16 families with high AMH levels, the defect was in the AMH type II receptor gene, with 10 of 16 having identical deletions.

Treatment consists of removal of as many of the müllerian structures as possible without causing damage to the testis, epididymis, or vas deferens.

Smith-Lemli-Opitz syndrome. Smith-Lemli-Opitz syndrome is an autosomal recessive disorder caused by mutations in the sterol Δ7-reductase gene. This prevents normal androgen synthesis. It is characterized by prenatal and postnatal growth retardation, microcephaly, ptosis, anteverted nares, broad alveolar ridges, syndactyly of the 2nd-3rd toes, and severe mental retardation. Its incidence is 1/20,000-1/60,000; 70% are male. 46,XY patients usually have genital ambiguity or completely female external genitals. Müllerian duct derivatives are usually absent. Affected 46,XX patients have normal genitalia. Patients with Smith-Lemli-Opitz syndrome may also develop adrenal insufficiency due to inability to produce sufficient steroid hormones.

Defects in Androgen Action

In the following group of disorders, fetal synthesis of testosterone is normal and defective virilization results from inherited abnormalities in androgen action.

Dihydrotestosterone deficiency. **Deficiency of steroid 5α-reductase type II (SRD5A2)**: SRD5A2 deficiency prevents the conversion of testosterone to dihydrotestosterone (DHT) in androgen target tissues. Decreased production of DHT in utero results in marked ambiguity of external genitalia of affected 46,XY infants because of the absolute requirement for DHT in completion of prenatal virilization. Biosynthesis and peripheral actions of testosterone are normal.

The phenotype most commonly associated with this condition in boys consists of a small phallus, bifid scrotum, urogenital sinus with perineal hypospadias, and a blind vaginal pouch (Fig. 23.7). Testes are in the inguinal canals or labioscrotal folds and are normal histologically. There are no müllerian structures. Wolffian (mesonephric) structures (i.e., the vas deferens, epididymis, and seminal vesicles) are present. Most affected patients have been assigned the female sex of

FIGURE 23.7 5α-Reductase deficiency. (From Wales JKH, Wit JM, Rogol AD. *Pediatric Endocrinology and Growth.* 2nd ed. Philadelphia: Elsevier; 2003:165.)

rearing. At puberty, virilization occurs; the phallus enlarges, the testes descend and grow normally, and spermatogenesis occurs, as DHT is ***not*** required for normal virilization at puberty. There is no gynecomastia. Beard growth is scanty, acne is absent, the prostate is small, and recession of the temporal hairline fails to occur. The prenatal virilization of the wolffian ducts is caused by the action of locally produced testosterone itself, although masculinization of the urogenital sinus and external genitals depends on the action of DHT during the critical period of fetal masculinization. Growth of facial hair and of the prostate postnatally also appears to be DHT dependent.

Several different gene defects of SRD5A2 have been identified in patients from throughout the world. Familial clusters have been reported from the Dominican Republic, Turkey, Papua New Guinea, Brazil, Mexico, and the Middle East. There is no reliable correlation between genotype and phenotype.

The disorder is inherited as an autosomal recessive trait but expression is limited to males. Normal homozygous females with normal fertility indicate that in females DHT has no significant role in sex differentiation or in ovarian function later in life. The clinical diagnosis should be made as early as possible in infancy. It is important to distinguish this from partial androgen insensitivity syndrome (PAIS), as patients with PAIS are far less sensitive to androgen treatment than are patients with SRD5A2 deficiency. The biochemical diagnosis of SRD5A2 deficiency is based on finding normal serum testosterone levels, and normal or low DHT levels with markedly increased basal and especially hCG-stimulated testosterone:DHT ratios (>17).

It is important to note that most but not all children with SRD5A2 deficiency reared as females in childhood have changed to identify as male around the time of puberty. It appears that exposures to testosterone in utero, early postnatally, and at puberty have variable

contributions to the formation of their male gender identity. Much more needs to be learned about the influences of hormones such as androgens as well as the influences of cultural, social, psychologic, genetic, and other biologic factors in gender identity and behavior. Infants with this condition should be reared as boys whenever practical. Treatment of male infants with DHT results in phallic enlargement. At this time, DHT is not commercially available in the United States, but can be obtained from European suppliers.

Deficiency of 3α-reductase (AKRC): Another cause of DHT deficiency is a block in an alternative pathway of DHT synthesis (see Fig. 23.5). Patients previously thought to have 46,XY DSD due to isolated deficiency of the 17,20-lyase activity of CYP17A1 have subsequently been characterized as having mutations in the *AKR1C2* gene (3α-reductase type III) or both the *AKR1C2* and *AKR1C4* (3α-reductase type IV) genes. These findings show that both the classical and alternative pathways to DHT production must be intact for normal prenatal virilization.

Androgen receptor defects: androgen insensitivity syndromes (AISs). The AISs are the **most common** forms of 46,XY DSD, occurring with an estimated frequency of 1/20,000 genetic males. This group of heterogeneous X-linked recessive disorders can result from 1 of more than 150 different mutations described in the androgen receptor gene, located on Xq11-12: single point mutations resulting in amino acid substitutions or premature stop codons, frameshift and premature terminations, gene deletions, and splice site mutations. Post-receptor defects have also been described.

The clinical spectrum seen in patients with AIS, all of whom have a 46,XY chromosomal complement, range from phenotypic females (complete AIS or CAIS) to males with various forms of atypical genitalia and undervirilization (partial AIS or PAIS, as well as clinical syndromes such as Reifenstein syndrome) (Fig. 23.8) to phenotypically normal-appearing males with infertility. In addition to normal 46,XY chromosomes, the presence of testes and normal or elevated testosterone and LH levels are common to all such patients.

In CAIS, an extreme form of failure of virilization, genetic males appear female at birth and are invariably reared accordingly as their condition often goes undetected until childhood or adolescence. The external genitalia are female. The vagina ends blindly in a pouch, and the uterus is absent due to the normal production and effect of AMH by the testes. In about one third of patients, unilateral or bilateral fallopian tube remnants are found. The testes are usually intraabdominal but may descend into the inguinal canal; they consist largely of seminiferous tubules. At puberty, there is normal development of breasts, and the habitus is female, but menstruation does not occur and sexual hair is absent. Adult heights of these women are commensurate with those of normal males despite profound congenital deficiency of androgenic effects.

The testes of affected adult patients produce normal to elevated male levels of testosterone that are converted to normal levels of DHT. Failure of normal male external genitalia differentiation during fetal life reflects a defective response to androgens including DHT starting very early in gestation.

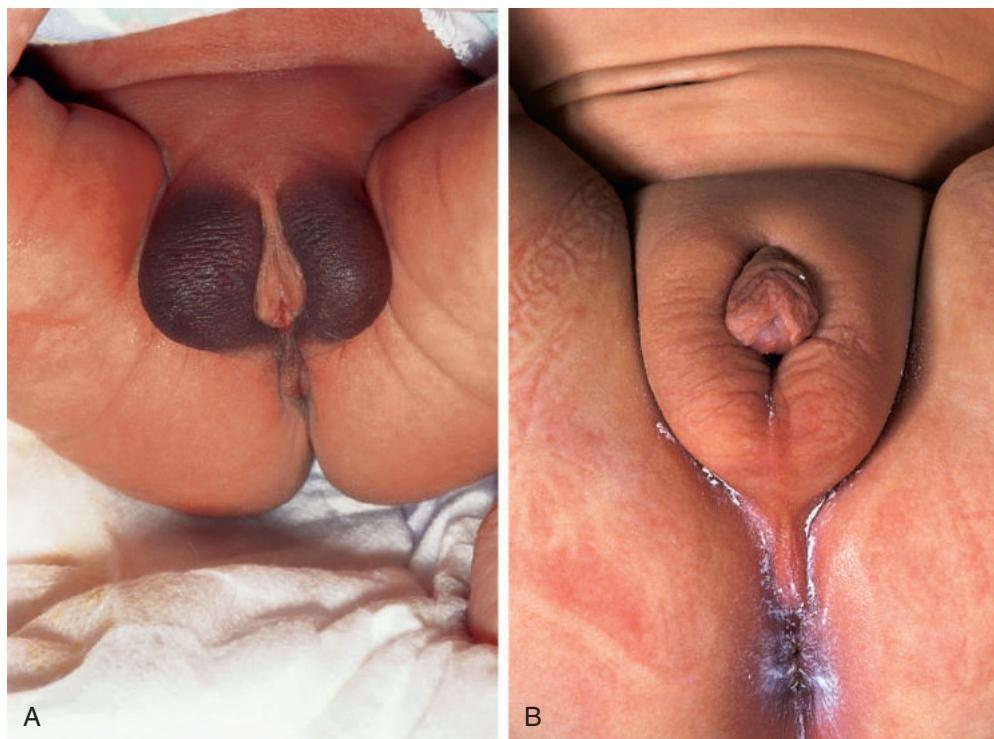
Prepubertal girls with this disorder are often detected when inguinal masses prove to be testes or when a testis is unexpectedly found during inguinal herniorrhaphy. *About 1-2% of girls with an inguinal hernia prove to have this disorder*. In infants, elevated LH levels should suggest the diagnosis. In older girls and adults, amenorrhea is the usual presenting symptom. In prepubertal children, the condition must be differentiated from other types of 46,XY undervirilized males in which there is complete feminization. These include 46,XY gonadal dysgenesis (Swyer syndrome), true agonadism, Leydig cell aplasia including LH receptor defects, and 17-ketosteroid reductase deficiency; all these conditions, unlike complete AIS, are characterized by low levels of testosterone as neonates and during adult life and by failure to respond


FIGURE 23.8 *A,* Partial androgen insensitivity with descended testes in bifid labioscrotal folds. *B,* Less severe partial androgen insensitivity with severe hypospadias and maldescent of testes. (From Wales JKH, Wit JM, Rogol AD. *Pediatric Endocrinolgy and Growth.* 2nd ed. Philadelphia: Elsevier; 2003:165.)

to hCG during the prepubertal years. Although patients with complete AIS have unambiguously female external genitals at birth, those with partial AIS have a wide variety of phenotypic presentations ranging from perineoscrotal hypospadias, bifid scrotum, and cryptorchidism to extreme undervirilization appearing as clitoromegaly and labial fusion. Some forms of partial AIS have been known as specific syndromes. Patients with Reifenstein syndrome have incomplete virilization characterized by hypogonadism, severe hypospadias, and gynecomastia (Fig. 23.9). Gilbert-Dreyfus and Lubs are additional syndromes classified as partial AIS. In all cases, abnormalities in the androgen receptor gene or post-receptor defects have been identified.

The diagnosis of patients with partial AIS may be particularly difficult in infancy. The postnatal surge in testosterone and LH is diminished in those with complete AIS (CAIS) but not in those with partial AIS (PAIS). In some, especially those sufficiently virilized in infancy, the diagnosis is not suspected until puberty when there is inadequate virilization with lack of facial hair or voice change and the appearance of unusually prominent gynecomastia. Azoospermia and infertility are common. Increasingly, androgen receptor defects are being recognized in adults who have a small phallus and testes and infertility. A single amino acid substitution in the androgen receptor was reported in a large Chinese family in whom some affected members were fertile while others had gynecomastia and/or hypospadias.

In girls or young women with CAIS, the historical recommendation has been that testes should be removed prior to adult life, or as soon as they are discovered. *In one third of patients, malignant tumors, usually seminomas, develop by 50 years of age.* Several teenage girls have acquired seminomas. Replacement therapy with estrogens is indicated

FIGURE 23.9 Partial androgen insensitivity syndrome at adolescence, male sex of rearing. Note gynecomastia from peripheral aromatase conversion of testosterone to estradiol. Abundant pubic hair implies only partial resistance. (From Wales JKH, Wit JM, Rogol AD. *Pediatric Endocrinology and Growth*. 2nd ed. Philadelphia: Elsevier; 2003:165.)

at the age of puberty if the gonads were removed prior to this age. Some patients prefer to retain their gonads until after puberty has completed in order to mimic a more natural pubertal progression based on their own body's timing of gonadotropins.

Normal breasts develop in affected girls who have not had their testes removed by the age of puberty. In these individuals, production of estradiol results from aromatase activity on testicular testosterone. The absence of androgenic activity also contributes to the feminization of these women.

The psychosexual and surgical management of patients with partial AIS is extremely complex and depends in large part on the presenting phenotype. Osteopenia is recognized as a late feature of AIS.

Molecular analyses have suggested that phenotype may depend in part on somatic mosaicism of the androgen receptor gene. This was based on the case of a 46,XY patient who had a premature stop codon in exon 1 of the AR gene but who also had evidence of virilization (pubic hair and clitoral enlargement) explained by the discovery of the wild-type alleles on careful examination of the sequencing data. The presence of mosaicism shifts the phenotype to a higher degree of virilization than expected from the genotype of the mutant allele alone. Genetic counseling is thus challenging in families with androgen receptor gene mutations. In addition to lack of genotype-phenotype correlations, there is a high rate (27%) of de novo mutations in families.

The degree of sex hormone-binding globulin reduction after exogenous androgen administration (stanozolol) has been shown to correlate with the severity of the receptor defect and may become a useful clinical tool. Successful therapy with supplemental androgens has been reported in patients with partial AIS and various mutations of the androgen receptor in the DNA-binding domain and the ligand-binding domain.

Mutant androgen receptors are also reported in patients with spinal and bulbar muscular atrophy in whom clinical manifestations including testicular atrophy, infertility, gynecomastia, and elevated LH, FSH, and estradiol levels usually manifest between the 3rd and 5th decades of life. Androgen receptor mutations have also been described in patients with prostate cancer.

Undetermined Causes of 46,XY Disorders of Sex Development

Other 46,XY undervirilized males display great variability of the external and internal genitalia and various degrees of phallic and müllerian development. Testes may be histologically normal or rudimentary, or there may only be 1 testis. Other complex genetic syndromes, many resulting from single-gene mutations, are associated with varying degrees of ambiguity of the genitalia, particularly in the male. These entities must be identified on the basis of the associated extragenital malformations. Examples include **bladder exstrophy** and **Eagle-Barrett syndrome** (formerly known as prune-belly syndrome). Another such complex syndrome is termed ATRX or X-linked α-thalessemia with mental retardation and genital abnormalities.

Ovotesticular Disorders of Sex Development

In ovotesticular DSD, both ovarian and testicular tissues are present, either in the same or in opposite gonads. Affected patients have ambiguous genitalia, varying from normal female with only slight enlargement of the clitoris to almost normal male external genitalia.

About 70% of all patients have a 46,XX karyotype. Ninety-seven percent of affected patients of African descent are 46,XX. Fewer than 10% of persons with ovotesticular DSD are 46,XY. About 20% have 46,XX/46,XY mosaicism. Half of these are derived from more than 1 zygote and are chimeras (chi 46,XX/46,XY). The presence of both paternal and maternal alleles for some blood groups are

demonstrated. An ovotesticular DSD chimera, 46,XX/46,XY, was reported as resulting from embryo amalgamation after in vitro fertilization. Each embryo was derived from an independent, separately fertilized ovum.

Examination of 46,XX ovotesticular DSD patients with Y-specific probes has detected fewer than 10% with a portion of the Y chromosome including the *SRY* gene. Ovotesticular DSD is usually sporadic, but a number of siblings have been reported. The cause of most cases of ovotesticular DSD is unknown.

The most frequently encountered gonad in ovotesticular DSD is an ovotestis, which may be bilateral. If unilateral, the contralateral gonad is usually an ovary but may be a testis. The ovarian tissue is often normal, but the testicular tissue is usually dysgenic. The presence and function of testicular tissue can be determined by measuring basal and hCG-stimulated testosterone levels as well as AMH levels. Patients who are highly virilized and have had adequate testicular function with no uterus are usually reared as males. If a uterus exists, virilization is often mild and testicular function minimal; assignment of female sex may be indicated. Selective removal of gonadal tissue inconsistent with sex of rearing may be possible. In a few families, 46,XY ovotesticular DSD subjects and 46,XX males have been described in the same sibship.

Defects in the ovarian developmental protein R-spondin 1, encoded by the *RSPO1* gene, have also been described in 46,XX ovotesticular DSD.

Pregnancies with living offspring have been reported in 46,XX ovotesticular DSD individuals reared as females, but very few males with ovotesticular DSD have fathered children. About 5% of patients will develop gonadoblastomas, dysgerminomas, or seminomas.

Sex Chromosome Disorders of Sex Development

Some ambiguity of the genitalia is associated with a wide variety of chromosomal aberrations (see Table 23.2), which must always be considered in the differential diagnosis, the most common being the 45,X/46,XY syndrome. It may be necessary to karyotype several tissues to establish mosaicism. The phenotype in 45,X/46,XY individuals may vary from completely female to completely male, and it is reported that there are probably a large number of patients who are never detected and are raised as normal males.

Other conditions included in the broad category of sex chromosome DSD include 45,X Turner syndrome, and 47,XXY Klinefelter syndrome, due to their associated gonadal failure. However, patients with these conditions have normal external genitalia at birth.

▋ RED FLAGS

Danger signs include manifestations of adrenal insufficiency, in addition to a male phenotype without a palpable testis in the scrotum, hyperpigmentation (increased ACTH production), and hypertension. Although normal at birth, male patients with CAH experience an adrenal crisis once circulating placental-maternal steroid hormones are catabolized and excreted. This phenomenon often occurs between the 3rd and 10th days of life. The initial diagnosis in the boy with salt-losing CAH may be sepsis, pyloric stenosis, meningitis, or other more common neonatal conditions.

Intellectual and Developmental Disability

Mark Simms

DEFINITIONS

Intellectual disability (ID) has replaced the older term mental retardation (MR), reflecting a more enlightened and progressive attitude toward individuals with disabilities. ID is characterized by significant limitations in intellectual functioning and in adaptive behavior that begin before age 18 years, and are expressed in conceptual, social, and practical adaptive skills. The impairments of ID extend beyond what is measured on a standardized test of intelligence, and must take into account the context of an individual's typical environment and their cultural and linguistic backgrounds. Adaptive functioning includes 3 broad domains: conceptual, social, and practical. The **conceptual domain** involves academic competence, the acquisition of practical knowledge, and judgment in novel situations. The **social domain** involves awareness of others' thoughts and feelings, empathy, friendships, and social judgment. The **practical domain** involves the ability to manage one's own affairs, including school and work responsibilities, money management, and recreation (Table 24.1). Although ID is a lifelong condition, it is recognized that "with appropriate personalized supports over a sustained period, the life functioning of the person with intellectual disability generally will improve." In a long-term study comparing ID and non-ID siblings, those with mild ID (intelligence quotient [IQ] between 64 and 75) were just as likely to find stable employment, to have similar total family incomes, to have stable marriages, and to raise children as their siblings. However, they reported higher rates of psychologic distress and lower rates of participation in formal organizations. Table 24.2 provides descriptions of typical adult functioning in individuals with varying degrees of ID.

The term **developmental disability** includes a diverse group of lifelong physical and mental impairments that negatively affect an individual's ability to function as well as their peers. These conditions begin during childhood (before 22 years of age), and interfere with mobility, acquisition of self-care ability, communication skills, social skills, general learning ability, and independent living. The specific types of conditions and categories of disabilities vary widely. The National Institute for Child Health and Development (NICHD) includes the following conditions: neurologic disorders: cerebral palsy, muscular dystrophy, epilepsy, genetic syndromes, autism, and degenerative disorders; sensory disorders: blindness and deafness; metabolic disorders: phenylketonuria (PKU); and cognitive disorders: intellectual impairment, learning disabilities, and attention-deficit/hyperactivity disorder (ADHD). Developmental disabilities may be isolated, as in a child with impaired vision, or may be multiple, as in a child with delays in motor, cognitive, language, and social functioning. There may be considerable overlap in specific disorders in terms of the affected functions (Fig. 24.1). In young children, developmental delays may result from a wide range of causes, including early environmental understimulation, chronic physical illness, neuromuscular disorders, central nervous system (CNS) abnormalities, genetic syndromes, etc. Some etiologies are fully or partly amenable to early educational and medical interventions, while others may lead to permanent intellectual impairment or progressive deterioration of functioning. Therefore, until a young child has had the benefit of early intervention services and he or she has matured to the point where formal cognitive, language, and adaptive measures are stable and predictive of future functioning, the descriptive term **global developmental delay** (GDD) is preferred.

EPIDEMIOLOGY

Intellectual Disability

The overall prevalence of ID varies from 1-3%, depending on the criteria used and the age of the individual at the time of evaluation. For example, standardized tests of intelligence have a mean of 100 and standard deviation of 15 points. Statistically, 2.5% of individuals should have an IQ score below 2 standard deviations (70 points) and fit the cognitive criterion for ID. However, because the standard error of measurement is approximately 5 points, extending the IQ score upward to 75 points would almost double the prevalence of ID. This might be countered by secondary criteria involving deficits in adaptive behaviors, since many children with IQ scores in the mildly low range (55-70) will not qualify for a diagnosis of ID because they have adequate adaptive functioning.

Many studies have documented a higher rate of mild ID in economically disadvantaged children that stems from a few highly significant sociodemographic factors. In 1 study, approximately half of the excess prevalence of mild ID among African-American 10-year-old children in the mid-1980s was related to the mother's level of education and her age at the time of delivery, birth order, sex of the child, and family's income level.

Developmental Disability

Developmental disabilities affect approximately 1 in 6 children in the United States (13.8%). The prevalence rates vary by specific condition: Learning disabilities (7.66%) and ADHD (6.69%) are the most

(See *Nelson Textbook of Pediatrics,* p. 216.)

(See *Nelson Textbook of Pediatrics,* p. 3412.)

common, while ID, epilepsy, autism, deafness, cerebral palsy, and blindness each affect less than 1%. Boys have more than twice the prevalence of any developmental disability, and children insured by Medicaid have a nearly 2-fold higher prevalence of disability compared with those with private insurance. The overall prevalence of disability increased by 17% between 1997 and 2008, mostly due to a nearly 4-fold change in autism (from 0.19% to 0.74%). In addition, the prevalence of Down syndrome increased by 31% (from 0.09% to 0.12%). Table 24.3 lists the prevalences of selected conditions.

DIAGNOSIS

Identification of a specific cause for delayed development in a child is important and may provide insight into prognosis, recurrence risk,

therapies, counseling, and linkage with a supportive group. From a community perspective, having a specific diagnosis for an affected individual helps in the development of treatment and prevention strategies. Identification of the child's functional abilities, strengths and weaknesses, overall physical health, and environmental factors is critical for optimizing the child's health, development, and functioning. In addition, the origin of developmental disability is not apparent in many children, or there may be multiple possible causal factors or multiple disabilities present. For example, 23% of children with developmental disabilities have 2 disabilities, and 6% have 3 or more. Even if a specific diagnosis cannot be made, early identification of developmental delay can lead to a program of early intervention or remediation that may improve the child's ultimate functioning. To identify those disorders, which are amenable to intervention, an international consortium has developed both a web-based tool and a mobile application (app) to assist expert clinicians and general practitioners alike in the evaluation and management of children with ID (http://www.treatable-id.org/).

IDENTIFICATION

Children who experience significant complications in the perinatal period or who are born with obvious congenital anomalies are at risk for developmental disabilities. In addition, newborn screening programs may identify children with rare but significant problems who require early treatments and interventions. Children with no apparent risk factors or obvious physical or neurologic symptoms may be

---

TABLE 24.1 Diagnosis of Intellectual Disability

Diagnostic Criteria

All 3 Criteria Must Be Met

A. Deficits in intellectual function, such as reasoning, problem solving, planning, abstract thinking, judgment, academic learning, and learning from experience, confirmed by both clinical assessment and individualized standardized testing.

B. Deficits in adaptive functioning that result in failure to meet developmental and sociocultural standards for personal independence and social responsibility. Without ongoing support, the adaptive deficits limit functioning in 1 or more activities of daily life, such as communication, social participation, and independent living, across multiple environments, such as home, school, work, and community.

C. Onset of intellectual and adaptive deficits during the developmental period.

Assumptions

1. Assessments performed on the child are sensitive to differences in culture, language, communication, and behavior.

2. The demands and constraints of the child's environment (home, neighborhood, school) must be considered.

3. Even children with limitations have strengths that should be considered.

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders (DSM-V)*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

FIGURE 24.1 Relationship of autism, language disorders, and intellectual disability. (Modified from Simms MD, Schum RL. Preschool children who have atypical patterns of development. *Pediatr Rev.* 2000;21:147-158.)

TABLE 24.2 Severity of Intellectual Disability and Adult Age Functioning

Level	Mental Age as an Adult*	Adult Adaptation
Mild	9-11 yr	Reads at 4th-5th grade level; simple multiplication/division; writes simple letters, lists; completes job applications; basic independent job skills (arrive on time, stay at task, interact with coworkers); uses public transportation, may qualify for driver's license; keeps house, cooks using recipes
Moderate	6-8 yr	Sight-word reading; copies information, e.g., address from card to job application; matches written number to number of items; recognizes time on clock; communicates; some independence in self-care; housekeeping with supervision or cue cards; meal preparation, can follow picture recipe cards; job skills learned with much repetition; uses public transportation with some supervision
Severe	3-5 yr	Needs continuous support and supervision; may communicate wants and needs, sometimes with augmentative communication techniques
Profound	<3 yr	Limitations of self-care, continence, communication, and mobility; may need complete custodial or nursing care

TABLE 24.3	**Prevalence of Select Conditions Associated with Developmental Delay**	
Condition	**Prevalence/100,000**	**Comments**
Cerebral palsy	250-270	Represents many causes
Significant hearing loss	150	In neonatal period
Down syndrome	98-125	Prevalence at birth
Fragile X syndrome	117	Predominantly in boys
Meningomyelocele	60-100	Prevalence at birth
Klinefelter syndrome	100	15% have intelligence quotient (IQ) <80
Fetal alcohol syndrome	60-800	Present at birth
Congenital HIV infection	5-50	Preventable with maternal and neonatal therapy
Blindness	41-88	At 10 yr of age
Infantile hydrocephalus	64	Prevalence at birth
Neurofibromatosis	33	5% have intellectual disability
Trisomy 18	30	Prevalence at birth
Trisomy 13	20	Prevalence at birth
Turner syndrome	20	IQ may be normal
Prader-Willi syndrome	13-20	In childhood
Galactosemia	14	In infancy
Phenylketonuria	6-12	In infancy
Anophthalmia	6	Consider other anomalies
Rett syndrome	4-5	In girls 2-18 yr of age
Histidinemia	3	At birth
Acrocephalosyndactylia (Apert syndrome)	1-2	Present at birth

identified through a process of surveillance and screening during routine child health care visits.

Developmental Risk Factors

Young children's development may be adversely affected by biologic and/or sociocultural risk factors (Table 24.4). Many risk factors can be graded according to severity (e.g., degree of prematurity, intracranial hemorrhage, intrauterine growth restriction), but it is often the cumulative effect of multiple factors that ultimately determines a child's developmental outcome, even when 1 or more "severe" risks are present. For example, it has been shown that low 5-minute Apgar scores, in the absence of other symptoms of neonatal encephalopathy, correlate poorly with long-term neurologic dysfunction. Sociocultural risks also can have profound effects on development and may interact with biologic risk factors to create a greater effect than any single factor alone (so-called "double jeopardy").

Developmental Protective Factors

During the process of developmental surveillance, the clinician should identify and acknowledge the influence of protective and supportive factors that may contribute to positive outcomes. For example, barring catastrophic circumstances, child-rearing conditions that support and enrich early development may compensate for biologic deficits. Sociocultural factors, such as small family size, higher level of parental education, and fewer changes in residence have a more powerful positive effect than many biologic risks and seem to be important predictors of developmental functioning beyond infancy. The brains of infants and young children are remarkably resilient and normal cognitive and language outcomes are often seen, even in the face of perinatal stroke or similar focal brain injuries. Neural plasticity also extends to situations of extreme environmental deprivation,

TABLE 24.4	**Risk Factors for Developmental Disabilities**
Biologic	**Sociocultural**
Male sex	Low parental education
Maternal age above 30 yr old	Maternal depression
Multiple pregnancies	Maternal substance abuse
High birth order	Low socioeconomic status
Preterm birth	Lack of prenatal care
Low birthweight (<750 g)	Inadequate environmental
Intrauterine growth restriction	stimulation
Small head circumference	
Brain malformations	
Holoprosencephaly	
Schizencephaly	
Lissencephaly	
Neonatal complications	
Neonatal encephalopathy	
Intracranial hemorrhage	
Symptomatic hypoglycemia	
Severe hyperbilirubinemia	
Congenital infections	
Acquired central nervous system infections	
Iron and iodine deficiencies	
Brain injury	
Malnutrition	

TABLE 24.5 Developmental Protective Factors

Biologic	Sociocultural
Neural plasticity	Small family size
Comprehensive and supportive health care	Higher level of parental education
	Few changes in residence
Early intervention services	Parental support system

providing interventions occur early enough. In addition, preschool early intervention programs that are designed to mitigate the factors that place children at risk for poor outcomes have been shown to have significant short- and long-term educational, behavioral, and economic benefits (Table 24.5).

SCREENING FOR SPECIFIC ABNORMALITIES

Deficits in vision, hearing, and language can have devastating effects on development; early intervention to ameliorate these problems can improve outcomes. All children should be screened on a regular basis for these conditions.

Visual Deficits

Children at high risk for development of deficits in vision (see Chapter 32) include those with strabismus (especially after 4 months of age), hydrocephalus, congenital infection, neonatal encephalopathy, congenital anomaly of the CNS, prematurity with overexposure to oxygen, and family history of a childhood onset of visual impairment. All neonates should routinely undergo an evaluation of their fundi for the presence of a red reflex, which can be obscured by cataract or tumor, as well as inspection of the globe, which may be affected by congenital glaucoma. Infants with nystagmus who do not follow visually by 3 months of age, who have dissociation between visual behavior and motor behavior, or whose parents express concern about their vision should undergo a formal ophthalmologic evaluation.

Preschool children should undergo periodic evaluations of extraocular movements to rule out strabismus and amblyopia; the evaluation should include visual inspection of the child's eyes, the Hirschberg light test, and the cover-uncover test. As early in the child's development as possible, specific tests of monocular and binocular vision such as Allen cards (3-5 years), the Snellen chart (>5 years), or the Titmus test (>4 years) should be performed.

Loss of Hearing

Early detection of hearing loss is critical for optimizing the language development of these children. Universal newborn hearing screening programs (UNHSP) have been in place since the 1990s to detect infants born with moderate, severe, or profound bilateral hearing impairment. More than 95% of all children born in the United States are screened for hearing loss shortly after birth. Although the prevalence of congenital deafness is low in the general population (1-3/1,000 infants), it is higher in infants who require neonatal intensive care services (2-4/100 infants). More than half of babies with permanent congenital hearing impairment do not have prospectively identifiable risk factors and would be missed without UNHSP. They would not receive hearing intervention within the 1st 6 months of life, a period that is critical for speech, language, and later learning development. Hearing loss can be acquired during infancy or childhood from infection (cytomegalovirus [CMV], meningitis), trauma (particularly basal skull and temporal bone fractures), ototoxic drugs (aminoglycosides, furosemide), or damaging noise levels. A number of **genetic syndromes** are associated

TABLE 24.6 Risk Indicators Associated with Permanent Congenital, Delayed-Onset, and/or Progressive Hearing Loss in Children

1. Caregiver concern* regarding hearing, speech, language, or developmental delay.
2. Family history* of permanent childhood hearing loss.
3. Neonatal intensive care of >5 days or any of the following, regardless of length of stay: ECMO,* assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide/Lasix), and hyperbilirubinemia that requires exchange transfusion.
4. In utero infections such as CMV,* herpes, rubella, syphilis, and toxoplasmosis.
5. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies.
6. Physical findings, such as a white forelock, that are associated with a syndrome known to include sensorineural or permanent conductive hearing loss.
7. Syndromes associated with hearing loss or progressive or late-onset hearing loss,* such as neurofibromatosis, osteopetrosis, and Usher syndrome; other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielsen.
8. Neurodegenerative disorders* such as Hunter syndrome or sensory motor neuropathies such as Friedreich ataxia and Charcot-Marie-Tooth syndrome.
9. Culture-positive postnatal infections associated with sensorineural hearing loss,* including confirmed bacterial and viral (especially herpes viruses and varicella) meningitis.
10. Head trauma, especially basal skull/temporal bone fracture* that requires hospitalization.
11. Chemotherapy.*
12. Recurrent or persistent otitis media for at least 3 mo.

*Risk indicators that are of greater concern for delayed-onset hearing loss.
ECMO, extracorporeal membrane oxygenation; CMV, cytomegalovirus.

with deafness (Waardenburg, Alport, Pendred, and Jervell and Lange-Nielsen) and progressive or late-onset hearing loss can occur in neurofibromatosis, Usher syndrome, Hunter syndrome, Friedreich ataxia, or Charcot-Marie-Tooth syndrome (Table 24.6). The American Academy of Pediatrics (AAP) recommends that children with 1 or more "risk factors" should have hearing screening again at 24-30 months, even if they passed the newborn screening test. In addition, parental concern about hearing loss has a sensitivity of approximately 44%. If parents express concern about their child's ability to hear and if the child has had recurrent episodes of otitis media, mastoiditis, or 1 of the perinatal or familial risk factors, a formal audiometric screening should be performed. Table 24.7 lists the latest acceptable age ("limit ages") for the appearance of skills related to hearing; absence of these milestones may indicate a disorder of hearing. *Deaf infants may smile, coo, and babble; however, their vocalizations usually cease after 8 months of age.*

Speech and Language Disorders

Disorders of speech and language development, prevalent in 3-20% of preschool children, are the most common reason for referral to early intervention programs and are correlated with subsequent learning

(See *Nelson Textbook of Pediatrics,* p. 3073.)

(See *Nelson Textbook of Pediatrics,* p. 207.)

TABLE 24.7   Latest Acceptable Age for Skills Related to Hearing*

Age (mo)†	Activity
3	Not startling to loud sounds
6	Not smiling to voice; not vocalizing
9	Does not localize speech or other sounds
12	Not babbling multiple sounds and syllables
18	No words
24	<50% of speech understandable

*A child who does not demonstrate the activity by the stated age should have formal audiometry performed.
†Corrected for gestational age.
Modified from the Arizona Speech, Language, Hearing Association.

TABLE 24.8   Speech-Language Screening for Pediatricians

At Age	Receptive	Expressive
15 mo	Does not look/point at 5-10 objects/people named by a parent	Not using 3 words
18 mo	Does not follow simple directions ("Get your shoes")	Not using Mamma, Dadda, or other names
24 mo	Does not point to pictures or body parts when they are named	Not using 25 words
30 mo	Does not verbally respond or nod/shake head to questions	Not using unique 2-word phrases, including noun-verb combinations
36 mo	Does not understand prepositions or action words; does not follow 2-step directions	Vocabulary <200 words; does not ask for things by name; echolalia to questions; regression of language after acquiring 2-word phrases

Refer for a Speech-Language Evaluation if:

From Schum RL. Language screening in the pediatric office setting. *Pediatr Clin North Am.* 2007;54:425-436.

problems. Speech refers to the mechanics of oral communication (sound production); language includes the understanding, processing, and production of communication (words). Speech problems may include articulation (pronunciation) deficits (phonologic or apraxic speech disorders), fluency disorders (stuttering), or unusual voice quality. Language delays may be confined to expression with normal receptive abilities, or may involve both expressive and receptive abilities. Language delays may be a feature of GDD/ID, autism spectrum disorders (ASDs), hearing impairment, or may be the result of an isolated disorder (specific language impairment).

Children with speech and language delays often experience emotional and social adjustment difficulties related to their inability to communicate effectively with parents and peers. In general, children with normal comprehension of language and normal nonverbal cognitive abilities have an excellent prognosis, while those with receptive delays are at risk for language-based learning disabilities (reading comprehension and writing disorders) (Table 24.8).

OTHER CONDITIONS

Prenatal and Newborn Screening Programs

Prenatal Screening

Prenatal screening has undergone significant changes with the advent of "next generation sequencing" (NGS) technologies. The traditional screening takes the form of biochemical and ultrasound tests, which may detect fetuses at high risk for chromosome anomalies and neural tube defects. In the 1st trimester (11-14 weeks' gestation), measurement of maternal serum levels of human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein A (PAPP-A), and a sonogram measurement of the fluid underneath the skin along the back of the fetus' neck (nuchal translucency) may identify Down syndrome, trisomy 13, or trisomy 18. In the 2nd trimester (15-22 weeks' gestation), a quad screen (α-fetoprotein, hCG, estriol, and inhibin A levels) may identify Down syndrome and neural tube defects (spina bifida, encephalocele). An abnormal result on these screenings is typically followed by high-resolution ultrasonography, chorionic villus sampling or amniocentesis, genetic testing (chomosome analysis or microarray), and genetic counseling. NGS technologies allow for noninvasive prenatal testing (NIPT) on maternal blood samples, also called *cell-free* fetal DNA prenatal testing. These technologies identify possible chromosomal and microdeletion disorders through maternal blood screening. If an abnormality is detected, a confirmatory test is still required through more invasive techniques such as amniocentesis. In addition, prenatal genetic carrier screening can be performed for a large number of disorders; at present, these are the only standard of care for individuals at high risk for certain genetic conditions (e.g., Tay-Sachs).

Newborn Screening

Uniform newborn screening has been highly successful in identifying children with rare but serious conditions who can benefit from early intervention. All 50 states, U.S. territories, and the U.S. military routinely test for inborn errors of metabolism (IEM), congenital hypothyroidism, congenital adrenal hyperplasia, severe T-cell immunodeficiency (SCID), cystic fibrosis, and hemoglobinopathies. Test samples should be collected between 24-48 hours of age, but results may be influenced by a variety of maternal and infant factors. For example, tests for congenital adrenal hyperplasia are sensitive to the weight of the infant and the use of steroids. Screening for hypothyroidism (thyroid-stimulating hormone [TSH]) may be falsely low in premature or low-birthweight infants. In addition, use of antibiotics and total parenteral nutrition (TPN) may interfere with interpretation of newborn metabolic screening tests. While all states screen for a "core panel" of 29 conditions, they vary in testing for other conditions. An additional 26 conditions have been recommended for inclusion in the U.S. Health and Human Services Recommended Uniform Screening Panel. Normal newborn screening test results do not eliminate the possibility that a clinically symptomatic child could have 1 of the disorders in the state's panel. Clinicians should familiarize themselves with the specific tests that are routinely performed in each state.

IDENTIFICATION OF CHILDREN WITH DEVELOPMENTAL DISABILITIES IN PRIMARY HEALTH CARE SETTINGS

Not all developmentally disabling conditions can be identified at or shortly after birth through newborn screening programs. Many disorders may not manifest until children are preschool or school age, and some infrequent disorders cause regression or deterioration of function beginning at different ages. Therefore, identification of

children with developmental disabilities is a continuous process that should take place throughout childhood.

Parents, caretakers, or teachers who have concerns about the child's behavior or his or her failure to meet age-appropriate developmental expectations often identify children with developmental disabilities. In 1 study, 14% of parents waiting for well child visits had a concern about their child's learning or cognition. Multiple studies have found parental concern to identify correctly 74-80% of preschool age children (0-6 years old) with cognitive delays, speech and language delays, and learning disabilities. Conversely, the absence of parental concern correctly identified 70-80% of children without a significant disability. Thus, reliance on parental concern alone as a means of identification (sensitivity and specificity) matches acceptable standards for more formal developmental screening tests. However, sole reliance on parental concerns will miss a substantial number of children with developmental concerns, especially those with more subtle disabilities, for a variety of reasons. Parents may be unaware of their child's delays, they may lack the confidence to raise their concerns to the health care provider, or the provider may dismiss these concerns and not pursue further investigation. In particular, children without obvious physical impairments may not be identified until they enter a formal school program. Complicating matters further, children with developmental disabilities may experience significant behavioral or emotional difficulties that "mask" (or distract from) their underlying developmental difficulties.

Developmental Screening

Developmental screening involves the routine application of a brief standardized tool when there is no obvious concern. Developmental screening tests for use by health care providers have been available for several decades, but they are rarely administered by pediatricians, and generally lack sufficient sensitivity to identify subtle disorders while falsely identifying a significant number of nonaffected children. Instead, physicians are more likely to rely on their own clinical judgment, which detects fewer than 30% of children with significant developmental disabilities, or on informal and nonstandardized lists of developmental milestones. A more practical and widely accepted alternative is the use of parent-completed developmental questionnaires, such as the Ages and Stages Questionnaire (ASQ) or the Parents' Evaluations of Developmental Status (PEDS) that can be scored by nonphysician staff and interpreted by the health care provider.

Developmental Surveillance

Developmental surveillance is a "flexible, continuous process whereby knowledgeable professionals perform skilled observations of children throughout all encounters during child health care." The goal of developmental surveillance is to identify children who may benefit from further diagnostic evaluations and early intervention services. To be effective, surveillance requires clinicians to be knowledgeable about child development and to recognize both variations of and deviations from normal patterns. Identification of children in need of further evaluation is believed to be improved by incorporating into the process developmental risk factors based on the child's medical history, family history, as well as social and environmental circumstances. Additionally, clinicians are encouraged to include the observations and impressions of preschool teachers, public health nurses, and other professionals involved in the child's care.

The AAP recommends a combination of both developmental surveillance at every well child visit and standardized developmental screening at the 9-, 18-, and 30-month visits (Fig. 24.2). At any point in this process, children who elicit concern about their development should be referred for further diagnostic evaluations and for early intervention and educational programs.

COMPREHENSIVE DEVELOPMENTAL ASSESSMENT

Children identified with developmental delays should receive a comprehensive, multidisciplinary evaluation including assessments of neurodevelopmental, cognitive, and communication functioning. These assessments should focus on both the child's strengths and functional abilities as well as on weaknesses and disabilities. Based on the findings from these evaluations, further subspecialty consultations (e.g., neurology, genetics, physical medicine and rehabilitation, ophthalmology, occupational and physical therapy, speech therapy) can be arranged, and a plan for specific laboratory investigations developed. The goals of the evaluations are to identify a specific etiologic diagnosis, prognosis, recurrence risk, and interventions to promote the child's optimal development. Parents may also benefit from associating with a disease-specific support group.

Neurodevelopmental Pediatric Assessment
History

Pediatric evaluation of a child with GDD or ID consists of a complete history and physical examination. Schedule the evaluation as a separate visit with sufficient uninterrupted time (at least 45-60 minutes) to focus on issues related to the child's behavior and development. Unless the child's and family's histories are well known to the provider, parents can be asked to complete detailed history questionnaires, developmental and behavioral rating scales, and to provide any additional information from outside sources (e.g., prior medical records, consultation reports, educational evaluations, etc.) prior to this visit that will contribute to assembling a complete record of the child's care. Previsit preparation may help parents to refresh their memory regarding their child's development and to focus their questions and concerns during the evaluation.

Many disabilities have their origin in the prenatal period, so the pregnancy and birth history are reviewed carefully for possible developmental risk factors (Table 24.9). Difficulty in conception or history of recurrent pregnancy loss may suggest the presence of an inherited chromosome anomaly. Maternal illnesses (toxoplasmosis, other [syphilis, varicella-zoster, parvovirus B19], rubella, CMV, and herpes [TORCH] infections; HIV infection) preceding or continuing through pregnancy, or exposure to potentially harmful or teratogenic substances (tobacco, alcohol, illicit drugs, radiation exposure, or medications) should be noted. Other pregnancy complications such as intrauterine growth restriction (which may reflect chronic placental insufficiency, uterine anatomic abnormality, or fetal genetic anomaly); bleeding (especially in the 3rd trimester), which can be caused by placenta previa; placental abruption; or hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome; hypertension (especially leading to eclampsia); complications of maternal diabetes; or limited prenatal care may be associated with poor fetal outcomes. In the perinatal period, signs of fetal distress during labor (heart rate and movement abnormalities associated with uterine contractions), low Apgar scores, neonatal seizures, or the need for extensive neonatal resuscitation may be the result of acute fetal CNS injury or preexisting congenital abnormalities that first manifest at the time of birth. The method of delivery and the reason(s) for nonvaginal delivery may reflect on fetal status at the time of birth. Neonatal physical measurements (weight, length, and head circumference) when compared with gestational age are helpful in determining whether the child experienced intrauterine growth restriction. Severe medical complications in the neonatal period such as the presence of neonatal encephalopathy syndrome including seizures and multiorgan compromise, intraventricular hemorrhage, neonatal infections, prolonged requirement for mechanical ventilation, need for extracorporeal

1 Pediatric patient at preventive care visit

Increasing Developmental Concern

FIGURE 24.2 Developmental surveillance and screening algorithm within a pediatric preventive care visit. Numbers refer to steps in the algorithm. (From Council on Children with Disabilities, et al. Identifying infants and young children with developmental disorders in the medical home: an algorithm for developmental surveillance and screening. *Pediatrics.* 2006;118:407.)

membrane oxygenation (ECMO), the presence of complex cardiac anomalies, and necrotizing enterocolitis may be associated with increased risk of developmental disabilities (Table 24.10). Conversely, an infant who did not require care in a neonatal intensive care unit (NICU) or prolonged stay in the hospital following birth likely experienced no significant perinatal developmental risk factors. When available, reviewing medical records from the neonatal period may be helpful in clarifying what actually transpired at the time of the infant's birth.

The social and economic circumstances of the family may reveal factors that place the infant at risk for developmental disabilities. The clinician should ask about the highest educational levels achieved by both parents, marital status or stability of the parents' relationship, parental mental health concerns, history of "high-risk behaviors" (illicit drug use), housing status, and presence of a parental support system (close friends and extended family members) to help with care of the infant.

The 1st weeks and months of life are a "transition period" for both the infant and the family. Children with developmental disabilities may begin to manifest symptoms in this period with difficulties nursing, excessive colic, poor weight gain, onset of seizures, or delayed achievement of motor milestones. Review of prior growth records may help differentiate between a congenital or acquired disorder. A history of recurrent illness, family/social or environmental stress, trauma (especially to the CNS), or epilepsy may be associated with poor development. *True regression, the loss of previously acquired skills, should be distinguished from failure of development.* Newly emerging skills may fluctuate until they are firmly established. In cases of true regression, multiple areas of functioning are affected and do not reemerge over time.

TABLE 24.9   Information to Obtain About a Child with Suspected Developmental Disabilities

Item	Possible Significance
Parental Concerns	Parents are quite accurate in identifying developmental problems
Current Levels of Developmental Functioning	Used to monitor child's progress
Temperament	May interact with disability or be confused with developmental delay
Prenatal History	
Alcohol ingestion	Fetal alcohol syndrome; an index of caretaking risk
Illegal drug, toxin, medication exposure	Developmental toxin (e.g., phenytoin); may be an index of caretaking risk
Radiation exposure	Damage to the CNS
Nutrition	Inadequate fetal nutrition
Prenatal care	Index of the social situation
Injuries, hyperthermia	Damage to the CNS
Smoking	Possible CNS damage
HIV exposure	Congenital HIV infection
Maternal PKU	Maternal PKU effect
Maternal illness	Toxoplasmosis, rubella, CMV, HIV, herpesvirus infections
Perinatal History	
Gestational age, birthweight	Biologic risk from prematurity and small for gestational age
Labor and delivery	Hypoxia or index of abnormal prenatal development
Apgar scores	Hypoxia, cardiovascular impairment
Specific perinatal adverse events; see Table 24.10	Increased risk for CNS damage
Neonatal History	
Illness: seizures, respiratory distress, hyperbilirubinemia, metabolic disorder; see also Table 24.10.	Increased risk for CNS damage
Malformations	May represent syndrome associated with developmental delay
Family History	
Consanguinity	Autosomal recessive condition more likely
Mental functioning	Increased hereditary and environmental risks
Illnesses (e.g., metabolic disease)	Hereditary illness associated with developmental delay
Family member died young or unexpectedly	May suggest inborn errors of metabolism or storage disease
Family member requires special education	Hereditary causes of developmental delay
Social History	
Resources available (e.g., financial, social support)	Necessary to maximize child's potential
Educational levels of parents	Family may need help to provide stimulation
Mental health problems	May exacerbate child's conditions
High-risk behaviors (illicit drug use, sexual promiscuity)	Increased risk for congenital infection; index of caretaking risk
Other stressors (e.g., marital discord)	May exacerbate child's conditions or compromise care
Other History	
Sex of the child	Important for X-linked conditions
Developmental milestones	Index of developmental delay, regression may indicate a progressive condition
Head injury	Even moderate trauma may be associated with developmental delay or learning disabilities
Serious infections (e.g., meningitis)	May be associated with developmental delay
Toxic exposure (e.g., lead)	May be associated with developmental delay
Physical growth	May indicate malnutrition; obesity, growth failure caused by genetic disorder
Recurrent otitis media	Associated with hearing loss and abnormal speech development
Visual and auditory functioning	Sensitive index of impairments in vision and hearing
Nutrition	Malnutrition during infancy may lead to delayed development
Chronic conditions such as renal or cyanotic cardiac	May be associated with delayed development

CMV, cytomegalovirus; CNS, central nervous system; HIV, human immunodeficiency virus; PKU, phenylketonuria.

TABLE 24.10 Findings that May Be Used to Identify Neonates at Increased Risk for Developmental Delay

Item	Comment
Apgar scores	<3 at 5 min or <5 at 10 min, and HIE
Abnormal EEG	
Neonatal seizures	Hypoglycemia, hypoxia, intracranial hemorrhage, or infection confer high risk
Intracranial	Grade III or higher; PVL hemorrhage
Hydrocephalus	Especially with other anomalies, thin cortical mantle, or parenchymal lesions
Central nervous system	Seen on CT scan or ultrasonography system anomalies
Prematurity	<32 wk
Small for gestational age	<3rd percentile (intrauterine growth age retardation)
Dysmorphic	3 or more minor or 1 or more major features
Chromosomal	Trisomies, fragile X, XO anomaly
Ventilation required	Longer than 2 wk
Small head	<3rd percentile circumference
Meningitis/encephalitis	Bacterial (group B streptococci, *Escherichia coli*) Viral (herpes simplex)
Hypoglycemia	Symptomatic
Congenital infection	Cytomegalovirus, toxoplasmosis, syphilis, rubella, herpes simplex, varicella-zoster, HIV
Hyperbilirubinemia	Requiring exchange transfusions
Associated medical problems	Such as retinopathy of prematurity, heart disease, bronchopulmonary dysplasia, necrotizing enterocolitis

EEG, electroencephalography; HIE, hypoxic-ischemic encephalopathy; PVL, periventricular leukomalacia.

Ages of achievement of common milestones in motor, language, cognitive, and social development should be reviewed. Parents of infants and toddlers may have more accurate recollections of their child's milestones than parents of older children. In some cases, parents may recall comparing their child's milestones to another child's (sibling, relative, neighbor), or may only recall their child's "major" milestones, such as ages at which the child began walking independently, waving "bye-bye," using 1st words, or talking in sentences.

A 3-generation family pedigree should be reviewed to identify other individuals with conditions similar to the child's, developmental/learning disabilities, or early deaths. Consanguinity may increase the risk of a recessive disorder. A family's ethnic ancestry may suggest potential etiology, since a number of conditions occur at increased frequency among certain ethnic groups (e.g., Tay-Sachs disease among Ashkenazi Jews).

Social and environmental factors such as parental physical or mental illness (including substance abuse), death of a close family member, divorce, domestic abuse, parental incarceration, multiple changes of dwelling, placement in foster care, or having a sibling with a serious chronic illness may have significant adverse effects on a child's development.

It is important to know whether the child has received any type of educational or therapeutic interventions and the impact those programs have had on his or her behavior and development.

For young children, a description of their play interests, self-help skills, and social interactions with parents, peers, and caretakers/teachers may provide valuable information about the child's level of overall development. A review of common activities of daily living (ADL), including dressing, eating, toileting, and motor skills, often provides insight about the integrity of the child's cognitive, communication, and neuromotor development. School experiences, academic readiness skills, educational achievement, and behavior patterns at home and school often reflect the cognitive and language development of school-age children and adolescents.

Physical Examination

The physical examination should begin with observations of the general appearance of the child, including overall state of health, visual and auditory responsiveness to the surroundings, and interactions with parents. When the child is at rest, subtle abnormalities of body proportions and movement patterns may be observed. Careful attention should also be paid to physical measurements (length/height, weight, *and head circumference*) with values plotted on standard reference curves. Both poor growth and excessive growth may be associated with metabolic disorders or genetic syndromes. Head circumference measurements may be abnormal (greater or less than 2 standard deviations [SD] from the mean) or disproportionate for body size (head circumference should correlate with length/height of the child). Although large or small head size may be associated with significant pathology, a benign form of familial micro- and macrocephaly may be ruled out if 1 or both parents share the same trait. **Dysmorphic features** may suggest a recognizable pattern of deformation or malformation (Table 24.11) (see Chapter 25). If the child has an unusual appearance, biologic family members should be examined either directly or from photographs to determine any resemblance. Additionally, examining serial photographs of a child at different ages can help to identify "coarsening" of facial features due to a storage disease (mucopolysaccharidosis). Abnormalities of skin pigmentation may suggest the presence of a neurocutaneous disorder (phakomatosis) associated with developmental disability (neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome) (see Chapter 30). A Wood's lamp examination may be helpful if a depigmented lesion is identified (ash-leaf spots in tuberous sclerosis). Measurements of facial features, such as inner canthal distance, palpebral fissure length, auricular size and position, and development of the philtrum and upper lip, may be associated with structural anomalies of craniofacial development caused by genetic or teratogenic exposure (fetal alcohol syndrome). The oral structures should be examined for the presence of cleft palate (velocardiofacial syndrome, Stickler syndrome), macroglossia (Beckwith-Wiedemann syndrome), or recessed jaw (Pierre-Robin sequence). Anomalies of the neck may indicate vertebral abnormalities (Klippel-Feil syndrome) or genetic disorders (Turner syndrome, Noonan syndrome, Down syndrome). Cardiac anomalies are associated with a large number of syndromes. The abdominal exam may reveal evidence of an enlarged liver (associated with glycogen storage diseases, sphingolipidoses, or mucopolysaccharidoses). Examination of the back should include the "forward bend test" for scoliosis, and the presence of dimpling or a hirsute area in the lower spine that could represent an occult form of spinal dysraphism (tethered cord or other spinal cord anomaly). Anomalies of the extremities (limb proportions, hands, feet, and nails) are associated with a wide range of birth defects and syndromes. The presence of multiple malformations may be an important key to identifying a specific developmental disorder or syndrome. Although minor physical anomalies may be associated with developmental delay, most children with minor anomalies develop normally (Table 24.12).

TABLE 24.11 Physical Examination of a Child with Suspected Developmental Disabilities

Item	Possible Significance	Item	Possible Significance
General appearance	May indicate significant delay in development or obvious syndrome	**Liver** Hepatomegaly	Fructose intolerance, galactosemia, glycogenosis types I-IV, mucopolysaccharidosis types I and II, Niemann-Pick disease, Tay-Sachs disease, Zellweger syndrome, Gaucher disease, ceroid lipofuscinosis, gangliosidosis
Stature Short stature	Malnutrition, many genetic syndromes are associated with short stature (e.g., Turner and Noonan syndromes)	**Genitalia** Macro-orchidism	Fragile X syndrome
Obesity	Prader-Willi syndrome	Hypogenitalism	Prader-Willi syndrome, Klinefelter syndrome, CHARGE syndrome
Large stature	Sotos syndrome		
Head Macrocephaly	Alexander syndrome, Canavan disease, Sotos syndrome, gangliosidosis, hydrocephalus, mucopolysaccharidosis, subdural effusion	**Extremities** Hands, feet, dermatoglyphics, and creases	May indicate a specific entity such as Rubinstein-Taybi syndrome or be associated with chromosomal anomaly
Microcephaly	Virtually any condition that can restrict brain growth (e.g., malnutrition, Angelman syndrome, de Lange syndrome, fetal alcohol effects)	Joint contractures	Signs of muscle imbalance around the joints; e.g., with meningomyelocele, cerebral palsy, arthrogryposis, muscular dystrophy; also occurs with cartilaginous problems such as mucopolysaccharidosis
Face Coarse, triangular, round, or flat face; hypotelorism or hypertelorism, slanted or short palpebral fissure; unusual nose, maxilla, and mandible	Specific measurements may provide clues to inherited, metabolic, or other diseases such as fetal alcohol syndrome, cri du chat (5p−) syndrome, or Williams syndrome	**Skin** Café-au-lait spots	Neurofibromatosis Tuberous sclerosis Chromosomal aneuploidy McCune-Albright syndrome Fanconi anemia Silver-Russell syndrome Ataxia telangiectasia Bloom syndrome Basal cell nevus syndrome Gaucher disease Chediak-Higashi syndrome Hunter syndrome Multiple endocrine neoplasia type 2b Bannayan-Riley-Ruvalcaba syndrome Maffucci syndrome
Eyes Prominent	Crouzon syndrome, Seckel syndrome, fragile X syndrome		
Cataract	Galactosemia, Lowe syndrome, prenatal rubella, hypothyroidism		
Cherry-red spot in macula	Gangliosidosis (GM_1), metachromatic leukodystrophy, mucolipidosis, Tay-Sachs disease, Niemann-Pick disease, Farber lipogranulomatosis, sialidosis type III		
Chorioretinitis	Congenital infection with cytomegalovirus, toxoplasmosis, or rubella	Seborrheic or eczematoid rash	Phenylketonuria, histiocytosis
Corneal cloudiness	Mucopolysaccharidosis types I and II, Lowe syndrome, congenital syphilis	Hemangiomas and telangiectasia	Sturge-Weber syndrome, Bloom syndrome, ataxia-telangiectasia
Ears Low-set or malformed pinnae	Trisomies such as Down syndrome, Rubinstein-Taybi syndrome, CHARGE syndrome, cerebrooculofacioskeletal syndrome, fetal phenytoin effects	Hypopigmented macules, streaks, adenoma sebaceum	Tuberous sclerosis, hypomelanosis of Ito
Hearing	Loss of acuity in mucopolysaccharidosis; hyperacusis in many encephalopathies	**Hair** Hirsutism	de Lange syndrome, mucopolysaccharidosis, fetal phenytoin effects, cerebrooculofacioskeletal syndrome, trisomy 18
Heart Structural anomaly or hypertrophy	CHARGE syndrome, velocardiofacial syndrome, glycogenosis type II, fetal alcohol effects, mucopolysaccharidosis type I; chromosomal anomalies such as Down syndrome; maternal PKU; chronic cyanosis may impair cognitive development	**Neurologic** Asymmetry of strength and tone	Focal lesion, hemiplegic cerebral palsy
		Hypotonia	Prader-Willi syndrome, Down syndrome, Angelman syndrome, gangliosidosis, early cerebral palsy, muscle disorders (dystrophy or myopathy)
		Hypertonia	Neurodegenerative conditions involving white matter, cerebral palsy, trisomy 18
		Ataxia	Ataxia-telangiectasia, metachromatic leukodystrophy, Angelman syndrome

CHARGE, **c**oloboma, **h**eart defects, **a**tresia choanae, **r**etarded growth, **g**enital anomalies, **e**ar anomalies (deafness); CATCH-22, **c**ardiac defects, **a**bnormal face, **t**hymic hypoplasia, **c**left palate, **h**ypocalcemia—defects on chromosome 22; PKU, phenylketonuria.

TABLE 24.12	**Examples of Minor Anomalies and Associated Syndromes**[*†]
Head	Flat occiput: Down syndrome, Zellweger syndrome; prominent occiput: trisomy 18
	Delayed closure of sutures: hypothyroidism, hydrocephalus
	Craniosynostosis: Crouzon syndrome, Pfeiffer syndrome
	Delayed fontanel closure: hypothyroidism, Down syndrome, hydrocephalus, skeletal dysplasias
Face	Midface hypoplasia: fetal alcohol syndrome, Down syndrome
	Triangular facies: Russell-Silver syndrome, Turner syndrome
	Coarse facies: mucopolysaccharidoses, Sotos syndrome
	Prominent nose and chin: fragile X syndrome
	Flat facies: Apert syndrome, Stickler syndrome
	Round facies: Prader-Willi syndrome
Eyes	Hypertelorism: fetal hydantoin syndrome, Waardenburg syndrome
	Hypotelorism: holoprosencephaly sequence, maternal phenylketonuria effect
	Inner canthal folds/Brushfield spots: Down syndrome; slanted palpebral fissures: trisomies
	Prominent eyes: Apert syndrome, Beckwith-Wiedemann syndrome
	Lisch nodules: neurofibromatosis
	Blue sclera: osteogenesis imperfecta, Turner syndrome, hereditary connective tissue disorders
Ears	Large pinnae/simple helices: fragile X syndrome
	Malformed pinnae/atretic canal: Treacher Collins syndrome, CHARGE syndrome
	Low-set ears: Treacher Collins syndrome, trisomies, multiple disorders
Nose	Anteverted nares/synophrys: de Lange syndrome; broad nasal bridge: fetal drug effects, fragile X syndrome
	Low nasal bridge: achondroplasia, Down syndrome
	Prominent nose: Coffin-Lowry syndrome, Smith-Lemli-Opitz syndrome
Mouth	Long philtrum/thin vermilion border: fetal alcohol effects
	Cleft lip and palate: isolated or part of a syndrome
	Micrognathia: Pierre-Robin sequence, trisomies, Stickler syndrome
	Macroglossia: hypothyroidism, Beckwith-Wiedemann syndrome
Teeth	Anodontia: ectodermal dysplasia
	Notched incisors: congenital syphilis
	Late dental eruption: Hunter syndrome, hypothyroidism
	Talon cusps: Rubinstein-Taybi syndrome
	Wide-spaced teeth: de Lange syndrome, Angelman syndrome
Hair	Hirsutism: Hurler syndrome
	Low hairline: Klippel-Feil sequence, Turner syndrome
	Sparse hair: Menkes disease, argininosuccinic acidemia
	Abnormal hair whorls/posterior whorl: chromosomal aneuploidy (e.g., Down syndrome)
	Abnormal eyebrow patterning: Cornelia de Lange syndrome
Neck	Webbed neck/low posterior hairline: Turner syndrome, Noonan syndrome
Chest	Shield-shaped chest: Turner syndrome
Genitalia	Macro-orchidism: fragile X syndrome
	Hypogonadism: Prader-Willi syndrome
Extremities	Short limbs: achondroplasia, rhizomelic chondrodysplasia
	Small hands: Prader-Willi syndrome
	Clinodactyly: trisomies, including Down syndrome
	Polydactyly: trisomy 13, ciliopathies
	Broad thumb: Rubinstein-Taybi syndrome
	Syndactyly: de Lange syndrome
	Transverse palmar crease: Down syndrome
	Joint laxity: Down syndrome, fragile X syndrome, Ehlers-Danlos syndrome
	Phocomelia: de Lange syndrome
Spine	Sacral dimple/hairy patch: spina bifida
Skin	Hypopigmented macules/adenoma sebaceum: tuberous sclerosis
	Café-au-lait spots and neurofibromas: neurofibromatosis
	Linear depigmented nevi: hypomelanosis of Ito
	Facial port-wine hemangioma: Sturge-Weber syndrome
	Nail hypoplasia or dysplasia: fetal alcohol syndrome, trisomies

[*]Increased incidence of minor anomalies have been reported in cerebral palsy, intellectual disability, learning disabilities, and autism.
[†]The presence of 3 or more minor anomalies implies a greater chance that the child has a major anomaly and a diagnosis of a specific syndrome.
CHARGE, **c**oloboma, **h**eart defects, **a**tresia choanae, **r**etarded growth, **g**enital anomalies, **e**ar anomalies (deafness).
Modified from Levy SE, Hyman SL. Pediatric assessment of the child with developmental delay. *Pediatr Clin North Am.* 1993;40:465-477.

The neuromotor examination should include observation of muscle bulk and presence or absence of muscle atrophy associated with myopathy. The assessment of cranial nerves includes evaluation for visual responsiveness, pupillary reactivity, presence of red reflexes, fullness of eye movements, and evidence of strabismus. Ptosis, asymmetry of facial expression, or abnormal tongue movement (deviation or fasciculation) suggests muscle weakness or partial paralysis. Muscle strength may be assessed by observing the child move about and manipulate objects. In the 1st year of life, motor milestones include the ability to sit independently, crawl, cruise, and walk. By 18 months, children should be able to squat and recover. The Gowers maneuver is helpful in assessing strength of the quadriceps muscles. Decreased muscle tone may be reflected in poor posture or hypermobile joints. Decreased stretch reflex responsiveness may be due to lower motor neuron disease or myopathy. In infants, the persistence of primitive reflexes or the absence of protective postural reflexes is suggestive of neuromotor dysfunction. In older children, the presence of increased stretch reflexes, clonus, and positive Babinski reflexes are signs of upper motor neuron dysfunction associated with spasticity. Normal gait requires intact and coordinated motor and sensory ability. Unsteady gait or tremor may be a sign of muscle weakness or abnormal cerebellar function or basal ganglia disease. Asymmetry of gait may reflect hemiplegia. Observing the child reaching for objects, extending the arms outstretched, or performing the finger-to-nose test may reveal tremors or difficulty with eye-hand coordination.

Neurodevelopmental Examination

Many pediatricians and developmental specialists incorporate a number of "informal" age-appropriate tasks into their evaluation that provide an opportunity to examine the child's development and behavior. This part of the examination may take 10-15 minutes. Parents should always be present while examining preschool children to provide comfort and reassurance. Older children (6 years and above) may respond better without their parents present for this part of the examination. It is important to recognize that a child's responses on "informal measures" in the context of a pediatric developmental assessment are not an adequate substitute for formal psychologic and communication evaluations. However, the clinician may observe how the child interacts with the examiner and parents, the child's ability to understand and communicate with the examiner and with the parents, and make some observations of the child's attention span, persistence with tasks, and frustration tolerance.

FORMAL NEURODEVELOPMENTAL ASSESSMENTS

Psychologic Evaluation

Evaluation by a child psychologist can provide an assessment of a child's strengths and weaknesses across a broad range of cognitive areas. For infants and young children, global measures of development are the most valuable, since the structure of intelligence develops from relatively "general" and homogeneous ability to more complex and differentiated functions over time. Few tasks on measures used for preschool children reflect "pure" abilities in any particular skill. Rather, tasks for infants reflect the child's ability to utilize a combination of cognitive, language, and motor skills to respond. However, tests vary in their ability to separate these component functions. The Bayley Scales of Infant and Toddler Development-3rd Edition (Bayley III) is a widely used tool for assessing children 0-42 months of age. There are several normed measures of verbal and nonverbal abilities that can be used with children older than 2 years of age. Many factors can contribute to the child's performance. Observing how the child responds to a task can be as informative as the accuracy of the

response. It is generally recognized that intelligence testing prior to age 6 years is not highly predictive of test results at older ages, but the evaluation provides a measure of the child's abilities at that point in time. In addition, a psychologist is able to observe the child's behavior, attention span, organizational skills, persistence, and frustration tolerance during the evaluation. These informal observations may help to determine the presence or absence of emotional or behavioral problems that stem from, or coexist with, the child's developmental disabilities.

Results of psychologic tests are not indicative of specific etiologies (genetic or acquired biologic conditions) and cannot determine whether a child has suffered a "brain injury," even in the context of a potentially traumatic event. Serial cognitive measures, particularly when there is premorbid information that has changed over time, may suggest the effects of trauma or a progressive disease process.

Speech-Language and Oral Motor Evaluation

The ability to understand and communicate with others has a very strong influence on a child's emotional, behavioral, and social functioning. Communication abilities may or may not reflect the child's intellectual ability. A speech-language pathologist can evaluate a wide range of communication and oral motor skills in children. For example, even prior to the use of words, infants display "preverbal" communication abilities (gestures), and may recognize a number of spoken words. Older children may suffer from delays in understanding of language (language disorders) or from disorders of speech sound production (apraxia, dysarthria). Many children with neurologic disabilities have oral motor coordination disorders (dysphagia) that interfere with chewing and swallowing and place them at risk for poor weight gain and/or pulmonary aspiration. Drooling management is also a problem for many children with oral motor coordination delays. While it is more common for receptive language ability to exceed expressive language ability, children with Williams syndrome and with spina bifida/hydrocephalus may display conversational skills that exceed their cognitive deficits ("cocktail conversation"). In both conditions, "basic" language abilities (vocabulary and grammar) are relatively well developed, while "higher-level" language functions (semantic knowledge and pragmatic aspects of communication) are deficient.

DIAGNOSTIC STRATEGY

Once a comprehensive profile of the child's strengths and weaknesses has been identified through neurodevelopmental, psychologic, and speech-language evaluations, the next step is to establish a developmental diagnosis.

Cognitive, language, and motor abilities typically develop in a coordinated fashion. Discrepancies in development between different areas of function may point to a specific area of concern or suggest possible clinical diagnoses (Table 24.13). Many disabilities can be identified by their characteristic pattern of development over time (e.g., hypotonia/hyperphagia in Prader-Willi syndrome, regression/microcephaly/hand-wringing behavior in Rett syndrome). In general, motor milestones do not correlate well with intellectual ability, since most children with ID walk at a normal age. Language abilities, when well developed, are usually an excellent indicator of intellectual function. Problem-solving skills (referred to as "adaptive" or "visual-motor" skills) often correlate with nonverbal cognitive abilities. Finally, psychosocial milestones often reflect language ability. A child with delays in all areas likely has a cognitive deficit, while a child whose communication skills are at variance with nonverbal cognitive abilities likely has a language disorder.

TABLE 24.13   Differential Diagnosis of Atypical Patterns of Development

	Intellectual Disability	Developmental Language Disorder	Specific Language Impairment	Autism Spectrum Disorder	Social Pragmatic Communication Disorder
Cognitive ability	Delayed	Normal/delayed	Normal	Normal/delayed	Normal
Language ability	Delayed	Disordered	Disordered	Disordered	Normal
Social ability	Normal	Normal	Normal	Abnormal	Abnormal
Family history	Negative	Speech/language	Speech/language	Affective disorder	Social deficits

Modified from Simms MD, Schum RL. Preschool children who have atypical patterns of development. *Pediatr Rev.* 2000;21:147-158.

TABLE 24.14   Select "Extrinsic" Conditions Associated with Developmental Regression

Neoplasms and their therapy
Leukemia
Tumors
Histiocytosis
Increased intracranial pressure
Hydrocephalus, including ventricular shunt malfunctions
Subdural hematoma or effusion
Infections
Encephalitis, including HIV infection
Meningitis
Endocrine disorders
Hypothyroidism
Adrenocortical insufficiency
Collagen vascular disease (e.g., systemic lupus erythematosus)

Delays isolated to a single, specific area such as expressive language are more likely to be transient than are generalized delays. If the child's development has deteriorated (regressed), a progressive encephalopathy may be present. Progressive disorders may be the result of metabolic or storage diseases, or due to a genetic syndrome (Rett syndrome). In contrast, static encephalopathies are usually the result of structural abnormalities due to abnormal development or trauma (Tables 24.14 and 24.15).

More than 300 neurodegenerative disorders have been described; additional classification based on progression and age is noted in Table 24.16 and in Figs. 24.3 and 24.4. Neurodegenerative disorders are often categorized as involving white matter, gray matter, basal ganglia, or the entire CNS. White matter diseases (e.g., adrenoleukodystrophy) affect long tracts and manifest with loss of motor skills, spasticity, disturbed gait, areflexia (if peripheral nerve also involved), or ataxia, whereas gray matter diseases (e.g., ceroid lipofuscinoses) manifest with seizures and abnormalities of cognition, vision, and hearing. Many disorders classified as "white matter" or "gray matter" manifest with a mixed picture of signs and symptoms. Diseases that involve primarily the basal ganglia, such as Huntington disease, manifest with mental deterioration, behavioral changes, rigidity, ataxia, dysarthria, seizures, and incoordination. As these diseases progress, neurologic signs and symptoms become more widespread and less specific.

To date, approximately 450 genes have been implicated in GDD/ID. Of these, 400 are associated with "syndromic" GDD/ID (i.e., cases in which abnormalities are identified on examination such as micro- or macrocephaly, dysmorphic features, congenital anomalies, abnormal neurologic examination, seizures, structural brain abnormalities, sensory deficits [vision or hearing], or autism). Approximately 50 genes have been associated with "nonsyndromic" GDD/ID.

A distinction should be made between a clinical diagnosis that is based on descriptions and measurements of various functional abilities and an etiologic diagnosis that attributes the problem(s) to a specific cause. For most developmental disabilities, a specific etiology cannot be established with absolute certainty. For example, clinical diagnoses such as cerebral palsy or ID can result from multiple etiologies, and conversely, the same etiology can manifest in a variety of ways. As medical diagnostic technologies have improved, the number of individuals for whom an etiologic diagnosis can be established has increased. Even when a specific etiologic diagnosis cannot be determined, an accurate clinical diagnosis is often helpful in designing treatment recommendations, since most treatments are based on an educational-developmental model and are successful for a range of underlying biomedical causes.

Although most parents will pursue further evaluations when they are concerned about their child's development, not all are willing or able to have their child undergo medical diagnostic testing procedures when he or she is very young. Instead, parents typically want to know what they can do to help their child "catch up" with his or her peers. This concept is often reinforced by referring to the problem as a developmental "delay." Unless there are signs of regression or failure to thrive that would make diagnostic testing urgent, "watchful waiting" while the child enters a program of interventions is a very reasonable strategy. If, despite these measures, the developmental concerns persist, families may be more willing to obtain further diagnostic testing. It is often helpful to share with parents that the probability of establishing a medical diagnosis with current technology is only 20-25%, unless specific syndromes or disorders are suspected from the history and physical examination. Further, in most situations, a specific diagnosis may not result in a cure for the basic disorder. However, if a specific etiology can be established, it may result in effective treatments and preventive measures, even when a cure for the underlying condition is not possible. For example, medical treatment for the circadian rhythm dysfunction associated with Smith-Magenis syndrome can be very successful in improving sleep patterns and daytime behaviors. In addition, children can be monitored on an expectant basis for complications that occur frequently with specific disorders (Wilms tumor in Beckwith-Wiedemann syndrome).

LABORATORY TESTING

With the rapid advances in diagnostic testing technologies over the past decade, evaluation strategies have undergone considerable scrutiny to determine the most effective approach to determining an etiologic diagnosis for individuals with GDD/ID. In general, when a specific diagnosis is suspected based on the history and physical

TABLE 24.15	**Select "Intrinsic" Conditions Associated with Developmental Regression**	
Age at Onset (yr)	**Conditions**	**Comments**
<2, with hepatomegaly (see Chapter 14)	Fructose intolerance	Vomiting, hypoglycemia, poor feeding, failure to thrive (when given fructose)
	Galactosemia	Lethargy, hypotonia, icterus, cataract, hypoglycemia (when given lactose)
	Glycogenosis (glycogen storage disease) types I-IV	Hypoglycemia, cardiomegaly (type II)
	Mucopolysaccharidosis types I and II	Coarse facies, stiff joints
	Niemann-Pick disease, infantile type	Gray matter disease, failure to thrive
	Tay-Sachs disease	Seizures, cherry-red macula, edema, coarse facies
	Zellweger (cerebrohepatorenal) syndrome	Hypotonia, high forehead, flat facies
	Gaucher disease type II	Extensor posturing, irritability
	Carbohydrate-deficient glycoprotein syndromes	Dysmyelination, cerebellar hypoplasia
<2, without hepatomegaly	Krabbe disease	Irritability, extensor posturing, optic atrophy, and blindness
	Rett syndrome	Girls with deceleration of head growth, loss of hand skills, hand wringing, impaired language skills, gait apraxia
	Maple syrup urine disease	Poor feeding, tremors, myoclonus, opisthotonos
	Phenylketonuria	Light pigmentation, eczema, seizures
	Menkes kinky hair disease	Hypertonia, irritability, seizures, abnormal hair
	Subacute necrotizing encephalopathy of Leigh	White matter disease
	Cerebrooculofacioskeletal syndrome (of Pena and Shokeir)	Reduced white matter, failure to thrive
	Canavan disease	White matter disease
	Pelizaeus-Merzbacher disease	White matter disease
2-5	Niemann-Pick disease types III and IV	Hepatosplenomegaly. gait difficulty
	Wilson disease	Liver disease, Kayser-Fleischer ring; deterioration of cognition is late
	Gangliosidosis type II	Gray matter disease
	Ceroid lipofuscinosis	Gray matter disease
	Mitochondrial encephalopathies (e.g., myoclonic epilepsy with ragged red fibers [MERRF])	Gray matter disease
	Ataxia-telangiectasia	Basal ganglia disease
	Huntington disease (chorea)	Basal ganglia disease
	Hallervorden-Spatz syndrome	Basal ganglia disease
	Metachromatic leukodystrophy	White matter disease
	Adrenoleukodystrophy	White matter disease, behavior problems, deteriorating school performance, quadriparesis
5-15	Adrenoleukodystrophy	Same as for adrenoleukodystrophy in 2-5-yr-olds
	Multiple sclerosis	White matter disease
	Neuronal ceroid lipofuscinosis, juvenile and adult (Spielmeyer-Vogt and Kufs disease)	Gray matter disease
	Schilder disease	White matter disease, focal neurologic symptoms
	Refsum disease	Peripheral neuropathy, ataxia, retinitis pigmentosa
	Sialidosis type II, juvenile form	Cherry-red macula, myoclonus, ataxia, coarse facies
	Subacute sclerosing panencephalitis	Diffuse encephalopathy, myoclonus; may occur years after measles

Aspartoacylase deficiency (Canavan disease)
Galactosemia: transferase deficiency*
Neonatal adrenoleukodystrophy
Pelizaeus-Merzbacher disease
Progressive cavitating leukoencephalopathy

Progressive Hydrocephalus*

Onset After Age 2 Years

Disorders of Lysosomal Enzymes
Gaucher disease type III (glucosylceramide lipidosis)
Globoid cell leukodystrophy (late-onset Krabbe disease)
Glycoprotein degradation disorders
Aspartylglycosaminuria
Mannosidosis type II
GM₂ gangliosidosis (juvenile Tay-Sachs disease)
Metachromatic leukodystrophy (late-onset sulfatide lipidoses)
Mucopolysaccharidoses types II and VII
Niemann-Pick type C (sphingomyelin lipidosis)

Infectious Disease
AIDS encephalopathy*
Congenital syphilis*
Subacute sclerosing panencephalitis

Other Disorders of Gray Matter
Ceroid lipofuscinosis
- Juvenile
- Late infantile (Bielschowsky-Jansky disease)
Huntington disease
Mitochondrial disorders
- Late-onset poliodystrophy
- Myoclonic epilepsy and ragged-red fibers
Progressive neuronal degeneration with liver disease
Xeroderma pigmentosum

Other Disorders of White Matter
Adrenoleukodystrophy
Alexander disease
Cerebrotendinous xanthomatosis
Progressive cavitating leukoencephalopathy
Epileptic aphasia
- Landau-Kleffner syndrome

*The most common conditions and the ones with disease modifying treatments.
Modified from Pina-Garza JE. *Fenichel's Clinical Pediatric Neurology: A Signs and Symptoms Approach*. 7th ed. Philadelphia: Saunders; 2013.

Clinical Signs and Symptoms	First Tier Tests to Consider	Diagnoses
A. Known perinatal risk factors	Microarray Brain MRI	1. Antenatal diseases (malformations/fetal infections) 2. Perinatal diseases
B. Dysmorphic features	Microarray Radiologic and/or metabolic tests*	1. Chromosome anomaly 2. Birth defect syndrome 3. Metabolic disorder
C. Abnormal neurologic examination	Microarray Brain MRI Metabolic tests†	1. CNS malformation 2. Chromosome anomaly 3. Metabolic disorder
D. Absence of known risk factors; normal neurologic examination; nondysmorphic "nonspecific global developmental delay"	Microarray Fragile X Brain MRI	1. Chromosome anomaly 2. CNS malformation

Results

Normal → Refer for further genetic evaluation

Abnormal → Refer for expert consultation and genetic counseling and management

examination, a "targeted" approach to confirm that condition (single-gene tests, specific metabolic studies, neuroimaging, etc.) is warranted (Tables 24.17 and 24.18). If no clinical diagnosis is suspected, current guidelines for comprehensive evaluation recommend a "tiered approach."

Genetic Tests

The 1st tier for all children with "nonspecific" GDD/ID should consist of genetic testing with chromosomal microarray (CMA) and Fragile X (Fra X) tests. If a specific diagnosis is not established from CMA/Fra X testing, referral for consultation with a geneticist should also be arranged. Next genome sequencing (NGS) technology has made available broad screening panels within a group of phenotypes (e.g., X-Linked Intellectual Disability [XLID] panel), but improved bioinformatics and accessibility to whole-exome sequencing (WES) are evolving into a new diagnostic era for children with disabilities. Diagnosis in up to 30% of affected children with syndromic GDD/ID can be achieved with WES; a clear causative etiology in autism or isolated GDD/ID is most often not found (see Fig. 24.3). The diagnostic yield of CMA in unexplained ID is 15-20%. The technology will not detect balanced translocations if there is no loss or gain of chromosomal material. Copy number variations (CNV) may identify known genetic disorders, but also patterns that have not yet been associated with

GDD/ID. In this case, it may be necessary to test both parents to determine if the CNV was inherited or de novo. If the same CNV is found in an unaffected parent, it is more challenging to interpret the significance of the variant. There are numerous case reports of unaffected parent carriers and wide variability in phenotypic expression. If the variant is de novo in the child, it is more likely to be significant.

Metabolic Tests

Routine neonatal screening for metabolic disorders may identify infants with inborn errors of metabolism (IEM) that are associated with GDD. However, not all children with IEM are found shortly after birth, and normal results do not eliminate the possibility that one of the screened for IEM is present. As with genetic testing, "targeted" biochemical lab testing can be performed when a specific disease is considered (7-dehydrocholesterol for Smith-Lemli-Opitz syndrome, very-long-chain fatty acids for peroxisomal disorders, T_4/TSH for hypothyroidism, creatinine kinase for Duchenne muscular dystrophy, mucopolysaccharides for lysosomal storage disorders such as Hunter or Hurler disease). In general, few metabolic conditions result in GDD/ID in the absence of other neurologic symptoms (Table 24.19). To date, 89 IEM have been identified that are amenable to treatment of the underlying defect and/or pathogenetic mechanism (Table 24.20). Of these, 54 (60%) can be identified by blood tests (plasma amino acids,

TABLE 24.17	**Chromosomal Abnormalities in Which Developmental Delay Is a Major Feature**	
Condition	**Incidence**	**Comments**
Trisomy 21	1/700	Down syndrome
Fragile X syndrome	1/800	Macro-orchidism, hyperactivity, autistic-like behavior
47,XXY (Klinefelter syndrome)	1/1000	Small testes, problems in language skills
47,XXX	1/1000	Girls with learning and language problems may have 48,XXXX
45,X (Turner syndrome)	1/2000	Girls with short stature, broad neck, gonadal dysgenesis; visuospatial deficits common
Prader-Willi syndrome (abnormality of contiguous genes on chromosome 15; inherited from deletions of paternal chromosomes—monoparental disomy)	1/5000	Hypotonia in infancy, obesity, short stature, mild intellectual disability
Angelman syndrome (chromosome anomaly similar to that in Prader-Willi syndrome; inherited from maternal deletion in chromosome 15—monoparental disomy)	Unknown	Ataxia, prognathism, absence of speech, severe intellectual disability, inappropriate laughter
Trisomy 18	1/8000	Multiple congenital anomalies, severe developmental delay
Trisomy 13	1/20,000	Multiple congenital anomalies, severe developmental delay
5p– (cri du chat syndrome)	1/100,000	High-pitched cry, small stature, speech and language delays
4p– (Wolf-Hirschhorn syndrome)	1/100,000	Midline deficiencies, profound intellectual disability, seizures
11p– (Wilms tumor, aniridia)	1/100,000	Ambiguous genitalia, aniridia, cataracts
17p– (Miller-Dieker syndrome)	1/100,000	Lissencephaly, microcephaly, seizures, cryptorchidism

TABLE 24.18   **Suggested Evaluation of the Child with Intellectual Disability/Global Developmental Delay**

Test	Comments
In-depth history	Includes pre-, peri-, and postnatal events (including seizures); developmental attainments; and 3-generation pedigree in family history
Physical examination	Particular attention to minor or subtle abnormalities; neurologic examination for focality and skull abnormalities Behavioral phenotype
Vision and hearing evaluation	Essential to detect and treat; can mask as developmental delay
Gene microarray analysis	A 7.8% yield overall (10% in syndromic and 6.5% in nonsyndromic intellectual disability) Better resolution than karyotype. May identify up to twice as many abnormalities as karyotyping. Excellent in detecting de novo microdeletions or microduplications
Karyotype	Yield: 4% in global developmental delay/intellectual disability Best for inversions and balanced insertions, reciprocal translocations, and polyploidy
Fragile X screen	Combined yield, 2% Preselection on clinical grounds can increase yield to 7.6%
X-linked candidate intellectual disability genes	May explain up to 10% of intellectual disability Yield may be as high as 42% if there is a definite family history and as high as 17% from a possibly linked kindred
Exomic gene sequencing	Detects inherited and de novo point mutations, especially in nonsyndromic severe intellectual disability
Neuroimaging	MRI preferred. Positives increased by abnormalities of skull contour or microcephaly and macrocephaly, or focal neurologic examination. Overall, has a higher yield Identification of specific etiologies is rare. Most conditions that are found do not alter the treatment plan. Need to weigh risk of sedation against possible yield
Thyroid (T_4, TSH)	Near 0% in settings with a universal newborn screening program
Serum lead	If there are identifiable risk factors for excessive environmental lead exposure
Metabolic testing	Yield: 0.2-4.6% based on clinical indicators and tests performed Urine organic acids, plasma amino acids, ammonia, lactate, and a capillary blood gas. Focused testing based on clinical findings is warranted Tandem mass spectrometry newborn screening has allowed for identification of many disorders in the perinatal period and has decreased yield in older children. Other disorders have emerged; e.g., congenital disorders of glycosylation and disorders of creatine synthesis and transport
MECP2 for Rett syndrome	1.5% of females with severe intellectual disability 0.5% of males
EEG	May be deferred in absence of history of seizures
Repeated history and physical examination	Can give time for maturation of physical and behavioral phenotype. New technology may be available for evaluation

EEG, electroencephalogram; CGH, comparative genomic hybridization; MECP2, methyl CpG binding protein 2; T_4, thyroxine; TSH, thyroid-stimulating hormone.

homocysteine, copper, ceruloplasmin) and urine (creatine metabolites, glycosaminoglycans, oligosaccharides, organic acids, and pyrimidines). The remaining 35 (40%) are identified by specific tests and molecular analysis. A digital app (TIDE BC) is available free (http://www.treatable-id.org) from the App Store, and provides an information portal about these diseases and their treatments. Although the yield from metabolic studies in "nonsyndromic" GDD/ID is relatively low (0.2-5%), IEM are amenable to treatment, so metabolic testing should be considered in all cases of unexplained GDD/ID.

Neuroimaging
Ultrasonography
An ultrasound study of the head performed before the anterior fontanel closes can provide a general anatomic picture of the brain, including a view of the posterior fossa. This technique is insensitive to lesions involving the subdural space, and its success depends more on the skill of the interpreter than that of the other imaging studies. It does not expose the child to radiation, nor is sedation required in most instances. Its primary uses include identifying and monitoring intraventricular

TABLE 24.19 Features Suggestive of Inherited Neurometabolic Disorders

Encephalopathy	Systemic Features
Intellectual disability	Urinary odor
Developmental regression	Intrauterine growth retardation
Cerebral palsy	Failure to thrive
Spastic diplegia	Poor sucking
Spastic quadriplegia	Vomiting repeatedly
Depressed sensorium	Weak cry
Lethargy	Cardiomyopathy
Irritability	Hepatomegaly
Stupor	Fatty liver
Coma	Fibrosis/cirrhosis
Dementia	Hepatosplenomegaly
Hypotonia	Renal Tubular Acidosis
Seizures	Susceptibility to Infections
Myoclonus	Bone Marrow Depression
Infantile spasms	Neutropenia
Extrapyramidal symptoms	Thrombocytopenia
Dystonia	Pancytopenia
Opisthotonos	Seborrhea
Choreoathetosis	Alopecia
Microcephaly	Abnormal Hair
Macrocephaly	Pili torti
Speech problems	Trichorrhexis nodosa
Eye-related problems	
Abnormal movements	
Apraxia	
Cherry-red spot	
Nystagmus	
Optic atrophy	
Tapetoretinal degeneration (hereditary)	

Modified from Chaves-Carballo E. Detection of inherited neurometabolic disorders. A practical clinical approach. *Pediatr Clin North Am.* 1992;39:801-820.

TABLE 24.20 Conditions in Which Early Treatment May Significantly Improve the Course of the Disease

Condition	Treatment
Galactosemia	Lactose-free diet
Fructosemia	Fructose-free diet
Hypoglycemia from any cause	Prevent hypoglycemia and/or provide glucose
Lead intoxication	Separate child from source of lead; chelation therapy
Hypothyroidism	Thyroid replacement
Phenylketonuria	Phenylalanine-free diet
Maternal phenylketonuria	Phenylalanine-free diet during pregnancy
Maple syrup urine disease	Diet restricted in branched-chain amino acids + dialysis or exchange transfusion
Recurrent otitis media	Antibiotic prophylaxis, pressure-equalizing tubes
Malnutrition	Adequate nutrition
Increased intracranial pressure (e.g., hydrocephalus, neoplasm)	Shunt ventricles or cystic structure
Congenital HIV infection	Prenatal/postnatal treatment with AZT (zidovudine)
Congenital toxoplasmosis	Prenatal treatment with spiramycin, pyrimethamine, and sulfonamide
Dopa-responsive dystonia	Responds to levodopa; may be misdiagnosed as cerebral palsy
Metachromatic leukodystrophy	Bone marrow transplantation
Niemann-Pick disease	Bone marrow transplantation, liver transplantation, implanted amniotic epithelial cells
Adrenoleukodystrophy	Bone marrow transplantation
Mucopolysaccharidosis type I	Bone marrow transplantation
Glycogen storage disease type IV	Liver transplantation
Menkes disease	Parenteral copper histidinate
Lesch-Nyhan syndrome	Allopurinol + bone marrow transplantation
Krabbe disease	Bone marrow transplantation

HIV, human immunodeficiency virus.

hemorrhage and hydrocephalus; these functions are useful, especially in the preterm infant.

Computed Tomography Scans

CT provides more detail than ultrasonography, including details of bone structures and the subdural space. Using contrast material will further delineate structures such as tumors, or differentiate white from gray matter. However, CT exposes the child to radiation, and most young children require sedation to undergo this procedure.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides the greatest detail of the nonbone aspects of the CNS. The scanning time is longer than for CT, and most young children require sedation. The contrast material used, gadolinium, is generally safer than the contrast agents used for CT. MRI is superior to CT in the evaluation of the posterior fossa. MRI is used for imaging the spinal cord. MRI can differentiate abnormalities of gray and white matter, as well as deep and cortical gray matter lesions. Special techniques include magnetic resonance angiography, which can identify blood flow, and cerebrospinal fluid flow imaging, which can identify flow in conditions such as Chiari II malformation. Magnetic resonance spectroscopy identifies metabolites in the brain such as lactate, *N*-acetylaspartate, and choline. Conditions such as phenylketonuria, maple syrup urine disease, and Canavan disease have distinctive patterns on spectroscopy.

Indications for Various Imaging Modalities

Many studies have identified abnormalities in the brains of children with developmental delay on MRI that were not evident on CT. These abnormalities include delayed myelination, focal lesions, and hypoplastic white matter. In approximately 33% of children with developmental delay, the MRI is abnormal. This increases if the child has microcephaly or associated neurologic findings such as focal motor deficits, seizures, or a pattern of regression/degeneration. Neuroimaging in

children with GDD may reveal evidence of cerebral injury, brain malformation, or markers of cerebral dysgenesis. Injury may be due to hypoxic-ischemic encephalopathy ("watershed" or deep gray matter lesions in term infants and periventricular leukomalacia common in premature infants) or signs of intrauterine infection. Malformations may result from disorders of ventral induction (holoprosencephaly, agenesis of the corpus callosum, septo-optic dysplasia), migrational abnormalities (lissencephaly, schizencephaly, pachygyria, polymicrogyria, band heterotopias), and aberrant white matter development (demyelinating/dismyelinating syndromes). At times, neuroimaging may provide information about the possible timing of the event (whether injury or dysgenesis). Serial imaging studies may help to distinguish a static from a progressive course and aid in prognosis. However, in many instances, abnormal findings may not be sufficient for determining the specific underlying cause of the disability. Furthermore, there may be a very weak correlation between neuroimaging findings and the child's clinical picture. As an unintended consequence, neuroimaging studies may reveal incidental findings that are unrelated to the child's developmental delay, for example, nonspecific findings such as mild ventriculomegaly and enlargement of the subarachnoid spaces, or patchy areas of white matter gliosis of uncertain origin (Table 24.21). In many instances, these are benign variations of normal or clinically insignificant anomalies. In some cases, these findings may require consultation with a pediatric neurosurgeon, but it is important to avoid unnecessary additional tests or interventions whenever possible.

Other Tests

Most neurometabolic disorders can be identified through serum, plasma, and urine tests in conjunction with neuroradiologic investigations. However, other tests can be helpful for identifying specific diseases. Analysis of cerebrospinal fluid for elevated protein levels may help in the diagnosis of a disease affecting white matter; the presence of measles antibody can help identify subacute sclerosing panencephalitis. On occasion, cerebrospinal fluid evaluation of lactate, pyruvate, and amino acids may be helpful. Peripheral nerve conduction tests and electromyography may help confirm that the condition is associated with peripheral neuropathy. Diminished deep tendon reflexes and prolonged nerve conduction times are noted in Krabbe disease, Refsum disease, metachromatic leukodystrophy, and infantile neuroaxonal dystrophy (see Chapter 29).

Skin and muscle biopsies may identify conditions in which abnormal material is stored in cells, such as neuronal ceroid lipofuscinosis. Brainstem auditory evoked response is useful as an evaluation of hearing in infants and is used to evaluate brainstem functioning. Visual evoked response can be useful in determining the integrity of the visual pathways; however, it cannot determine visual acuity.

Discussing a Developmental Diagnosis with Parents

When a specific developmental diagnosis is established, it should be shared with the family in an objective but sensitive manner. Facts about the condition and prognostic information should be presented with an explanation of the margin of uncertainty around any disorder. Each child is unique; therefore, making a prognosis for an individual child solely based on data is risky. When appropriate, parents should be reassured that they did not do anything to cause the child's disease, since feelings of guilt in this situation are universal. All parents want some measure of hope and assurance that they will have help from competent professionals who will care for their child.

When the child is an infant or toddler, a frank discussion about the child's profile of developmental strengths and weaknesses relating skills to a "developmental age" may help parents to align their expectations to the child's functional abilities. All parents want to help their child grow and develop to his or her potential, and the clinician should make a plan for follow-up to evaluate the child's progress. For children under age 3 years, follow-up in 6 months will provide a time frame in which significant change can be observed. For older children, yearly intervals are appropriate.

SPECIFIC CONDITIONS

Cerebral Palsy

Cerebral palsy (CP) is the leading cause of motor disability in children. CP is a clinical diagnosis characterized by significant impairment of movement and posture that begins in infancy or early childhood. Worldwide, CP affects 1-5 in every 1000 live births. The cause is often brain dysgenesis or injury (prenatal or perinatal from hypoxic-ischemic encephalopathy, intraventricular hemorrhage, or periventricular leukomalacia). There is an inverse relationship between birthweight and CP, ranging from 51-73/1000 in very low birthweight (<1500 g) neonatal survivors to 1-2/1000 in normal birthweight (>2500 g) infants. The effects of improvements in neonatal intensive care have both increased the survival of low birthweight and premature infants, and have decreased the incidence of CP among survivors. However, more than half of children diagnosed with CP were born at term or near term, and there has not been a decrease in CP prevalence over time. In a large population-based study in Western Australia, approximately 76% of children with CP were born at term after an uncomplicated perinatal course without evidence of neonatal encephalopathy. A recent study identified clinically significant CNV in 31% of children with no obvious etiology (so-called "cryptogenic" CP). Thus, the etiology of CP appears to be multifactorial with a largely prenatal onset including genetic, environmental, inflammatory, and infectious influences on fetal development.

TABLE 24.21 Types of Abnormalities Identified by Neuroimaging

- Malformations of Cortical Development:
  - Midline defects: holoprosencephaly; callosal agenesis; cerebellar hypoplasia
  - Migration defects: lissencephaly; bands; schizencephaly; pachygyria/microgyria
  - Hydrocephalus, hemimegalencephaly
  - Neurocutaneous syndromes: tuberous sclerosis; neurofibromatosis
  - Trauma: hypoxic-ischemic encephalopathy; stroke
- Metabolic and Neurodegenerative Disorders:
  - Cortical gray matter: lysosomal enzyme defects (lipidoses: GM_1 gangliosidosis, neuronal ceroid lipofuscinosis) and mucolipidoses
  - Corpus striatum (caudate and putamen): mitochondrial disorders, organic acidopathies, aminoacidopathies, Wilson disease, juvenile Huntington disease
  - Globus pallidus: Hallervorden-Spatz disease, methylmalonic acidemia, hyperbilirubinemia
  - White matter (leukoencephalopathies): peroxisomal disorders (adrenoleukodystrophies), lysosomal leukodystrophies (metachromatic, globoid cell); other white matter diseases (Pelizaeus-Merzbacher, Canavan, Alexander, Cockayne)
- Congenital infection: cytomegalovirus; human immunodeficiency virus; toxoplasmosis
- Neoplastic disorders

(See *Nelson Textbook of Pediatrics,* p. 2896.)

Although the underlying pathology is nonprogressive, the clinical manifestations may change over time. For example, an infant with CP may initially present as hypotonic but then develop spasticity, and functional disability may increase if joint contractures or scoliosis develops. CP is associated with a wide range of other disabilities, including sensory impairment (hearing and vision), dysphagia, epilepsy, and ID (40-65%).

Some IEM present with features of CP ("CP mimics") and are amenable to treatment that can improve the neurologic outcome. A number of symptoms should raise the "index of suspicion" that an IEM may be responsible for the clinical picture of CP:

- Severe symptoms in the absence of a history of perinatal injury
- Normal brain MRI findings
- Abnormalities isolated to the globus pallidus
- Neurodevelopmental regression or progressively worsening symptomatology
- Isolated muscular hypotonia
- Rigidity as opposed to spasticity
- Paraplegia
- A pattern of disease inheritance or consanguinity

Autism Spectrum Disorder

Individuals with ASD have pervasive impairments in reciprocal social communication and social interactions, and circumscribed interests and repetitive patterns of behavior and activities that limit or impair their daily functioning. The disorder is present from early childhood, although approximately 25-30% of children with ASD experience a regression of skills, often between the ages of 15 and 24 months. Regression may be gradual or rapid, and usually encompasses the loss of communication (words and gestures) and social skills (eye contact). However, the regression does not appear to be progressive, and most children "plateau" at this regressed state (Table 24.22). The prevalence of ASD among children aged 8 years is 1:68, with a male-to-female ratio of 4.5:1. ASD is a neurodevelopmental disorder with multifactorial etiology, with genetic factors playing a significant role. It occurs with high frequency in a number of known genetic disorders (Down syndrome, Fra X syndrome, tuberous sclerosis, Rett syndrome, Angelman syndrome). Hereditary factors also play a role, since ASD also has an elevated recurrence rate within certain families. Other biologic risk factors for ASD include children born to older parents and children born prematurely or with low birthweight.

Fragile X Syndrome

FRAXA syndrome is the most commonly diagnosed genetic cause of ID in males. It affects 1 in 4000 males and 1 in 8000 females. FRAXA syndrome is found in all racial and ethnic groups. The disorder is the result of an inheritable unstable DNA in the *FMR1* gene of the X chromosome. Normal individuals may have less than 40 triplet repeats. Females with between 55 and 200 repeats are said to have *FMR1* premutation, since the number of repeats is likely to expand in cells that become eggs. Males with greater than 200 repeats are clinically symptomatic and will likely have a moderate degree of ID. In addition, speech and language delays, attention difficulty, anxiety disorder, and autism are associated with FRAXA syndrome. Full-mutation females may have a mild degree of ID. Because characteristic physical symptoms of FRAXA are difficult to identify in infants and young children, routine molecular testing for the *FMR1* gene may identify 2-6% of males and 2-4% of females with nonspecific ID. In older children and adults, characteristic physical features and a distinct "behavioral phenotype" may suggest a diagnosis of FRAXA syndrome (Table 24.23).

TABLE 24.22 Autism Spectrum Disorder

Diagnostic Criteria

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive):

1. Deficits in social-emotional reciprocity, ranging, for example, from an abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity: Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least 2 of the following, currently or by history (examples are illustrative, not exhaustive):

1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take the same route or eat the same food every day).
3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity: Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for the general developmental level.

(See *Nelson Textbook of Pediatrics,* p. 176.)

TABLE 24.23	Scoring System for Screening Individuals for Fragile X Syndrome*		
Category	**Score**	**Criteria**
Family history	2	Retarded sibling, maternal uncle, aunt, nephew, niece, 1st cousin
	1	Any other affected relative
	0	No family history of retardation
Personality	2	Shyness, lack of eye contact followed by friendliness, verbosity, and echolalia
	1	Some of these characteristics
	0	No characteristic
Ears	2	Large and protruding
	1	Large, not protruding
	0	Other
Face	2	Long jaw, high and wide forehead
	1	Only 1 finding
	0	No findings
Body habitus	2	Slim, tall, rounded shoulders, hyperextensible fingers, lack of body hair, **or** obese with female fat distribution, striae, soft skin, lack of body hair (in boys and men)
	2	Slim **or** obese (girls and women)
	1	Only some features
	0	No features

*A score of 5 or greater has a sensitivity of 0.88 and specificity of 0.98 in comparison with chromosome analysis.

Inborn Errors of Metabolism and Storage Diseases

IEM may manifest as an acute encephalopathy (from an organic acidemia or hyperammonemia) or as a chronic progressive encephalopathy (cardiomyopathy, spasticity, hyperreflexia, liver dysfunction), often as a result of mitochondrial disorders or storage diseases (see Table 24.19).

- *Sphingolipidoses* (Tay-Sachs disease, Niemann-Pick disease, GM_1 gangliosidosis) are associated with a cherry-red retinal spot, organomegaly, and ID.
- *Glycoprotein degradation disorders* (e.g., mannosidosis, fucosidosis) may variably manifest with coarse facies, ID, hepatosplenomegaly, and vacuolated lymphocytes.
- *Mucopolysaccharidoses* (e.g., the Hurler, Hunter, and Sanfilippo syndromes) may manifest with coarse facies, ID, hepatosplenomegaly, dysostosis multiplex, and corneal clouding.
- *Neuronal ceroid lipofuscinosis* may manifest with ID, vision loss, ataxia, and myoclonic seizures.
- *Peroxisomal disorders* (Zellweger syndrome, X-linked adrenoleukodystrophy, Refsum disease) variably manifest with ID, encephalopathy, seizures, blindness, dysmorphic features, and deafness.

IEM should also be suspected in children with acute neurologic abnormalities in whom there is unexplained vomiting, an unusual smell to the urine or body odor, acidosis, or renal stones.

Congenital Infections

Bacteria, parasites, or viruses acquired before, during, or after birth may cause CNS infection and injury. The diagnosis is based on the clinical manifestations (Table 24.24) and culture or serologic evidence of infection (Table 24.25).

Postnatal Infections

CNS infection during infancy or childhood may cause encephalitis or meningoencephalitis with resultant ID. Bacterial (pneumococcus, *Mycobacterium tuberculosis*, meningococcus) and viral (herpes simplex type 1 or 2, eastern or western equine encephalitis virus, West Nile virus, St. Louis encephalitis virus, HIV; in rare cases, mumps, enteroviruses, or California encephalitis virus) cases occur in infancy and early childhood and variably have neurodevelopmental sequelae. Secondary problems caused by the infection such as hearing or visual loss must also be considered. Late sequelae or prior viral infection such as measles or rubella panencephalitis may appear 10-20 years after the initial CNS disease and manifest as dementia, poor school performance, and progressive encephalopathy.

TREATMENT

The treatment of a child with a developmental or intellectual disability includes routine health maintenance, treatment of the underlying condition (if possible), treatment of associated conditions (such as hyperactivity, seizures, or drooling), relief of symptoms, anticipatory guidance to prevent secondary conditions, and environmental, educational, and family support. The overriding goal is to optimize the functional status and prognosis of the child.

Health maintenance for children with developmental disabilities should be the same as that provided for all children, including immunizations, regular monitoring of physical growth and development, and screening for conditions such as anemia, tuberculosis, and lead intoxication. Use of standardized growth charts will reflect the child's individual pattern over time. Specific growth charts are available for some conditions, including Down syndrome, Prader-Willi syndrome, and FRAXA syndrome. Nutritional recommendations are available for children with CP.

Very few conditions (see Table 24.20) that lead to developmental delay can be "cured." However, medical treatment of associated conditions can help reduce pain and discomfort. For example, many children with CP have drooling and spasticity. Drooling can be controlled by the use of glycopyrrolate, scopolamine patch, or surgery to the salivary glands. Spasticity can be managed with oral baclofen, periodic injections of botulinum toxin, tizanidine, or dorsal root rhizotomy. Behavioral or psychiatric problems may benefit from counseling, support, or psychopharmacologic medications. These medications can be used to reduce arousal symptoms and to improve affect, perceptual functioning, cognitive processing, communication, and behavior (Table 24.26). Attention must be paid to the use of medications in specific conditions. For example, valproic acid is more likely to cause hepatotoxicity in GM_2 gangliosidosis, spinocerebellar degeneration, Friedreich ataxia, Lafora body disease, Alpers disease, and myoclonic epilepsy with ragged red fibers. Parents and capable children should be informed about the medication prescribed, including side effects. Some written guidelines for parents and youth are available for psychopharmacologic medications.

Anticipatory guidance for parents of children with developmental disabilities involves the same categories used in all children but may be modified because of the unique features of the child's condition. For example, parents of children with CP should be aware of the possibility that their child may be at risk for poor weight gain and aspiration pneumonia because of oral-motor dysphagia, for strabismus, spinal scoliosis and deformities (contractures) of the foot, knee, and hip because of muscle spasticity, osteoporosis, decubitus ulcers, epilepsy, and learning difficulties.

Although there are many different causes, children with developmental disabilities and their families share many common characteristics, including chronicity of the condition (with no cure in most instances); inability to participate in peer activities; parental feelings of guilt and loss of the "ideal" child; increased expense to care for a

TABLE 24.24	**Distinguishing Features of Perinatal Congenital Infections**	
Agent	**Maternal Epidemiology**	**Neonatal Features**
Toxoplasma gondii	Heterophile-negative mononucleosis Exposure to cats or raw meat or immunosuppression High-risk exposure at 10-24 wk gestation	Hydrocephalus, abnormal spinal fluid, intracranial calcifications, chorioretinitis, jaundice, hepatosplenomegaly, fever, ID if symptomatic Many infants asymptomatic at birth Treatment: pyrimethamine plus sulfadiazine
Rubella virus	Unimmunized seronegative mother; fever ± rash Detectable defects with infection: by 8 wk, 85% 9-12 wk, 50% 13-20 wk, 16% Virus may be present in the infant's throat for 1 yr Prevention: vaccine	Intrauterine growth restriction, microcephaly, microphthalmia, cataracts, glaucoma, "salt-and-pepper" chorioretinitis, hepatosplenomegaly, jaundice, PDA, deafness, blueberry muffin rash, anemia, thrombocytopenia, leukopenia, metaphyseal lucencies, B- and T-cell deficiency, ID Infant may be asymptomatic at birth
Cytomegalovirus (CMV)	Primary infection may be asymptomatic Heterophile-negative mononucleosis; infant may have viruria for 1-6 yr	Sepsis, intrauterine growth restriction, chorioretinitis, microcephaly, periventricular calcifications, blueberry muffin rash, anemia, thrombocytopenia, neutropenia, hepatosplenomegaly, jaundice, deafness, pneumonia Many asymptomatic at birth, ID if symptomatic Prevention: CMV-negative blood products
Herpes simplex type 2 virus	STD; primary genital infection may be asymptomatic; intrauterine infection rare, acquisition at time of birth more common	Intrauterine infection: chorioretinitis, skin lesions, microcephaly, ID Postnatal infection: encephalitis, localized or disseminated disease, skin vesicles, keratoconjunctivitis, ID if CNS infection Treatment: acyclovir
Varicella-zoster virus	Intrauterine infection with chickenpox during 1st trimester Infant develops severe neonatal varicella when maternal illness occurs 5 days before or 2 days after delivery	Microphthalmia, cataracts, chorioretinitis, cutaneous and bone aplasia/hypoplasia/atrophy, cutaneous scars, ID Zoster as in an older child Prevention of neonatal condition: VZIG Treatment of ill neonate: acyclovir
Treponema pallidum (syphilis)	STD Maternal primary asymptomatic: painless "hidden" chancre Penicillin, not erythromycin, prevents fetal infection	Presentation at birth as nonimmune hydrops, prematurity, anemia, neutropenia, thrombocytopenia, pneumonia, hepatosplenomegaly Late neonatal presentation as snuffles (rhinitis), rash, hepatosplenomegaly, condylomata lata, metaphysitis, cerebrospinal fluid pleocytosis, keratitis, periosteal new bone, lymphocytosis, hepatitis; ID possible Late-onset abnormalities: teeth, eye, bone, skin, CNS, ear Treatment: penicillin
Parvovirus B19	Etiology of 5th disease; fever, rash, arthralgia in adults	Nonimmune hydrops, fetal anemia Treatment: in utero transfusion
Human immunodeficiency virus (HIV)	AIDS: most mothers are asymptomatic and HIV-positive; high-risk history: prostitute, drug abuse, sexual partner of bisexual person, or hemophiliac	AIDS symptoms develop between 3-6 mo of age in 25-40%; failure to thrive, recurrent infection, hepatosplenomegaly, neurologic abnormalities, ID Management: IVIG, trimethoprim-sulfamethoxazole, antiretroviral therapy Prevention: maternal and infant antiretroviral therapy
Hepatitis B virus	Vertical transmission common; may result in cirrhosis, hepatocellular carcinoma	Acute neonatal hepatitis; many become asymptomatic carriers Prevention: HBIG, vaccine
Borrelia burgdorferi	Lyme disease, erythema chronicum migrans, meningitis, arthritis, carditis	Prematurity, rash, cortical blindness, fetal death?

TABLE 24.24	Distinguishing Features of Perinatal Congenital Infections—cont'd	
Agent	**Maternal Epidemiology**	**Neonatal Features**
Neisseria gonorrhoeae	STD, infant acquires at birth Treatment: cefotaxime, ceftriaxone	Gonococcal ophthalmia, sepsis, meningitis Prevention: silver nitrate, erythromycin eye drops Treatment: intravenous ceftriaxone
Chlamydia trachomatis	STD, infant acquires at birth Treatment: oral erythromycin	Conjunctivitis, pneumonia Prevention: erythromycin eye drops Treatment: oral erythromycin
Mycobacterium tuberculosis	Positive PPD skin test, recent converter, positive chest roentgenogram, positive family member Treatment: INH and rifampin ± ethambutol	Congenital rare septic pneumonia; acquired primary pulmonary TB; ID if CNS symptoms; if asymptomatic, follow PPD Prevention: INH, BCG, separation Treatment: INH, rifampin, pyrazinamide
Trypanosoma cruzi (Chagas disease)	Central South American native, immigrant, travel Chronic disease in mother	Failure to thrive, heart failure, achalasia Treatment: nifurtimox

AIDS, acquired immunodeficiency syndrome; BCG, bacillus Calmette-Guérin; CNS, central nervous system; HBIG, hepatitis B immune globulin; ID, intellectual disability; INH, isoniazid; IVIG, intravenous immunoglobulin; PDA, patent ductus arteriosus; PPD, purified protein derivative; STD, sexually transmitted disease; TB, tuberculosis; VZIG, varicella-zoster immune globulin.

TABLE 24.25 Diagnosis of Congenital Infections

Serologic Findings

Syphilis: nontreponemal (VDRL) or treponemal (FTA-ABS)
Toxoplasmosis: ELISA, Sabin-Feldman dye test
Rubella: latex agglutination, enzyme immunoassay
Cytomegalovirus: ELISA
Herpes simplex viruses: several methods
Varicella-zoster virus: fluorescent antimembrane antibody
Lyme disease: ELISA
Human parvovirus B19: ELISA or RIA
Arboviruses: antibody capture ELISA (blood or CSF)

Serologic Studies Should Include

An acute sample from the infant for agent-specific IgM and IgG
A convalescent sample from the infant for agent-specific antibodies
A maternal sample for agent-specific IgG

Virologic Findings (Culture and PCR)

Cytomegalovirus: urine, saliva, blood leukocytes, occasionally CSF
Rubella virus: urine, nasopharyngeal secretions
Herpes simplex viruses: skin lesions, throat, rectum, CSF, blood
Varicella-zoster virus: skin lesions
Enteroviruses: CSF, throat, stool, blood
Arboviruses: blood, CSF
When the agent is unknown, samples should include urine, throat washing, CSF, blood, rectal swab, and fluid from skin vesicles, if present.

CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; FTA-ABS, fluorescent treponemal antibody absorption; IgG, immunoglobulin G; IgM, immunoglobulin M; PCR, polymerase chain reaction; RIA, radio-immunoassay; VDRL, Venereal Disease Research Laboratory.

TABLE 24.26 Psychopharmacologic Agents That May Be Useful in the Treatment of Children with Developmental Disabilities

Medication	Possible Indications
Carbamazepine	Mania, bipolar disorder, impulsivity, aggression, seizures, trigeminal neuralgia
Clomipramine	Obsessive-compulsive disorder, depression
Clonazepam	Mania, bipolar disorder, seizure
Clonidine, guanfacine	Manic episodes, attention-deficit/hyperactivity disorder, aggression
Sertraline, other SSRIs, risperidone, olanzapine, aripiprazole	Obsessive-compulsive disorder, depression, anxiety Aggressive, self-injurious behavior
Methylphenidate	Attention-deficit/hyperactivity disorder: dextroamphetamine Aggression, impulsivity
Valproic acid	Bipolar disorder, especially rapidly cycling

SSRIs, selective serotonin reuptake inhibitors.

disabled child; lost economic opportunities (such as the inability of a parent to return to work because he or she must care for the child at home); need for personal care (because the child cannot be left alone or with a sitter); confusing systems of health care, insurance coverage, and governmental agencies and rules; and social isolation.

Environmental support may be needed and may take the form of family therapy, financial counseling, and referral to a disease-oriented volunteer support group or in a "Big Brothers/Big Sisters" program. Formal support includes early intervention for children from birth to 3 years of age, preschool intervention through the school district for children 3-5 years of age, and special education services provided under the Individuals with Disabilities Education Act (IDEA) and Section 504 of the Rehabilitation Act for school-age children. Families may also need assistance in transitioning their adolescent child from

TABLE 24.27 Providing Primary Care to Children with Developmental Disabilities Using the Mnemonic "Md's DD BASICS"

MD's DD BASICS	Things to Check	Potential Consultant(s)
Motor	Ambulation, seating, position, spine	Orthopedist, physiatrist, PT, OT
Diet	Weight, fat stores, diet, feeding problems	Nutritionist/dietitian, speech pathologist, OT
Seizures	Seizure record; drug levels and side effects	Neurologist
Dermatology	Skin breakdown	Nursing, plastic surgeon
Dentistry	Teeth, gums	Dentist
Behavior	Aggression, self-injury, sleep, pica, interfering behavior	Psychologist, psychiatrist
Advocacy	Finances, family support, program aid	Social worker
Sensory	Vision, hearing	Ophthalmologist, audiologist
Infections	Immunizations, environment, lungs, urine	Infection control nurse
Constipation	Stools, gastroesophageal reflux	Gastroenterologist
Sexuality	Menses, sexual activity, masturbation, contraception, prevention of sexually transmitted diseases	Gynecologist, habilitation program

OT, occupational therapist; PT, physical therapist.
Modified from Sulkes S. MD's DD BASICS: identifying common problems and preventing secondary disabilities. *Pediatr Ann.* 1995;24:245-254.

TABLE 24.28 Medical Checklist for a Child with Down Syndrome

Age	Condition	Monitoring
Birth to 2 mo	Etiology, recurrence risk	Chromosome analysis and genetic counseling
	Hypothyroidism	TSH, T_3, and T_4
	Congenital heart defect	Pediatric cardiology evaluation, including echocardiography
	Family stress	Referral to Down Syndrome Association
2-12 mo	Refractive errors, cataracts	Pediatric ophthalmologic evaluation
	Hearing loss; recurrent otitis media	Auditory brainstem evoked response
	Delayed development	Formal developmental evaluations
1-12 yr	Delayed development	Enrollment in early intervention program
	Hypothyroidism	Annual TSH
	Hearing loss	Auditory testing: annually between 1 and 3 yr and every 2 yr between 3 and 13 yr
	Refractive error	Ophthalmologic examination every 2 yr
	Atlantoaxial instability	Cervical spine roentgenography at 2 and 12 yr
	Routine care	Dental examination at 2 yr, then every 6 mo (prophylaxis for subacute bacterial endocarditis, if indicated)
12-18 yr	Hypothyroidism	TSH annually
	Decreased hearing	Auditory testing every 2 yr
	Refractive error	Ophthalmologic examination every 2 yr
	Mitral valve prolapse	Echocardiography

T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid-stimulating hormone.

school to a work or independent living situation. At each stage in the child's life, the clinician should review the services the child is receiving and determine whether the family might benefit from additional support. The mnemonic "MD's DD BASICS" provides a list of content areas for review at each visit (Table 24.27). Checklists to monitor the care of children with specific problems such as Down syndrome are also available, often through the AAP (Table 24.28).

Complementary and Alternative Therapies

Because conventional medical care cannot cure many conditions associated with developmental disability, a wide range of "complementary and alternative medications" (CAM) and therapies have arisen. The rate of CAM use by children with special health care needs is ~30-70%. CAM may include biochemical therapies (herbal remedies, vitamin and mineral supplements), nutritional supplements, biomechanical therapies (massage, chiropractic), bioenergetic therapies (acupuncture, homeopathy), and lifestyle/mind-body therapies including dietary manipulations (Feingold diet, sugar elimination diet), relaxation training, and biofeedback. In some instances, CAM may include potentially toxic treatments (antifungal medications, chelation, vitamin B_{12} injections). In most instances, families use CAM to supplement conventional services and treatments. While the research basis for the effectiveness or harm of CAM is limited, it is also true that the literature addressing the appropriate and effective use of "mainstream" pharmacologic agents to treat children with developmental disabilities

is also quite limited. Clinicians should ask about all therapies the family is using to help the child. Unless there are identified health risks, clinicians should refrain from disparaging the use of CAM. Acknowledging and discussing the use of CAM is not the same as recommending or prescribing them. It is better to know what treatments and services a child is receiving and to factor them into an overall plan of care than to be unaware of what the family is doing for their child. The clinician should keep an "open mind" about CAM, but maintain a focus on the safety and efficacy of all treatments for children with developmental disabilities.

PITFALLS AND HAZARDS IN DEVELOPMENTAL DIAGNOSIS

The identification of "risk factors" does not imply a specific etiology or diagnosis. It is important to avoid a logical fallacy (post hoc attribution) and not base a diagnosis on a specific cause unless there is positive evidence to confirm that cause. For example, a history of a low 5-minute Apgar score with no other symptoms of neonatal encephalopathy is not likely to be the cause of a child's subsequent developmental disability.

Dysmorphic and physically disabled children are often assumed to have GDD/ID, and conversely, children with normal facial appearance and motor skills may not be identified early as having GDD/ID. Cognitive development is usually unaffected in a number of striking dysmorphic syndromes (e.g., Treacher Collins syndrome, achondroplasia).

Identifying a child as being "at risk" for developmental delay may alter the family's perceptions, making the child vulnerable. This might lead to constraints on the child's experiences and diminished expectations of performance. When a child is born with a single risk factor, such as prematurity, the parents may be afraid to place demands on the child, creating a vicious cycle of "learned helplessness" and immature behaviors.

Parents of children who are informed that their child is not normal often grieve for their "lost" (typically developing) child. This process of grieving involves stages that include denial, sadness, anger, and guilt. One parent may be experiencing persistent anger while another is still sad or depressed. This difference in stages may make communication between them exceedingly difficult. Grieving may occur at times other than the initial diagnosis, for example, on the 1st day of kindergarten. These feelings may be expressed in nonfunctional ways, such as denial that leads to unending shopping for professionals who will "cure" the child or anger that is expressed at the clinician, thereby thwarting efforts at building a trusting and supportive relationship. However, many authorities believe that these emotions are essential steps that allow the parents to release the old dreams and secure new ones. The goal of the therapeutic clinician is to accept the parents at whatever stage they are in and to help them understand the normalcy of the stages.

SUMMARY AND RED FLAGS

Developmental disabilities are common. Identifying children with developmental delay involves both specific attention to children with biologic and/or sociocultural risks and routine developmental surveillance and screening during well child visits. All children with suspected developmental delay should receive a formal multidisciplinary assessment that includes a systematic diagnostic approach with a "tiered" strategy for laboratory and neuroimaging evaluations. Developmental regression, vomiting, seizures, or lethargy suggests the presence of a potentially life-threatening metabolic disorder. Parents need to understand that it is not always possible to identify a single defined disease process responsible for their child's developmental disability. Even if a specific etiology is not found, comprehensive clinical assessments can identify the child's profile of strengths and weaknesses. Children with developmental disabilities will require meticulous monitoring over time and coordination of care to optimize their functional status. All children with developmental disabilities will benefit from early intervention, therapeutic, and special education services to help maximize their developmental potential and to promote independence and personal autonomy.

Red flags include developmental regression (see Tables 24.14 and 24.15), developmental delay associated with vomiting or lethargy (see Table 24.19), and recognition of a treatable cause of delay or CP (see Table 24.20).

Dysmorphology

Donald Basel

Dysmorphology evolved as a subset of clinical genetics that focused on standardizing the descriptive terminology used to define deviations from normal structural development in the context of syndromic disorders. These traits were termed *birth defects* and result from malformations, deformations, or disruptions, which generally have a significant and obvious effect on appearance (Table 25.1 and Fig. 25.1). To identify the abnormal state, one has to be familiar with normal developmental stages, the timing of specific organ development, and developmental vulnerable periods (Fig. 25.2). The dysmorphic physical examination is directed to overcome some of the clinical challenges of identifying and describing birth defects by providing a framework in which to differentiate normal human variable morphology from the abnormal in the context of a specific diagnosis.

An international initiative to standardize the nosology used in clinical dysmorphology has been adapted to the Internet as an online resource supported by the National Human Genome Research Institute (NHGRI): https://elementsofmorphology.nih.gov/. These terms in themselves are of no clinical utility (aside from communicating the appropriate malformation to other providers) but when used with available database tools, can be a powerful adjunct to determining the final diagnosis. Examples of these terms are noted in Table 25.2. The importance of reaching a diagnosis is to provide insight into the nature of the condition, enable appropriate counseling of recurrence risk, guide the necessary management recommendations, and provide the family with an overall framework of the natural history and prognosis of the disorder.

DIAGNOSTIC APPROACHES

Often the geneticist-dysmorphologist is asked to view a child with the expectation that the total picture will lead to an instant identification of a syndrome or condition. Instant identification happens more frequently with the more common or better known conditions. Most often a diagnosis is difficult with many complex disorders; knowledge, skill, attention to detail, the use of the current tools, review of literature, and standard reference sources are required for diagnosis.

Human Variation

Normal human variation is enormous. A common sense argument can be made for variation by pointing out the ability of people to recognize and differentiate thousands of individuals whom they have met; computer programs for facial recognition are based on this premise. Nonetheless, humans differ little from one another at their DNA level; variation is currently estimated at approximately 0.1% or 1 base of DNA/1000 bases, which equates to roughly 6 coding variants/gene. The advent of molecular and biochemical diagnostic methods for identifying genes and gene products has begun to ease the burden on the geneticist by providing diagnostic and confirmatory tests for syndrome identification. Sequencing of the Human Genome clarified many prior preconceived notions regarding human genetics. Prior to the completion of the project, it was estimated that humans had approximately 100,000 genes, whereas in reality this number is closer to 23,000 genes. Of these genes, less than half have been associated with human disease and many have no clear function assigned to them at this time. This gene coding portion of the genome only accounts for approximately 1% of the total genomic code, which consists of roughly 6 billion nucleotides. DNA analysis when available may provide the genotype and confirm the diagnosis, but it cannot unerringly define the phenotype.

There is still much to learn about our genetic code and how genes are expressed and regulated; even if we could perform genomic sequencing on every patient, there would be a number of patients in whom the molecular diagnosis remained elusive. The current diagnostic rate for exome sequencing is approximately 25%, this improves to about 30% with exome trios in which selected relatives are sequenced along with the affected individual and used to assess allele segregation with the phenotype.

There are common genetic pathways that relate genes within a pathway to common groups of disorders. This has provided an explanation to clinicians why seemingly disparate disorders share certain disease associations but remain clinically distinct. An example of this is the **RASopathies** (Fig. 25.3), in which *germline* pathogenic variants in *KRAS* can result in the classic Noonan phenotype or cardiofaciocutaneous syndrome. There is genetic heterogeneity in this group of disorders which share several overlapping features. In addition, *somatic* mosaicism for genes in this pathway has been identified to cause several capillary/vascular malformation disorders. Another example is the allelic disorders involving the *TRPV4* gene, which include brachyolmia type 3, digital arthropathy–brachydactyly, hereditary motor and sensory neuropathy type IIc, metatropic dysplasia, parastremmatic dwarfism, scapuloperoneal spinal muscular atrophy, spondyloepiphyseal dysplasia Maroteaux type, spinal muscular atrophy, and spondylometaphyseal dysplasia Kozlowski type. The wide phenotypic variability ranging from primary skeletal dysplasias to isolated neuromuscular disease speaks to the complexities of gene regulation and tissue-specific expression.

In addition to the primary gene code, there are tertiary elements that can be *imprinted*, in which gene expression is controlled by parent of origin or even be affected by the environment, the concept of **epigenetic** control. Further variability exists in genomic **copy number variations**, some of which are considered normal variants, while others result in recognizable microdeletion or microduplication disorders such as velocardiofacial syndrome (VCFS) and Smith–Magenis syndrome.

Not all congenital malformations or birth defects are primarily genetic. Teratogenic exposure, vascular events, and extrinsic factors, such as amniotic bands, all have the potential to result in deviations from normal morphologic development (Fig. 25.4).

(See *Nelson Textbook of Pediatrics,* p. 899.)

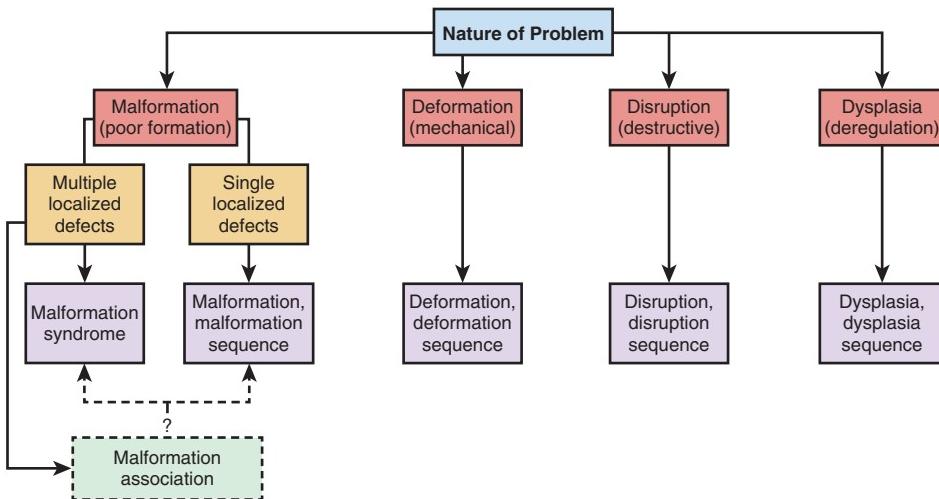
TABLE 25.1	Mechanisms, Terminology, and Definition of Dysmorphology	
Terminology	**Definition**	**Example**
Malformation sequence	Single, local tissue morphogenesis abnormality that produces a chain of subsequent defects	DiGeorge sequence of primary 4th brachial arch and 3rd and 4th pharyngeal pouch defects that lead to aplasia or hypoplasia of the thymus and parathyroid glands, aortic arch anomalies, and micrognathia
Deformation sequence	Mechanical (uterine) forces that alter structure of intrinsically normal tissue	Oligohydramnios produces deformations by in utero compression of limbs (dislocated hips, equinovarus foot deformity), crumpled ears, dislocated nose, or small thorax
Disruption sequence	In utero tissue destruction after a period of normal morphogenesis	Amnionic membrane rupture sequence, leading to amputation of fingers/toes, tissue fibrosis, and destructive tissue bands
Dysplasia sequence	Poor organization of cells into tissues or organs	Neurocutaneous melanosis sequence with poor migration of melanocyte precursor cells from the neural crest to the periphery, manifesting as melanocytic hamartomas of skin, meninges, and so forth
Malformation syndrome	Appearance of multiple malformations in unrelated tissues without an understandable unifying cause; with enhanced genetic investigation, a single etiology may become identified	Trisomy 21 Teratogens


FIGURE 25.1 Most patients with multiple structural defects will fall into one of these categories (e.g., malformation; deformation; disruption; or dysplasia). The prognosis, management, and recurrence-risk counseling may vary considerably among these categories. (From Jones KL, Jones MC, Del Campo M, eds. *Smith's Recognizable Patterns of Human Malformation.* 7th ed. Philadelphia: Elsevier; 2013:3.)

TERATOLOGY

Teratogens are agents that affect normal development and can give rise to congenital birth defects. For the most part, teratogens are considered to be chemical agents, such as thalidomide or alcohol. However, perinatal infections with cytomegalovirus would fall into this broad category as would significant radiation exposure. The minority of fetuses exposed to potential teratogens show effects, even if exposed at the same time with the same dose of the agent (e.g., alcohol, 30%; thalidomide, 20%; hydantoins, 10%; warfarin, 8%; lithium, 7%; and diazepam, 1%). The exact determinants why some fetuses are affected are poorly understood.

Embryologic timing is one of the critical elements that define the final outcome. There are broadly 3 periods identified in fetal development (see Fig. 25.2).

Implantation: Period of fertilization through gastrulation and formation of the embryonic plate (first 2 weeks after fertilization). Significant interference with development during this time usually results in loss of conceptus.

Embryonic: This is the period of primary tissue differentiation, and thus, the period at greatest risk for major malformations (weeks 3 through 8).

Fetal: At this time, primary organogenesis is complete, but growth and neuronal migration proceed. The central nervous system (CNS) is at risk and many of the minor birth defects arise during this time (9 weeks through birth).

Some teratogens may have delayed effects, and these do not result in an overt congenital malformation; diethylstilbestrol (DES) exposure in a female fetus can predispose to vaginal clear cell carcinoma in puberty.

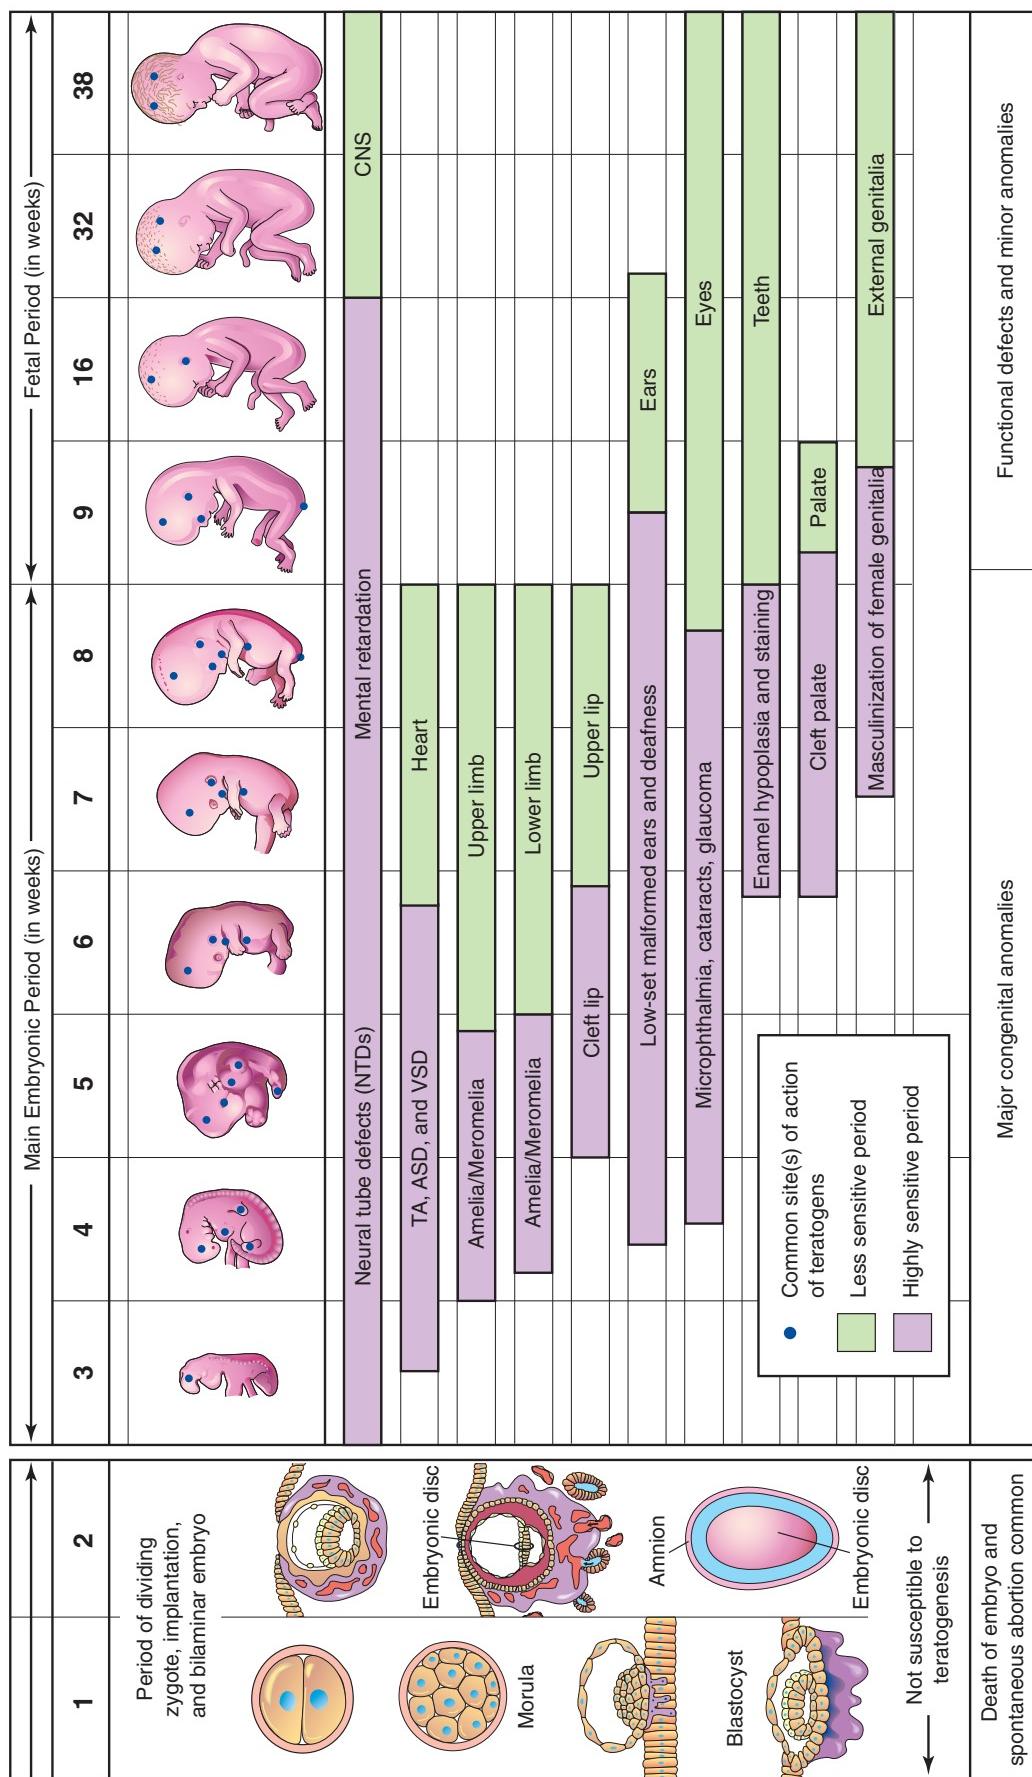
(See *Nelson Textbook of Pediatrics,* p. 814.)


FIGURE 25.2 Critical Periods in Human Prenatal Development. During the first 2 weeks of development, the embryo is usually not susceptible to teratogens; a teratogen damages all or most of the cells, resulting in death of the embryo, or damages only a few cells, allowing the conceptus to recover and the embryo to develop without birth defects. During highly sensitive periods *(mauve)*, major birth defects may be produced (e.g., amelia, absence of limbs, neural tube defects, spina bifida cystica). During stages that are less sensitive to teratogens *(green)*, minor defects may be induced (e.g., hypoplastic thumbs). ASD, atrial septal defect; CNS, central nervous system; TA, truncus arteriosus; VSD, ventricular septal defect. (From Moore KL, Persaud TVN, et al. *The Developing Human.* 10th ed. Philadelphia: Elsevier; 2016.)

TABLE 25.2   Glossary of Selected Terms Used in Dysmorphology

Terms Pertaining to the Face and Head

Brachycephaly: A condition in which head shape is shortened from front to back along the sagittal plane; the skull is rounder than normal

Canthus: The lateral or medial angle of the eye formed by the junction of the upper and lower lids

Columella: The fleshy tissue of the nose that separates the nostrils

Glabella: Bony midline prominence of the brows

Nasal alae: The lateral flaring of the nostrils

Nasolabial fold: Groove that extends from the margin of the nasal alae to the lateral aspects of the lips

Ocular hypertelorism: Increased distance between the pupils of the 2 eyes

Palpebral fissure: The shape of the eyes based on the outline of the eyelids

Philtrum: The vertical groove in the midline of the face between the nose and upper lip

Plagiocephaly: A condition in which head shape is asymmetric in the sagittal or coronal planes; can result from asymmetry in suture closure or from asymmetry of brain growth

Scaphocephaly: A condition in which the head is elongated from front to back in the sagittal plane; most normal skulls are scaphocephalic

Synophrys: Eyebrows that meet in the midline

Telecanthus: A wide space between the medial canthi

Terms Pertaining to the Extremities

Brachydactyly: A condition of having short digits

Camptodactyly: A condition in which a digit is bent or fixed in the direction of flexion (a "trigger finger"–type appearance)

Clinodactyly: A condition in which a digit is crooked and curves toward or away from adjacent digits

Hypoplastic nail: An unusually small nail on a digit

-melia: A suffix meaning "limb" (e.g., amelia—missing limb; brachymelia—short limb)

Polydactyly: The condition of having 6 or more digits on an extremity

Syndactyly: The condition of having 2 or more digits at least partially fused (can involve any degree of fusion, from webbing of skin to full bony fusion of adjacent digit)

From Behrman RE, Kliegman RM. *Nelson Essentials of Pediatrics*. 4th ed. Philadelphia: Saunders; 2002:149.

Embryogenesis

The developmental timing of the event that results in the final phenotype is one of the critical determinants of the phenotypic outcome. When considering embryologic processes, timing is one element but other important concepts are important to aid understanding of the final outcome. The timing is important because multiple developmental processes are occurring at the same time and thus a number of malformations present concomitantly as a result of interference with everything developing at the same embryonic time; radial ray defects may be seen with cardiac septal defects as in Holt–Oram syndrome. The common embryologic origin of various elements can give rise to overlapping disorders with shared elements: branchial arch developmental field defects in VCFS or disorders caused by abnormal neural crest cell migration. Critical embryologic events can give rise to disorders due to failure of a specific embryologic process: Neural tube defects arise as a result of abnormal neural tube fusion/closure.

BIRTH DEFECTS

It is estimated that approximately 15% of newborns have 1 minor anomaly; 0.8% have 2 minor anomalies, and 0.5% have 3. The more minor anomalies that are present, the greater is the probability that an underlying syndrome or a major organ anomaly is also present. Statistically, this equates to a 5-fold risk if 2 minor anomalies are present and a 20-30% probability that there is a major anomaly (congenital heart disease, renal, CNS, limb) if 3 minor anomalies are present. Approximately 50% of major anomalies involve the head and neck region. The Centers for Disease Control and Prevention statistics for the United States assert that a baby is born with a birth defect every 4.5 minutes; in 2010, birth defects accounted for about 1 in 5 infant deaths in the United States. Examples and potential etiologies are noted in Table 25.3.

Persons in the same family or ethnic groups may superficially resemble one another; any attempt at identifying a condition as an abnormality should include inspection of close relatives. *Unusual morphologic findings in a child who resembles his or her parents does not exclude a dysmorphic condition.* The parents might have variation in expression of the disorder or there could be additional features which are distinct that need to be separated from the common familial morphology.

CLINICAL CLASSIFICATION

Single-System Defects

- Most common of all birth defects
- Isolated to a single organ system
- Clinically similar to organ malformations seen in syndromes due to common pathways and same-organ end-point
- Examples: isolated cleft lip/palate; congenital heart disease; distal limb anomalies

Association

- Statistically ascertained nonrandom co-occurrences of multiple anomalies in which a single underlying cause is not identifiable. Usually, a diagnosis of exclusion.
- Creates an awareness to evaluate for associated anomalies
- <1% risk for recurrence
- Example: VATER/VACTERL (vertebral, anal atresia, cardiac, tracheoesophageal fistula, renal anomalies, limb malformations—typically radial ray) (Figs. 25.5 and 25.6)

Sequence

- A cascade of effects from a single localized abnormality in early morphogenesis that results in multiple congenital anomalies
- Example: Potter sequence secondary to renal agenesis and severe oligohydramnios (Figs. 25.7 and 25.8)

Syndrome

- The presence of multiple structural/functional defects due to a single cause.
- Example: Down syndrome caused by trisomy for chromosome 21 (Fig. 25.9) or other trisomies (Fig. 25.10 and Tables 25.4, 25.5, and 25.6)

Complex

- Denotes a malformation arising from the effects of an event affecting a single developmental field in the embryo. Typically relates to aberrant vasculature or vascular events
- Example: sacral agenesis, Poland anomaly

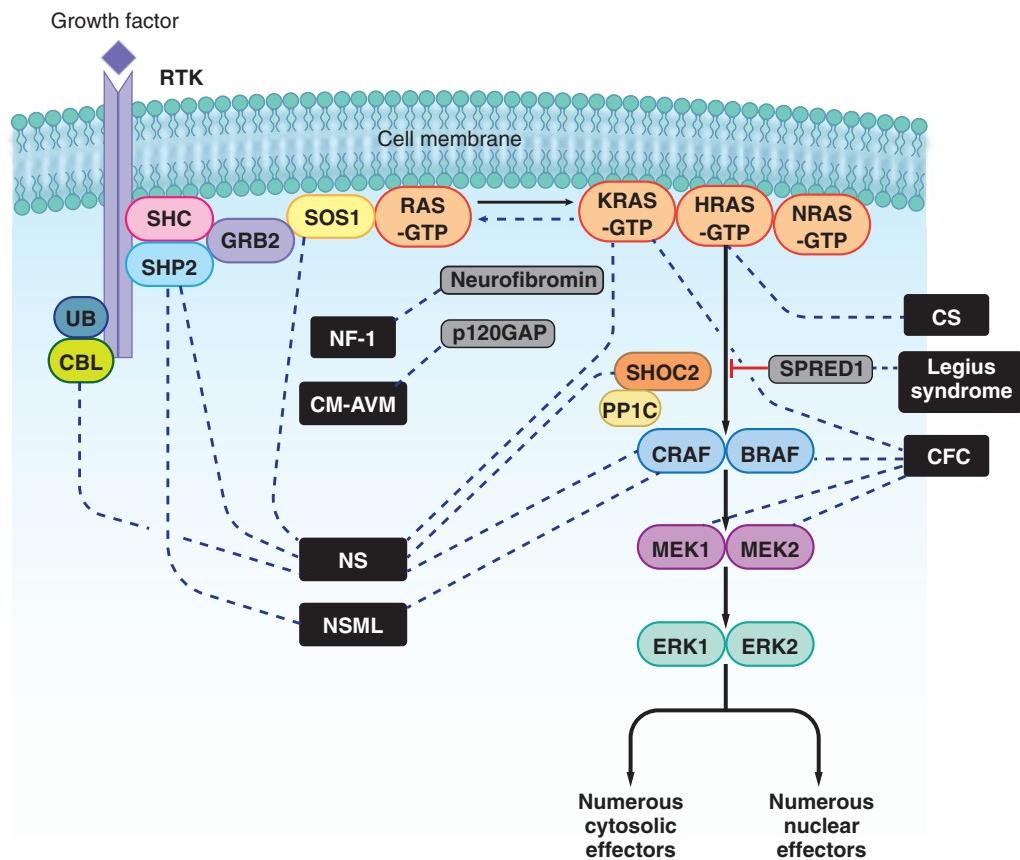
(See *Nelson Textbook of Pediatrics,* p. 899.)


FIGURE 25.3 The RAS/MAPK signal transduction pathway. The MAPK signaling pathway of protein kinases is critically involved in cellular proliferation, differentiation, motility, apoptosis, and senescence. The RASopathies are medical genetic syndromes caused by mutations in genes that encode components or regulators of the Ras/MAPK pathway (indicated by *dashed lines*). These disorders include neurofibromatosis type 1 (NF1), Noonan syndrome (NS), Noonan syndrome with multiple lentigines (NSML), capillary malformation–arteriovenous malformation syndrome (CM-AVM), Costello syndrome (CS), cardiofaciocutaneous syndrome (CFC), and Legius syndrome. RAS/MAPK, RAS protein family/mitogen-activated protein kinase. (From Rauen KA. The RASopathies. *Annu Rev Genomics Hum Genet*. 2013;14:355-369.)
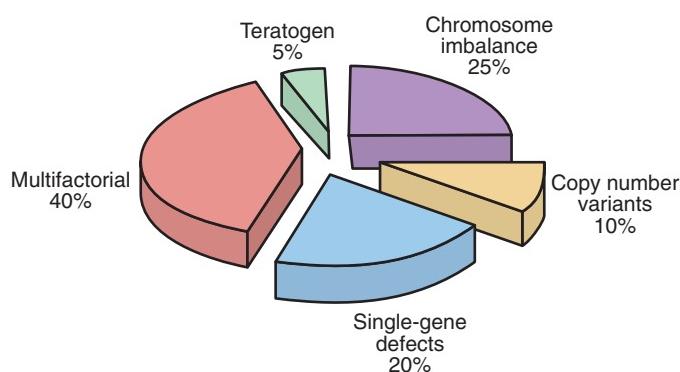

FIGURE 25.4 Causes of Congenital Malformation. (From Nussbaum RL, et al. *Thompson and Thompson Genetics in Medicine*. 8th ed. Philadelphia: Elsevier; 2016.)

DYSMORPHIC EVALUATION

The first step toward a dysmorphic evaluation is an index of suspicion. In a neonate with birth defects, this is often a logical step, but in a child with failure to thrive or short stature, someone has to initiate a more detailed evaluation for a syndromic entity or it will be delayed. It is not uncommon for a young female to be diagnosed with monosomy X (Turner syndrome) when she fails to enter puberty.

Components of Dysmorphic Evaluation
Detailed History
- A family health history (3-generation pedigree analysis) (Figs. 25.11 and 25.12) (about 5% of children have a biologic father who is not the reported partner)
- Pregnancy history with detail to exposures (teratogens) and general health (gestational diabetes)
- Birth history and neonatal status
- Participation in state newborn screening
- General growth and developmental history; *regression is very important to document*
- Complete medical history, including details of the minutiae of symptom presentation and progression

Some sensitivity surrounding the history taking should be exercised as it is common for a parent to perceive responsibility for the outcomes. Most birth defects occur sporadically without a family history. Autosomal recessive disorders typically happen in 1 or more siblings without a family history; many autosomal dominant conditions occur as new mutations. Sex-linked conditions may have no prior family occurrence or an occurrence identified in a remote relative such as the maternal grandmother's brother.

TABLE 25.3 **Causes of Congenital Malformations**	
Monogenic (7.5% of Serious Anomalies) X-linked hydrocephalus Achondroplasia Ectodermal dysplasia Apert disease Treacher Collins syndrome	Mercury Alcohol **Medications (% Unknown)** Thalidomide Diethylstilbestrol Phenytoin Warfarin Cytotoxic drugs Isotretinoin (vitamin A) D-Penicillamine Valproic acid
Chromosomal (6% of Serious Anomalies) Trisomies 21, 18, 13 XO, XXY Deletions 4p– 5p–, 7q–, 13q–, 18p–, 18q–, 22q– Prader–Willi syndrome (50% have partial deletion of chromosome 15)	
Maternal Infection (2% of Serious Anomalies) Intrauterine infections (e.g., herpes simplex, CMV, varicella-zoster, rubella, and toxoplasmosis)	**Unknown Etiologies** *Polygenetic* Anencephaly/spina bifida Cleft lip/palate Pyloric stenosis Congenital heart disease
Maternal Illness (3.5% of Serious Anomalies) Diabetes mellitus Phenylketonuria Hyperthermia	
Uterine Environment (% Unknown) *Deformation* Uterine pressure, oligohydramnios: clubfoot, torticollis, congenital hip dislocation, pulmonary hypoplasia, 7th nerve palsy	*Imprinting of Genes* Prader–Willi syndrome Beckwith–Wiedemann syndrome
Disruption Amniotic bands, congenital amputations, gastroschisis, porencephaly, intestinal atresia	*Sporadic Syndrome Complexes (Anomalads)* CHARGE syndrome VATER syndrome Pierre Robin syndrome Prune-belly syndrome
Twinning Conjoined twins, intestinal atresia, porencephaly	**Nutritional** Low folic acid–neural tube defects
Environmental Agents (% Unknown) Polychlorinated biphenyls Herbicides	

CMV, cytomegalovirus; CHARGE, coloboma, heart defects, atresia choanae, retarded growth, genital anomalies, ear anomalies (deafness); VATER, vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial and renal anomalies.
